ISBN 9788891910776

Contents

Specialized sessions

Accounting for record linkage errors in inference (S2G-SIS) 2

Probabilistic record linkage with less than three matching variables. 3
Tiziana Tuoto and Marco Fortini

Advanced methods for measuring and communicating uncertainty in official statistics 9

A model for measuring the accuracy in spatial price statistics using scanner data. 10
Ilaria Benedetti and Federico Crescenzi

Communication of Uncertainty of Official Statistics. 16
Edwin de Jonge and Gian Luigi Mazzi

Measuring uncertainty for infra-annual macroeconomic statistics. 22
George Kapetanios, Massimiliano Marcellino and Gian Luigi Mazzi

Bayesian methods in biostatistics 27

Network Estimation of Compositional Data. 28
Nathan Osborne, Christine B. Peterson and Marina Vannucci

Using co-data to empower genomics-based prediction and variable selection. 34
Magnus M. Münch, Mirrelijn M. van Nee and Mark A. van de Wiel

Data integration versus privacy protection: a methodological challenge? 40

Statistical Disclosure Control for Integrated Data. 41
Natalie Shlomo

The Integrated System of Statistic Registers: first steps towards facing privacy issues. 47
Mauro Bruno and Roberta Radini

Trusted Smart Surveys: a possible application of Privacy Enhancing Technologies in Official Statistics. 53
Fabio Ricciato, Kostas Giannakouris, Albrecht Wirthmann and Martina Hahn

Designing adaptive clinical trials 59

Optimal designs for multi-arm exponential trials. 60
Rosamarie Frieri and Marco Novelli

Education: students' mobility and labour market 66

From measurement to explanatory approaches: an assessment of the attractiveness of the curricula programs supplied by Italian universities. 67
Isabella Sulis, Silvia Columbu and Mariano Porcu

Pull factors for university students' mobility: a gravity model approach. 73
Giovanni Boscaino and Vincenzo Giuseppe Genova

Spatial autoregressive gravity models to explain the university student mobility in Italy. 79
Silvia Bacci, Bruno Bertaccini and Chiara Bocci

Environmental Statistics (GRASPA-SIS) 85
A Time Clustering Model for Spatio-Temporal Data. 86
Clara Grazian, Gianluca Mastrantonio and Enrico Bibbona

Reconstruction of sparsely sampled functional time series using frequency domain functional principal components. 93
Amira Elayouty, Marian Scott and Claire Miller

Methods for High Dimensional Compositional Data Analysis 98
Algorithms for compositional tensors of third-order. 99
Violetta Simonacci

High-dimensional regression with compositional covariates: a robust perspective. 105
Gianna Serafina Monti and Peter Filzmoser

Three-way compositional analysis of energy intensity in manufacturing. 111
Valentin Todorov and Violetta Simonacci

Modern Statistics for Physics Discoveries 117
Identification of high-energy λ-ray sources via nonparametric clustering. 118
Giovanna Menardi, Denise Costantin, and Federico Ferraccioli

Statistical Analysis of Macroseismic Data for a better Evaluation of Earthquakes Attenuation Laws. 124
Marcello Chiodi, Antonino D'Alessandro, Giada Adelfio and Nicoletta D'Angelo

Network Modelling in Biostatistics.....130
Natural direct and indirect relative risk for mediation analysis. 131
Monia Lupparelli and Alessandra Mattei

New issues on multivariate and univariate quantile regression 137
Mixtures of quantile regressions for longitudinal data: an R package. 138
Maria Francesca Marino, Maria Giovanna Ranalli and Marco Alfò

Multivariate Mixed Hidden Markov Model for joint estimation of multiple quantiles. 144
Luca Merlo, Lea Petrella and Nikos Tzavidis

Recent methodological advances in finite mixture modeling with applications (CLADAG-SIS) 150
Aggregating Gaussian mixture components. 151
Roberto Rocci

Local and overall coefficients of determination for mixtures of generalized linear models. 157
Roberto Di Mari, Salvatore Ingrassia and Antonio Punzo

Statistical Analysis of Satellite Data (SDS-SIS) 163
Functional Data Analysis for Interferometric Syntethic Aperture Radar Data Post-Processing: The case of Santa Barbara mud volcano. 164
Matteo Fontana, Alessandra Menafoglio, Francesca Cigna and Deodato Tapete

Recent Contributions to the Understanding of the Uncertainty in Upper-Air Reference Measurements. 170
Alessandro Fassò

Statistical models and methods for Business and Industry 176
Modelling and monitoring of complex 3D shapes: a novel approach for lattice structures. 177
Bianca Maria Colosimo, Marco Grasso and Federica Garghetti

Open data powered territorial planning - Case study: The Turin historical center. 183
Silvia Casagrande, Gianmaria Origgi, Alberto Pasanisi, Martina Tamburini, Pascal Terrien, Tania Cerquitelli and Alfonso Capozzoli

Process optimization in Industry 4.0: Are all data analytics models useful? 189
Alberto Ferrer

Technology and demographic behaviours (AISP-SIS) 195
Internet and the Timing of Births. 196
Maria Sironi, Osea Giuntella and Francesco C. Billari

The Internetization of Marriage: Effects of the Diffusion of High-Speed Internet on Marriage, Divorce, and Assortative Mating. 202
Francesco C. Billari, Osea Giuntella and Luca Stella

Solicited Sessions

Advanced Statistical Methods in Health Analytics 209
Assessing the impact of the intermediate event in a non-markovian illness-death model. 210
Davide Paolo Bernasconi, Elena Tassistro, Maria Grazia Valsecchi and Laura Antolini

Big data and AI: challenges and opportunities in healthcare. 216
Vieri Emiliani, Gian Luca Cattani and Fabrizio Selmi

Statistical methodology for volume-outcome studies. 222
Marta Fiocco and Floor van Oudenhoven

Advances in textual data mining 228
Distance measures for exploring pairs of novels in a large corpus of Italian literature. 229
Matilde Trevisani and Arjuna Tuzzi

Supervised vs Unsupervised Latent Dirichlet Allocation: topic detection in lyrics. 235
Mariangela Sciandra, Alessandro Albano and Irene Carola Spera

Advances in the interaction between artificial intelligence and official statistics 241
Automated Land Cover Maps from Satellite Imagery by Deep Learning. 242
Fabrizio De Fausti, Francesco Pugliese and Diego Zardetto

CROWD4SDG: Crowdsourcing for sustainable developments goals. 248
Barbara Pernici

Permanent Population Census: evaluation of the effects of regional strategies on the process efficiency. The direct experience of Tuscany. 253
Linda Porciani, Luisa Francovich, Luca Faustini and Alessandro Valentini

Capture-recapture methods 259
Bayesian Model Averaging for Latent Class Models in Capture-Recapture. 260
Davide Di Cecco

Combining “signs of life” and survey data through latent class models to consider over-coverage in Capture-Recapture estimates of population counts. 266
Marco Fortini, Antonella Bernardini, Marco Caputi and Nicoletta Cibella

Population size estimation with interval censored counts and external information. 272
Alessio Farcomeni

Changes in environment extremes and their impacts 278
FPCA Clustering of rainfall events. 279
Gianluca Sottile, Antonio Francipane, Leonardo Noto and Giada Adelfio

Trends in rainfall extremes in the Venice lagoon catchment. 285
Ilaria Prosdocimi and Carlo Gaetan

Copulas: models and inference 291
Analysis of district heating demand through different copula-based approaches. 292
F. Marta L. Di Lascio and Andrea Menapace

CoVaR and backtesting: a comparison between a copula approach and parametric models. 298
Michele Leonardo Bianchi, Giovanni De Luca and Giorgia Rivieccio

Estimating Asymmetric Dependence via Empirical Checkerboard Copulas. 304
Wolfgang Trutschnig and Florian Griessenberger

Strong Convergence of Multivariate Maxima. 310
Michael Falk, Simone A. Padoan and Stefano Rizzelli

Data Science: when different expertise meet 316
Bayesian stochastic modelling of the temporal evolution of seismicity. 317
Elisa Varini and Renata Rotondi

Cluster Analysis for the Characterization of Residential Personal Exposure to ELF Magnetic Field. 323
Gabriella Tognola, Silvia Gallucci, Marta Bonato, Emma Chiaramello, Isabelle Magne, Martine Souques, Serena Fiocchi, Marta Parazzini and Paolo Ravazzani

Statistical Assessment and Validation of Ship Response in High Sea State by Computational Fluid Dynamics. 328
Andrea Serani, Matteo Diez and Frederick Stern

Uncertainty Quantification for PDEs with random data using the Multi-Index Stochastic Collocation method. 334
Lorenzo Tamellini and Joakim Beck

Emerging challenges in official statistics: new data sources and methods 340
Small area poverty indicators adjusted using local spatial price indices. 341
Stefano Marchetti, Luigi Biggeri, Caterina Giusti and Monica Pratesi

Smart solutions for trusted smart statistics: the European big data hackathon experience. 347
Francesco Amato, Mauro Bruno, Tania Cappadozzi, Fabrizio De Fausti and Manuela Michelini

The ESSnet Project Smart Surveys: new data sources and tools for Surveys of Official Statistics 353

Factorial and dimensional reduction methods for the construction of indicators for evaluation (SVQS-SIS) 359
A comparison of MBC with CLV and PCovR methods for dimensional reduction of the soccer players' performance attributes. 360
Maurizio Carpita, Enrico Ciavolino and Paola Pasca

A framework of cumulated chi-squared type statistics for ordered correspondence analysis. New tools and properties. 366
Antonello D'Ambra, Pietro Amenta and Luigi D'Ambra

Exploring drug consumption via an ultrametric correlation matrix. 372
Giorgia Zaccaria and Maurizio Vichi

Ranking extraction in ordinal multi-indicator systems. 378
Marco Fattore and Alberto Arcagni

Gender statistics 384
Gender differences in Italian STEM degree courses: a discrete-time competing-risks model. 385
Marco Enea and Massimo Attanasio

Some Challenges and Results in Measuring Gender Inequality. 391
Fabio Crescenzi and Francesco Di Pede

How Deep is Your Plot? Young SIS and deep statistical learning (ySIS)..397
A modal approach for clustering matrices. 398
Federico Ferraccioli and Giovanna Menardi

A Note on Detection of Perturbations in Biological Networks. 404
Vera Djordjilović

Bayesian inference for DAG-probit models. 410
Federico Castelletti

Variational Bayes for Gaussian Factor Models under the Cumulative Shrinkage Process. 416
Sirio Legramanti

Measuring poverty and vulnerability 421
Choosing the vulnerability threshold using the ROC curve. 422
Chiara Gigliarano and Conchita D'Ambrosio

New advances in applications, a Bayesian nonparametric perspective 428
Bayesian Mixture Models for Latent Class Analysis. 429
Raffaele Argiento, Bruno Bodin and Maria De Iorio

Non-Parametric Inference and Forecasting of Functional and Object Data 435
An interpretable estimator for the function-on-function linear regression model with application to the Canadian weather data. 436
Fabio Centofanti and Matteo Fontana

Statistical process monitoring of multivariate profiles from ship operating conditions. 440
Christian Capezza

Prior choice in Bayesian Modelling (SISbayes) 446
Bayesian Learning of Multiple Essential Graphs. 447
Luca La Rocca, Federico Castelletti, Stefano Peluso, Francesco Claudio Stingo and Guido Consonni

Bayesian post-processing of Gibbs sampling output for variable selection. 453
Stefano Cabras

Priors on precision parameters of IGRMF models. 459
Aldo Gardini, Fedele Greco and Carlo Trivisano

Sequence Analysis: methods and applications 465
Internal migration, family formation and social stratification in Europe. A life course approach. 466
Roberto Impicciatore, Gabriele Ballarino and Nazareno Panichella

Socio economic integration of migrants 472
A study on the characteristics of spouses who intermarry in Italy. 473
Agnese Vitali and Romina Fraboni

Statistical Analysis for mobility and transportation 479
A multilevel Analysis of University attractiveness in the network flows from Bachelor to Master's degree. 480
Silvia Columbu and Ilaria Primerano

Analysis of mobility data through a novel Cheng and Church algorithm for functional data. 486
Marta Galvani, Agostino Torti and Alessandra Menafoglio

Bridge closures in a transportation network: analysis of the impacts in the region of Lombardy. 491
Agostino Torti, Marika Arena, Giovanni Azzone, and Piercesare Secchi

Statistical Methods and Applications in Social Network Analysis 496
A clustering procedure for ego-networks data: an application to Italian elders living in couple. 497
Elvira Pelle and Roberta Pappadà

Analysing the mediating role of a network: a Bayesian latent space approach. 503
Chiara Di Maria, Antonino Abbruzzo and Gianfranco Lovison

Network-time autoregressive models for valued network panel. 509
Viviana Amati

University student mobility flows and network data structures. 515
Maria Prosperina Vitale, Giuseppe Giordano and Giancarlo Ragozini

Statistical Methods in Psychometrics 521
A simple probabilistic model to evaluate questionable interim analysis strategies. 522
Francesca Freuli and Luigi Lombardi

Incorporating Expert Knowledge in Structural Equation Models: Applications in Psychological Research. 528
Gianmarco Altoè, Claudio Zandonella Callegher, Enrico Toffalini and Massimiliano Pastore

Predicting social media addiction from Instagram profiles: A data mining approach. 534
Antonio Calcagnì, Veronica Cortellazzo, Francesca Guizzo, Paolo Girardi, Natale Canale

Structural entropy based modeling for psychological measurement. 540
Enrico Ciavolino, Mario Angelelli, Paola Pasca and Omar Carlo Gioacchino Gelo

Statistical modelling in environmental epidemiology 546
A Time Varying Coefficient Model to Estimate the Short-Term Effects of Air Pollution on Human Health. 547
Pasquale Valentini, Luigi Ippoliti and Clara Grazian

Joint Analysis of Short and Long-Term Effects of Air Pollution. 551
Annibale Biggeri, Dolores Catelan, Giorgia Stoppa and Corrado Lagazio

Statistical Modelling of Scientific Evidence for Forensic Investigation and Interpretation 557
DNA mixtures with related contributors. 558
Peter J. Green and Julia Mortera

Forensic Statistics: How to estimate life expectancy after injury. 564
Jane L. Hutton

The additional contribution of combining genetic evidence from multiple samples in a complex case. 570
Giampietro Lago

The history of forensic inference and statistics: a thematic perspective. 576
Franco Taroni and Colin Aitken

Topological learning: interpretable representations of complex data.....581
Comparing Neural Networks via Generalized Persistence. 582
Mattia G. Bergomi and Pietro Vertechi

On the topological complexity of decision boundaries. 588
António Leitão and Giovanni Petri

Persistence-based Kernels for Data Classification. 594
Ulderico Fugacci

Topological and Mixed-type learning of Brain Activity. 600
Tullia Padellini, Pierpaolo Brutti, Riccardo Giubilei

Contributed papers and Posters

Bayesian Statistics 607

A Bayesian approach for modelling dependence among mixture densities. 608
Mario Beraha, Matteo Pegoraro, Riccardo Peli and Alessandra Guglielmi

A change of glasses strategy to solve the rare type match problem. 614
Giulia Cereda and Fabio Corradi

A new prior distribution on the simplex: the extended flexible Dirichlet. 620
Roberto Ascari, Sonia Migliorati and Andrea Ongaro

ABC model choice via mixture weight estimation. 626
Gianmarco Caruso, Luca Tardella and Christian P. Robert

An ABC algorithm for random partitions arising from the Dirichlet process. 632
Mario Beraha and Riccardo Corradin

Bayesian Inference of Undirected Graphical Models from Count Data. 638
Pier Giovanni Bissiri, Monica Chiogna and Nguyen Thi Kim Hue

Bayesian IRT models in NIMBLE. 644
Sally Paganin, Chris Paciorek and Perry de Valpine

Bayesian modelling of Facebook communities via latent factor models. 650
Emanuele Aliverti

Bayesian nonparametric adaptive classification with robust prior information. 655
Francesco Denti, Andrea Cappozzo and Francesca Greselin

Choosing the right tool for the job: a systematic analysis of general purpose MCMC software. 661
Mario Beraha, Giulia Gualtieri, Eugenia Villa, Riccardo Vitali and Alessandra Guglielmi

Empirical Bayes estimation for mixture models. 667
Catia Scricciolo

Improving ABC via Large Deviations Theory. 673
Cecilia Viscardi, Michele Boreale and Fabio Corradi

Learning Bayesian Networks for Nonparanormal Data. 679
Flaminia Musella and Vincenzina Vitale

Measuring well-being combining different data sources: a Bayesian networks approach. 685
Federica Cugnata, Silvia Salini and Elena Siletti

Penalising the complexity of extensions of the Gaussian distribution. 691
Diego Battagliese and Brunero Liseo

Predictive discrepancy of credible intervals for the parameter of the Rayleigh distribution. 697
Fulvio De Santis and Stefania Gubbiotti

Small-area statistical estimation of claim risk. 702
Francesca Fortunato, Fedele Greco and Pierpaolo Cristaudo

Subject-specific Bayesian Hierarchical model for compositional data analysis. 708
Matteo Pedone and Francesco C. Stingo

Wasserstein consensus for Bayesian sample size determination. 714
Michele Cianfriglia, Tullia Padellini and Pierpaolo Brutti

Biostatistics 720

A comparison of the CAR and DAGAR spatial random effects models with an application to diabetics rate estimation in Belgium. 721
Vittoria La Serra, Christel Faes, Niel Hens and Pierpaolo Brutti

A functional approach to study the relationship between dynamic covariates and survival outcomes: an application to a randomized clinical trial on osteosarcoma. 727
Marta Spreafico, Francesca Ieva and Marta Fiocco

A Statistical Approach to the Alignment of fMRI Data. 733
Angela Andreella, Ma Feilong, Yaroslav Halchenko, James Haxby and Livio Finos

Adaptive clinical trials: Bayesian decision-theoretic and frequentist approaches for cost-effectiveness analysis. 739
Martin Forster and Marco Novelli

Bootstrap corrected Propensity Score: Application for Anticoagulant Therapy in Haemodialysis Patients. 745
Maeregu W. Arisido, Fulvia Mecatti and Paola Rebora

Combining multiple sources to overcome misclassification bias in epidemiological database studies. 751
Francesca Beraldi, Rosa Gini, Emanuela Dreassi, Leonardo Grilli and Carla Rampichini

Deep Sparse Autoencoder-based Feature Selection for SNPs Validation in Prostate Cancer Radiogenomics. 756
Michela Carlotta Massi, Francesca Ieva, Anna Maria Paganoni, Andrea Manzoni, Paolo Zunino, Nicola Rares Franco, Tiziana Rancati and Catharine West

Graphical models for count data: an application to single-cell RNA sequencing. 762
Nguyen Thi Kim Hue, Monica Chiogna and Davide Risso

Interregional mobility, socio-economic inequality and mortality among cancer patients. 768
Claudio Rubino, Mauro Ferrante, Antonino Abbruzzo, Giovanna Fantaci and Salvatore Scondotto

PET radiomics-based lesions representation in Hodgkin lymphoma patients. 774
Lara Cavinato, Martina Sollini, Margarita Kirienko, Matteo Biroli, Francesca Ricci, Letizia Calderoni, Elena Tabacchi, Cristina Nanni, Pier Luigi Zinzani, Stefano Fanti, Anna Guidetti, Alessandra Alessi, Paolo Corradini, Ettore Seregni, Carmelo Carlo-Stella, Arturo Chiti and Francesca Ieva

Prediction of late radiotherapy toxicity in prostate cancer patients via joint analysis of SNPs sequences. 780
Nicola Rares Franco, Michela Carlotta Massi, Francesca Ieva, Anna Maria Paganoni, Andrea Manzoni, Paolo Zunino, Tiziana Rancati and Catharine West

Predictive versus posterior probabilities for phase II trial monitoring. 785
Valeria Sambucini

Profile networks for precision medicine. 791
Andrea Lazzerini, Monia Lupparelli and Francesco C. Stingo

Proton-Pump Inhibitor Provider Profiling via Funnel Plots and Poisson Regression. 797
Dario Delle Vedove, Francesca Ieva and Anna Maria Paganoni

Selecting optimal thresholds in ROC analysis with clustered data. 803
Duc Khanh To, Gianfranco Adimari and Monica Chiogna

Environment, Physics and Engineering 809

A hidden semi-Markov model for segmenting environmental toroidal data. 810
Francesco Lagona and Antonello Maruotti

An experimental analysis on quality and security about green communication. 816
Vito Santarcangelo, Emilio Massa, Davide Scintu, Michele Di Lecce and Massimiliano Giacalone

An improved sensitivity-data based method for probabilistic ecological risk assessment. 822
Sonia Migliorati and Gianna Serafina Monti

Comparing predictive distributions in EMOS. 828
Giummolè Federica and Mameli Valentina

Compositional analysis of fish communities in a fast changing marine ecosystem. 834
Pierfrancesco Alaimo Di Loro, Marco Mingione, Giovanna Jona Lasinio, Sara Martino and Francesco Colloca

FDA dimension reduction techniques and components separation in Fourier-transform infrared spectroscopy. 840
Francesca Di Salvo, Elena Piacenza and Delia Francesca Chillura Martino

Functional Data Analysis for Spectroscopy Data. 846
Mara S. Bernardi, Matteo Fontana, Alessandra Menafoglio, Diego Perugini, Alessandro Pisello, Marco Ferrari, Simone De Angelis, Maria Cristina De Sanctis and Simone Vantini

Functional graphical model for spectrometric data analysis. 852
Laura Codazzi, Alessandro Colombi, Matteo Gianella, Raffaele Argiento, Lucia Paci and Alessia Pini

Local LGCP estimation for spatial seismic processes. 857
Nicoletta D'Angelo, Marianna Siino, Antonino D'Alessandro and Giada Adelfio

Observation-driven models for storm counts. 863
Mirko Armillotta, Alessandra Luati and Monia Lupparelli

Statistical control of complex geometries, with application to Additive Manufacturing. 869
Riccardo Scimone, Tommaso Taormina, Bianca Maria Colosimo, Marco Grasso, Alessandra Menafoglio, Piercesare Secchi

Tree attributes map by 3P sampling in a design-based framework. 875
Lorenzo Fattorini and Sara Franceschi

Unsupervised classification of texture images by gray-level spatial dependence matrices and genetic algorithms. 880
Roberto Baragona and Laura Bocci

Finance, business and official statistics 886

A discrete choice approach to analyze contractual attributes in the durum wheat sector in Italy. 887
Stefano Ciliberti, Simone Del Sarto, Giulia Pastorelli, Angelo Frascarelli and Gaetano Martino

A fuzzy approach to the measurement of the employment rate. 893
Bruno Cheli, Alessandra Coli and Andrea Regoli

A proposal to model credit risk contagion using network count-based models. 898
Arianna Agosto and Daniel Felix Ahelegbey

A similarity matrix approach to empower ESCO interfaces for testing, debugging and in support of users' experience. 904
Adham Kahlawi, Cristina Martelli, Lucia Buzzigoli, Laura Grassini

Adding MIDAS terms to Linear ARCH models in a Quantile Regression framework. 910
Vincenzo Candila and Lea Petrella

Company requirements in Italian tourism sector: an analysis for profiles. 916
Paolo Mariani, Andrea Marletta, Lucio Masserini and Mariangela Zenga

Determinants of Firms' Default Risk after the 2008 and 2011 Economic Crises: a Latent Growth Models Approach. 921
Lucio Masserini, Matilde Bini and Alessandro Zeli

Double Asymmetric GARCH-MIDAS model - new insights and results. 927
Alessandra Amendola, Vincenzo Candila and Giampiero M. Gallo

European SMEs and Circular Economy Activities: Evaluating the Advantage on Firm Performance through the Estimation of Average Treatment Effects. 933
Luca Secondi

Financial Spillover Measures to Assess the Stability of Basket-based Stablecoins. 939
Paolo Pagnottoni

Forecasting Banknote Flows in BdI Branches: Speed-up with Machine Learning. 945
Marco Brandi, Monica Fusaro, Tiziana Laureti and Giorgia Rocco

Fully reconciled GDP forecasts from Income and Expenditure sides. 951
Luisa Bisaglia, Tommaso Di Fonzo and Daniele Girolimetto

GLASSO Estimation of Commodity Risks. 957
Beatrice Foroni, Saverio Mazza, Giacomo Morelli and Lea Petrella

Measuring the Effect of Unconventional Policies on Stock Market Volatility. 963
Giampiero M. Gallo, Demetrio Lacava and Edoardo Otranto

Multidimensional versus unidimensional poverty measurement. 969
Michele Costa

Multiple outcome analysis of European Agriculture in 2000-2016: a latent class multivariate trajectory approach. 975
Alessandro Magrini

Nowcasting GDP using mixed-frequency based composite confidence indicators. 981
Maria Carannante, Raffaele Mattera, Michelangelo Misuraca, Germana Scepi and Maria Spano

On the tangible and intangible assets of Initial Coin Offerings. 987
Paola Cerchiello and Anca Mirela Toma

Seasonality variation of electricity demand: decompositions and tests. 993
Luigi Grossi and Mauro Mussini

SMEs circular economy practices in the European Union: Implications for sustainability. 999
Nunzio Tritto, Josè G. Dias and Francesca Bassi

Tax Incentives' Effect on the Provision of Occupational Welfare in Italian Enterprises. 1005
Alessandra Righi

The determinants of eco-innovation: a country comparison using the community innovation survey. 1011
Ida D'Attoma and Silvia Pacei

World ranking of urban sustainability through composite indicators. 1017
Elena Grimaccia, Alessia Naccarato and Silvia Terzi

Machine Learning and Data Science.....1023

A novel approach for Artificial Intelligence through Lorenz zonoids and Shapley Values. 1024
Paolo Giudici and Emanuela Raffinetti

A warning signal for variable importance interpretation in tree-based algorithms. 1030
Anna Gottard and Giulia Vannucci

Assessment of the effectiveness of digital flyers: analysis of viewing behavior using eye tracking. 1036
Gianpaolo Zammarchi, Claudio Conversano and Francesco Mola

At risk mental status analysis: a comparison of model selection methods for ordinal target variable. 1042
Elena Ballante, Silvia Molteni, Martina Mensi and Silvia Figini

Categorical Encoding for Machine Learning. 1048
Agostino Di Ciaccio

Dynamic Quantile Regression Forest. 1054
Mila Andreani and Lea Petrella

Estimating the UK Sentiment Using Twitter. 1059
Stephan Schlosser, Daniele Toninelli and Michela Cameletti

Forecasting local rice prices from crowdsourced data in Nigeria. 1065
Ilaria Lucrezia Amerise and Gloria Solano Hermosilla

Generalized Mixed Effects Random Forest: does Machine Learning help in predicting university student dropout? 1071
Massimo Pellagatti, Chiara Masci, Francesca Ieva and Anna Maria Paganoni

HateViz: a textual dashboard Twitter data-driven. 1077
Emma Zavarrone, Maria Gabriella Grassia, Marina Marino, Rocco Mazza and Nicola Canestrari

How to perform cyber risk assessment via cumulative logit models. 1083
Silvia Facchinetti, Silvia Angela Osmetti and Claudia Tarantola

Machine learning prediction for accounting system. 1087
Chiara Bardelli and Silvia Figini

Teaching statistics: an assessment framework based on Multidimensional IRT and Knowledge Space Theory. 1093
Cristina Davino, Rosa Fabbricatore, Carla Galluccio, Daniela Pacella, Domenico Vistocco, Francesco Palumbo

The weight of words: textual data versus sentiment analysis in stock returns prediction. 1099
Riccardo Ferretti and Andrea Sciandra

Unsupervised Energy Trees: clustering with complex and mixed-type variables. 1105
Riccardo Giubilei, Tullia Padellini and Pierpaolo Brutti

Using anchoring vignettes to adjust self-reported life satisfaction: a nonparametric approach leading to a Semantic Differential scale. 1111
Sara Garbin, Serena Berretta, Maria Iannario and Omar Paccagnella

Variable selection for robust model-based learning from contaminated data. 1117
Andrea Cappozzo, Francesca Greselin and Thomas Brendan Murphy

Variable Selection in Text Regressions: Back to Lasso? 1123
Marzia Freo and Alessandra Luati

Web Usage Mining and Website Effectiveness. 1129
Maria Francesca Cracolici and Furio Urso

Models and methods - Categorical, Ordinal, Rank Data 1135

Aberration for the analysis of two-way contingency tables. 1136
Roberto Fontana and Fabio Rapallo

An investigation of the paradoxical behaviour of **κ**-type inter-rater agreement coefficients for nominal data. 1142
Amalia Vanacore and Maria Sole Pellegrino

Analyzing faking-good response data: Combination of a Replacement and a Binomial (CRB) distribution approach. 1148
Luigi Lombardi and Antonio Calcagnì

BOD – min range: A Robustness Analysis Method for Composite Indicators. 1154
Emiliano Seri, Leonardo Salvatore Alaimo and Vittoria Carolina Malpassuti

Comparing classifiers for ordinal variables. 1160
Silvia Golia and Maurizio Carpita

Discovering Interaction Effects Between Subject-Specific Covariates: A New Probabilistic Approach For Preference Data. 1166
Alessio Baldassarre, Claudio Conversano, Antonio D'Ambrosio, Mark De Rooij and Elise Dusseldorp

Hybrid random forests for ordinal data. 1171
Rosaria Simone and Gerhard Tutz

Model-based approach to biclustering ordinal data. 1177
Monia Ranalli and Francesca Martella

New algorithms and goodness-of-fit diagnostics for ranked data modelling with the Extended Plackett-Luce distribution. 1183
Cristina Mollica and Luca Tardella

Non-metric unfolding on augmented data matrix: a copula-based approach. 1189
Marta Nai Ruscone and Antonio D'Ambrosio

Ordinal probability effect measures for dyadic analysis in cumulative models. 1194
Maria Iannario and Domenico Vistocco

Simulated annealing for maximum rater agreement. 1200
Fabio Rapallo and Maria Piera Rogantin

Models and methods – Regression.....1206

A Clusterwise regression method for Distributional-valued Data. 1207
Rosanna Verde, Francisco de A. T. de Carvalho and Antonio Balzanella

A nonparametric approach for nonlinear variable screening in high-dimensions. 1213
Francesco Giordano, Sara Milito and Lucia Maria Parrella

Adjusted scores for inference in negative binomial regression. 1219
Euloge C. Kenne Pagui, Alessandra Salvan and Nicola Sartori

Estimation of the treatment effect variance in a difference-in-differences framework. 1224
Marco Doretti and Giorgio E. Montanari

Exploring multicollinearity in quantile regression. 1230
Cristina Davino, Tormod Naes, Rosaria Romano and Domenico Vistocco

Generalized M-quantile random effects model. 1236
Francesco Schirripa Spagnolo and Vincenzo Mauro

Goodness-of-fit assessment in linear quantile regression. 1242
Ilaria Lucrezia Amerise and Agostino Tarsitano

Joint Redundancy Analysis by a multivariate linear predictor. 1248
Laura Marcis and Renato Salvatore

M-quantile regression shrinkage and selection via the lasso. 1254
M. Giovanna Ranalli, Lea Petrella and Francesco Pantalone

New insights into the Conditioning and Gain Score approaches in multilevel analysis. 1260
Bruno Arpino, Silvia Bacci, Leonardo Grilli, Raffaele Guetto and Carla Rampichini

Simultaneous confidence regions and curvature measures in nonlinear models. 1265
Claudia Furlan and Cinzia Mortarino

Models and methods – Sampling 1271

Design-based consistency of the Horvitz-Thompson estimator for spatial populations. 1272
Lorenzo Fattorini, Marzia Marcheselli, Caterina Pisani and Luca Pratelli

Empirical likelihood in the statistical matching for informative samples. 1278
Daniela Marella and Danny Pfeffermann

Evaluating a Hybrid One-Staged Snowball Sampling through Bootstrap Method on a Simulated Population. 1284
Venera Tomaselli and Giulio Giacomo Cantone

How optimal subsampling depends on guessed parameter values. 1290
Laura Deldossi and Chiara Tommasi

Indicators for risk of selection bias in non-probability samples. 1296
Emilia Rocco and Alessandra Petrucci

On the behaviour of the maximum likelihood estimator for exponential models under a fixed and a two-stage design. 1302
Caterina May and Chiara Tommasi

Pseudo-population based resamplings for two-stage design. 1308
Pier Luigi Conti, Daniela Marella and Vincenzina Vitale

Models and methods - Theoretical Issues in Statistical Inference 1314

A new mixture model for three-way data. 1315
Salvatore D. Tomarchio, Antonio Punzo and Luca Bagnato

A Sequential Test for the Cpmk Index. 1320
Michele Scagliarini

Probability Interpretations and the Selection of the Most Effective Statistics Method. 1326
Paolo Rocchi

Robust Composite Inference. 1332
Valentina Mameli, Monica Musio, Erlis Ruli and Laura Ventura

Statistical hypothesis testing within the Generalized Error Distribution: Comparing the behavior of some nonparametric techniques. 1338
Massimiliano Giacalone and Demetrio Panarello

Stochastic dependence with discrete copulas. 1344
Fabrizio Durante and Elisa Perrone

Models and methods - Time Series and Longitudinal Data.....1350

Bootstrap test in Poisson–INAR models. 1351
Lucio Palazzo and Riccardo Ievoli

Preface

The COVID-19 pandemic is putting our society under incredible health, emotional, and economic stress. Facing its harmful effects and their uncertainty, the Executive Board of the Italian Statistical Society (SIS) and the Local Organizing Committee, to ensure the highest level of safety for members and delegates, deliberated to cancel the 50th Meeting of the Italian Statistical Society originally planned to be held in Pisa in June 2020 and to postpone the conference to June 2021. The Executive Board and the Local Organizing Committee continue to monitor closely the pandemic evolving situation, and keep the members of SIS and the researchers informed about the potential new dates for the next meeting. To give value to the work of those who prepared their presentation for the conference, the Program Committee decided to publish the volume *Book of short papers - SIS 2020* despite the conference cancellation.

The conference program included 4 plenary sessions, 16 specialized sessions, 24 solicited sessions, 32 contributed sessions and the poster exhibition. Plenary sessions concerned with robust statistics, human longevity, statistical models for climate changes and small area estimation for educational poverty. The meeting had to host also 2 round tables on data privacy and innovation in statistics. Activities focused on topics of interest for a wider audience included two round tables on Teaching Statistics and on the SIS journal Statistical Methods & Applications, and the Stats Under the Stars (SUS6) competition for young statisticians. The SUS6 event attracted many sponsors from statistical, financial and editorial firms as well as numerous students. The conference committee had registered 345 accepted submissions, including 143 to be presented in invited plenary, specialized and solicited sessions, and 202 spontaneously submitted for oral and poster sessions.

This book includes most of the scientific contributions that had to be presented at the 50th Meeting of the Italian Statistical Society. It is organized into 49 chapters corresponding to 15 specialized, 23 solicited sessions, and to 11 general topics for contributed papers and posters. All 268 contributions provide a wide overview of the state-of-the-art of the subjects, from methodological and theoretical contributions, to applied works and case studies. The result is a very lively picture of the Italian statistical community with its international connections.

We would like to thank all contributors for having submitted their work to the conference, the members of the Program Committee and the extra reviewers for their efforts in this difficult period. Although the Conference did not take place, the organization went on until cancellation was decided for safety reasons. It would have been impossible without the joint effort of Università di Pisa, Scuola Superiore Sant'Anna and National Research Council of Pisa. Members these three institutions took part actively in the Local Organizing Committee. Finally we wish to express our gratitude to the publisher Pearson Italia for all the support received.

This book is our contribution to encourage the scientific community and the network of the Italian Statistical Society to go on and transform this difficult period into an opportunity of scientific debate for better statistics in a better world.

Accounting for record linkage errors in inference (S2G-SIS)

Probabilistic record linkage with less than three matching variables

Record linkage probabilistico con meno di tre variabili di confronto

Tiziana Tuoto and Marco Fortini

Abstract Probabilistic record linkage based on Fellegi-Sunter theory is a methodology for integrating data collected in different sources when a unique common identifier is not available. It requires at least three matching variables are available to identify the probability model. In official statistics, it is emerging the need to join archives even with less than three common variables, this is the case for instance of addresses and business archives of poor quality. For this problem, we compare available common variables by means of string comparators and propose mixtures of continuous and categorical distributions rather than usual the latent class models to estimate linkage probabilities.

Abstract *Il record linkage probabilistico basato sulla teoria di Fellegi-Sunter è una metodologia per integrare dati raccolti in fonti diverse quando non è disponibile un codice identificativo comune univoco. In questo caso, sono necessarie almeno tre variabili di confronto per identificare il modello di probabilità. Nella statistica ufficiale, emerge la necessità di abbinare archivi anche quando sono disponibili meno di tre variabili in comune, come ad esempio nel caso di archivi di indirizzi o di imprese di scarsa qualità. Per questo problema, confrontiamo le variaibli disponibili mediante comparatori di stringhe e proponiamo misture di distribuzioni continue e categoriche piuttosto che i modelli a classi latenti solitamente utilizzati per la stima delle probabilità di abbinamento.*

Key words: Fellegi-Sunter record linkage, mixture models, string metrics

1 Introduction

[1] Marco Fortini, Istat; email: fortini@istat.it
Tiziana Tuoto, Istat; email: tuoto@istat.it

Data linkage is a common practice in National Statistical Offices and in many other Institutions to enlarge and enrich the availability of information without incurring the costs of new surveys and burden to respondents. Nowadays in many National Statistical Institutes a new statistical production system has been established, mainly based on integrated datasets, including both administrative archives and traditional sample surveys. This new statistical production system has been by the large availability of administrative data, often with unique identifiers for the units of interest, and almost unlimited computing and storage capacity. Integrated datasets provide complementary variables for the same units; they make it possible to discover relationships between different types of units (e.g. households and enterprises, households and schools) and to study the changes over time of the units and the variables.

When units unique identifiers are not available or corrupted, e.g. for privacy reasons or for lack of quality in the data sources, the data linkage is a not trivial task. The most widespread methodology to face linkage issues is the probabilistic record linkage. Probabilistic Record Linkage, according to the theory by Fellegi and Sunter (1969) and the implementation proposed by Jaro (1989) requires at least three matching variable to identify the probability model. This minimum number of common variables is easily available when the reference units are people (e.g. names, surnames, date and place of birth, gender). Unfortunately, this is not the case when integration is needed between other reference units, such as addresses or businesses. In this paper, we propose a model for probabilistic record linkage that uses less than three matching variables. The method is applied to link data from the Palestinian Business Census and an administrative business register. The behaviour of the proposed model is discussed by means of a simulation study.

2 Mixture models for probabilistic record linkage

In this section we shortly recall the well-known probability model for record linkage as proposed by Jaro (1989), that requires at least three matching variables are available, to move to the description of our proposal, that allows probabilistic record linkage with only two matching variables. Both models rely on mixture models.

2.1 Probabilistic record linkage

The goal of record linkage is to recognize records referred to the same unit even when this is differently represented in different sources. To fix the idea, let us consider two data sources, file A and file B, of size N_A and N_B, respectively. The whole comparisons between records *(a,b)* from A and B generate a comparison pairs space Ω of size $N_\Omega = N_A \times N_B$. The goal of linkage procedure is to identify in Ω two disjoint sets M and U such that $\Omega = M \cup U$ and $M \cap U = \emptyset$, where M is the set of Matches, i.e. $\omega = (a,b)$ represents the same unit, $a=b$; while U is the set of Non-matches, i.e.

$\omega = (a,b)$ refer to two different units. $a \neq b$. The pairs assignment to the sets M and U is determined on the basis of K common matching variables, and the comparison vector $\boldsymbol{\gamma} = \{\gamma_1, \gamma_2, \dots, \gamma_K\}$ reporting the agreement/disagreement between the matching variables. When the comparison on the matching variables admits dichotomous outcome, the vector $\boldsymbol{\gamma}$ assumes 2^K possible patterns. Jaro (1989) firstly approaches the record linkage problem by means of mixture models with latent variables. The not observed variable representing the real matching status is the latent one, to be predicted by observing the results of the comparisons vector $\boldsymbol{\gamma} = \{\gamma_1, \gamma_2, \dots, \gamma_K\}$ on the K observed matching variables.

Probabilistic record linkage models the 2^K observed frequencies of pairs of the comparison vector $\boldsymbol{\gamma}$ as a mixture coming from two different distributions, $p_{\boldsymbol{\gamma}} = p \cdot m_{\boldsymbol{\gamma}} + (1-p) \cdot u_{\boldsymbol{\gamma}}$, the distribution of the comparisons $\boldsymbol{\gamma}$ given that the pairs belong to the population of Matches, i.e. $m_{\boldsymbol{\gamma}} = P(\boldsymbol{\gamma} \mid M)$, and the distribution of comparisons $\boldsymbol{\gamma}$ given that the pairs belong to the population of Non-Matches, $u_{\boldsymbol{\gamma}} = P(\boldsymbol{\gamma} \mid U)$. The probability of the set Matches over the comparison space Ω, $p = P(M)$, is the weight of the mixture.

We aim to estimate of the probability of a pair to be a match among those showing the pattern $\boldsymbol{\gamma}$: $\pi_{\boldsymbol{\gamma}} = P(\omega \in \mathrm{M} \mid \boldsymbol{\gamma}), \forall \boldsymbol{\gamma}$. To solve this problem, Jaro (1989) suggests applying the EM algorithm: with at least three variables and under the conditional independence assumption, we obtain estimated distributions $\hat{m}(\gamma)$ and $\hat{u}(\gamma)$. Hence, applying the Bayes rule we can evaluate the probability of a pair to be a match given its pattern $\boldsymbol{\gamma}$:

$$\pi_{\boldsymbol{\gamma}} = (p \cdot m_{\boldsymbol{\gamma}}) / (p \cdot m_{\boldsymbol{\gamma}} + (1-p) \cdot u_{\boldsymbol{\gamma}}).$$

The most likely pairs to be Matches are those with values of $\pi_{\boldsymbol{\gamma}}$ close to 1.

To be identifiable, the model needs at least three matching variables, in this way we have $2^3 = 8$ observed frequencies and need to estimate 7 parameters $p, m_1, m_2, m_3, u_1, u_2, u_3$

2.2 Mixture of Beta and Bernoulli distribution for record linkage

In some real cases, some of them described in the following paragraph, the matching variables are less than three, preventing the application of the previous models. However, it is quite common the matching variables are strings of characters and are compared via string comparators that result in [0, 1] intervals rather than dichotomous outcomes. The most common and widespread string comparators for names are Levenstein, Jaro, Jaro-Winkler, qgram, Jaccard. In principle, to obtain comparison outcome in the range [0,1] we don't need to constrain ourselves to string variables, but the same reasoning can be applied to numeric variables, adopting the most convenient comparison function.

When only two matching variables are available, we propose the following model for record linkage: for each pair $\omega \in \Omega$ we consider a first variable with outcome $\delta_\omega \in [0,1]$ and the other variable with dichotomous outcome $\gamma_\omega \in \{0,1\}$.

The joint probability of observing δ_ω and φ_ω can be still modeled as a mixture of Matches and Non-matches distributions:

$$P(\delta_\omega, \varphi_\omega) = P(\omega \in M)P(\delta_\omega, \varphi_\omega|\omega \in M) + \big(1 - P(\omega \in M)\big)P(\delta_\omega, \varphi_\omega|\omega \in U).$$

Under the usual conditional independence assumption, we can factorize the joint observed probability:

$$P(\delta_\omega, \varphi_\omega) = P(\omega \in M)P(\delta_\omega|\omega \in M)P(\varphi_\omega|\omega \in M)$$

$$+ \big(1 - P(\omega \in M)\big)P(\delta_\omega|\omega \in U)P(\varphi_\omega|\omega \in M).$$

where $P(\omega \in M) = p; \quad P(\delta_\omega|M) = m_\delta(\omega); \quad P(\varphi_\omega|M) = m_\varphi(\omega);$

$$P(\delta_\omega|U) = u_\delta(\omega); \quad P(\varphi_\omega|U) = u_\varphi(\omega).$$

Let us assume the following probability distributions:

- $m_\delta(\omega) = Beta(\delta_\omega; \alpha_M, \beta_M), \quad \alpha_M, \beta_M > 0;$
- $u_\delta(\omega) = Beta(\delta_\omega; \alpha_U, \beta_U), \quad \alpha_U, \beta_U > 0;$
- $m_\varphi(\omega) = Bernoulli(\ \ _\omega; m_\varphi), \quad m_\varphi \in [0,1];$
- $u_\varphi(\omega) = Bernoulli(\varphi_\omega; u_\varphi), \quad u_\varphi \in [0,1].$

This allow us to write the compete likelihood, which includes also the latent variable, which can be factorized for the parameters $p, m_\varphi, u_\varphi, \alpha_M, \beta_M, \alpha_U, \beta_U$ and solved via an EM algorithm. Dealing with Beta distributions, the EM algorithm requires the solution of a system of partial derivatives involving non linear equations, its description and the related algebra can be provided in Appendix.

3 An application to real data and a simulation

The method proposed above might be applied when less than three matching variables are available, as it is the case, e.g. in the linkage of some residual addresses in the Italian Statistical Addresses Register. In this section, we propose a real-case application to the first version of the Palestinian Statistical Business Register, built through the linkage of several statistical and administrative registers. Moreover, to understand the behaviour of the proposed modelling, we show the results of a simulation with fictitious data where the linkage status is known.

Among others, the Palestinian Statistical Business Register links the 2017 Palestinian Business Census, managed by the Palestinian Central Bureau of Statistics PCBS and the Municipality Business Archive, managed by each Municipality for administrative reasons, as e.g. the delivery of services such as water, electricity, etc. For the municipality of Salfit, the census counts 662 establishments and the Salfit municipality archive reports 394 establishments. The data sets have some common

variables, i.e. owner name, kind of activity, address; unfortunately the kind of activity is not coded in the same way, preventing the comparison of the reported information, and the address are often missing or registered in an incomparable way, referring to rural areas. This implies the only available matching variable is the owner name. This info from the Salfit municipality archive can be compared to both the owner name and the commercial name in Census. In this exercise, we model the linkage process as follows: the Jaccard distance between owner names in both sources is modelled as a mixture of two Beta for M and U, the Jaro-Winker distance between owner name and commercial name is dichotomised and modelled as a Bernoulli. The proposed model identifies 198 matches, with $\pi_{\gamma} > 0.5$, whilst the deterministic linkage performed at PCBS mainly via manual inspection identifies 171 matches. Manual check to evaluate the goodness of the additional matches is not trivial, due to the Arabic language of the reported information.

To facilitate the performance evaluation of the proposed method a simulation is performed, using public synthetic data for which the true match status is known, i.e the dataset created for the ESSnet Data Integration project (Essnet DI, 2011). The database consists of over 26000 records, with matching variables such as names, dates of birth and addresses. The matching variables contain simulated missing values and typos, mimicking those encountered in reality. From this database, 100 samples of size 1000 are independently selected, each by simple random sampling without replacement. From each sample of 1000 units, two files A and B are independently created by Bernoulli sampling with probability of selection $p_A = 0.93$ and $p_B = 0.92$, respectively, i.e. the two files to be linked are of sizes $N_A = 930$ and $N_B = 920$ on average over the 100 replications, and the number of true matches between them is 858 on average.

Three linkage models are compared: the first (*mod1*) models the Jaccard distance on *Surname* with Beta distribution and Bernoulli distribution for the matching variable *Year of Birth*. In the second model (*mod2*) we create a new variable pasting "*Surname*" and "*Name*" and model the Jaccard distance on the *SurnameName* variable with Beta distribution and again Bernoulli distribution for the matching variable *Year of Birth*. This second model aims at introducing more information into the linkage, so to apply a standard procedure in the third model (*mod3*) where we consider the traditional Fellegi-Sunter model based on the three variables, *Name*, *Surname* and *Year of Birth*. It's worthwhile noting that we introduce a constraint on the Beta distribution for *mod2*, i.e. we fix the parameters of the Beta distribution for the M set to be $\alpha_M = \beta_M = 0.5$, in order to evaluate the modelling adequacy of the Beta distribution for linkage purpose, comparing results from *mod1* and *mod2*. Some results from the simulation are shown in table 1, where match rate and false match rate are reported, averaging over the 100 simulation. The simulation results allow for deeper analysis, presented in Appendix.

Table 1: *Results from the simulation*

Linkage Model	***Match rate***	***False Match rate***
Mod1	0.77	0.28
Mod2	0.82	0.05

Mod3	0.88	0.02

4 Concluding remarks

The proposed method seems a valid alternative to judgmental deterministic record linkage in situations with little information, when less than three matching variables are available.

The methodology can be extended in several ways, based on the specific features of the real data. A possible extension is presented in the simulation, where we compare the results of modelling Beta distributions where all the parameters vary in the parameter space, with Beta distributions whit the parameters constrained to fixed values. Other possible extensions include modelling a mixture of two Beta distributions, as well as extending the mixture of Beta and Bernoulli distributions to the comparison of three (or more) matching variables. To this extent, the simulation provides some insights yet. In the proposed setting, the standard Fellegi-Sunter approach seems exploiting the identification power of the matching variables in a way that over-performing the Beta-Bernoulli mixture, in terms of both match rate and false match rate. Obviously, to some extent, this is due to the use of three variables instead of two. Actually, whether the proposed modelling might substitute the standard approach based on multinomial distribution is still an open question and need further analysis. The intent of this contribution is not to provide an alternative of the Jaro implementation of the Fellegi Sunter model, but rather to provide a probabilistic solution in cases where the standard model is not applicable at all.

Accounting for record linkage errors in inference (S2G-SIS)

A model for measuring the accuracy in spatial price statistics using scanner data

Un modello per la misurazione dell'accuratezza nell'indice spaziale dei prezzi tramite l'uso degli scanner data

Benedetti Ilaria and Crescenzi Federico

Abstract Scanner data coming from the retail trade outlets of modern distribution has the potential to significantly change how to compile spatial price indexes. Over the last years, the availability of new sources of data have stimulated various research studies for adopting more developed statistical techniques for constructing price indexes and assessing their accuracy. In order to evaluate the accuracy associated to point estimates of sub-national PPPs, the Jackknife replication technique is suggested and an empirical application is provided by ISTAT 2018 Scanner Data for the Tuscany region for the basic heading "mineral water", "coffee" and "dried pasta".

Abstract *L'uso degli scanner data provenienti dai punti vendita al dettaglio della grande distribuzione organizzata rappresentano una sfida cruciale per la compilazione di indici di prezzo spaziali. La disponibilità di questi nuovi dati ha stimolato i ricercatori nell'introduzione di tecniche statistiche al fine di valutare l'accuratezza degli indici dei prezzi. Con l'obiettivo di quantificare l'accuratezza associata alle stime puntuali delle stime sub-nazionali delle PPP, il metodo di replicazione Jackknife è stato suggerito e un applicazione empirica è stata realizzata da ISTAT tramite l'uso dei dati scanner del 2018. Questo studio è limitato alla regione Toscana per gli aggregati di consumo: acqua minerale, caffè e pasta secca.*

1 Introduction

Spatial price indexes (SPIs), that measure the differences in price levels across geographical areas, are essential for comparing real income, standards of living and consumer expenditure patterns. Therefore, it is extremely important to provide accurate point estimates of price differences across space with information about the presence and magnitude of uncertainty. Yet, despite the importance attached to these indicators, no standard errors or reliability measures are computed and published both at an international and national level. Little research has been done for measuring and communicating errors inherent in official spatial price indices (Manski, 2015). Nevertheless, during the last years there has been a growing interest for a more explicit evaluation of the accuracy of official economics statistics (Spiegelhalter et al., 2011) including the problems related to the uncertainty of the Purchasing Power Parities PPPs (Deaton, 2012; Deaton and Aten, 2017; Rao and Hajargasht, 2016). Uncertainty in the PPPs comes, not only from the choice of index number formula, but also from the dispersion of relative prices. A first attempt to solve the accuracy issue in PPPs is provided whithin the stochastic approach (Hajargasht and Rao, 2010) based on the country-product dummy method which can be viewed as a signal extraction problem. This approach derive the index numbers using different formulae used in the computation of PPPs which in turn could be used in the computation of standard errors (Rao and Hajargasht, 2016). Scanner Data (SD) has the potential to improve the accuracy of temporal and spatial price indices thus increasing NSOs' credibility and reputation. The aim of this paper is to contribute to the advancement of spatial price index literature by exploring the issue of evaluating the uncertainty associate to point estimates of sub-national PPPs using SD and the Jackknife replication technique (JRR). The paper is structured as follows. Features of SD in term of accuracy in the computation of spatial price index are presented in Section 2. The replication methodology used for estimating variance in sub-national PPPs is described in Section 3 while in Section 4 some of the results obtained are presented and discussed for a set of product aggregates (called in the international terminology Basic Headings-BHs).

2 The use of SD to improve the accuracy of spatial price indexes

In order to classify the several possible errors which can arise when estimating price indexes, we followed the mean-square error model suggested by Biggeri and Giommi (1987) in which the total error is defined as:

$$MSE = \mathrm{E}[P - \mathrm{E(P)}]^2 + [\mathrm{E(P)} - P'']^2 + [P'' - P^*]^2 + 2[\mathrm{E(P)} - P''][P'' - P^*] \quad (1)$$

Where P is the estimated survey index, E(P) is the expected value of the index, P'' is the defined goal of the index, P^* is the ideal goal of the index. In this model, $E[P - \mathrm{E(P)}]^2$ represents total variance including both sampling and measurement variance.

These errors are due to samples of representative products and point of sales, $[\mathrm{E(P)} - P'']^2$ includes measurement errors resulting from surveys for collecting prices and defining weights, $[P'' - P^*]$ indicates errors arising when the computational formula or the definition of the index are not adequate with the respect to the ideal goal of the index.

The availability of SD, which contain transactions of all goods that have been sold, the prices actually paid by consumers, and the quantities sold for each item code or GTIN[1] may significantly improve the accuracy of SPIs (Laureti and Polidoro, 2018). In this contex, SD has proved to be extremely useful for constructing official price index for temporal comparisons given its extensive coverange of transaction, information on weights, price and characteristics of items.

Unfortunately, a few of theoretical research has been conducted on SPIs in particular no standard errors or reliability measures are computed and published for PPPs. To this aim, the mean square error model, generally applied to temporal price index, should be extended to SPIs in order to evaluate their accuracy.

By using SD it is possible to calculate indices based on a variety of "superlative" index number formulae, including the Fisher ideal index, thus reducing the amount of $[P'' - P^*]$. In this framework, several studies evaluated the effect of using different price index formulae based on SD (Imai, Diewert e Shimizu, 2015; Laureti and Polidoro, 2018).

Measurement errors $[\mathrm{E(P)} - P'']^2$ are also reduced when using SD for replacing on-field collected prices thanks to the increased number of products priced, the improved territorial and population coverage (prices may be collected in each city across the province and not only in the provincial capital). In contrast, the traditional basket is a relatively small sample of the complete universe of goods and quantities sold are not available. Moreover, the use of unit value as "price", calculated as the total expenditure for that item code divided by the total quantities sold, represents a more accurate measure of transaction price than an isolated price quotation (Diewert 1995) moreover, it is a representative price paid by consumers over the reference period, thus reducing conceptual uncertainty.

The accuracy of a price index depends also on the selection of representative items: with SD it is possible to obtain probabilistic sample for products sold in modern retail chains. Empirical approaches for measuring variance for temporal price index are based on the use of replication technique repeated sampling techniques from a model population (Heravi and Morgan, 2014).

The jackknife method of variance estimation could provide a way to get index variability information by resampling from a single sample. This is the aim of our paper, the innovative contribution of our paper is to estimate the accuracy of PPP obtained by using ISTAT SD.

Since January 2018 Italy has been using SD for compilying official CPI. However, standard error are not computed even if a measure of transitory uncertainty is published in new releases. lmost a third of EU countries are using SD for compiling

[1] Global Trade Item Number is the current name of the barcode and it identifies a unique product over time and space.

CPIs even if using different methos. However, little is done to used SD for spatial price comparison.

3 Jackknife replications for computing PPP uncertainty

Originally introduced as a technique of bias reduction, the Jackknife method has by now been widely tested and used for variance estimation (Durbin, 1959). Efron and Stein (1981) and Efron (1982) provide a discussion of the Jackknife methodology. Verma (1993) and Verma and Betti (2011) provide a general description of JRR and other practical variance estimation methods in large-scale surveys. Like other resampling procedures, the JRR method estimates the sampling error from comparisons among sample replications which are generated through repeated resampling of the same parent sample. Each replication needs to be a representative sample in itself and to reflect the full complexity of the parent sample. The JRR variance estimates take into account the effect on variance of aspects of the estimation process which are allowed to vary from one replication to another. In principle, these can include complex effects such as those of imputation and weighting. The basic JRR model which shall be adopted in this work can be summarized as follows. Consider a design in which two or more primary units have been selected independently from each stratum in the population. As in the case of the linearization approach, subsampling of any complexity may be involved within each PSU, this does not affect the variance computation formulae. In the standard 'delete one-PSU at a time Jackknife' version, each JRR replication is formed by eliminating one sample PSU from a particular stratum at a time and increasing the weight of the remaining sample PSU's in that stratum appropriately so as to obtain an alternative but equally valid estimate to that obtained from the full sample. This procedure involves creating as many replications as the number of primary units in the sample.

Let j be a subscript to indicate a sample PSU and let k indicate its stratum; moreover, let $a_k \geq 2$ be the number of PSU in stratum k, assumed to be selected independently. Let λ be a full sample estimate of any complexity, and $\lambda_{(kj)}$ the estimate obtained after eliminating primary unit j in stratum k and increasing the weight of the remaining $a_k - 1$ units in that stratum Also, let $\lambda_{(k)}$ be the simple average of the $\lambda_{(kj)}$ over the a_k values of j in k. The variance of λ is then estimated as follows:

$$var(\lambda) = \sum_k \left[(1 - f_k) \frac{a_k - 1}{a_k} \sum_j (\lambda_{(kj)} - \lambda_{(k)})^2 \right] \tag{2}$$

Where $(1 - f_k)$ is the finite population correction which in typical social surveys is approximately equal to 1.

Under quite general conditions for the application of the procedure, the same and relatively simple variance estimation formula (**??**) holds for λ of any complexity. This in fact is the major attraction of the JRR method for practical application.

In this framework we use the rationale behind JRR to estimate the uncertainty due to the selection of the retail trade outlets as well as the sampling error component in (1).

4 Data and results

The analysis has been carried out by ISTAT using 2018 SD for all outlets of the Tuscany region. Annual provincial average prices which are obtained by aggregating the weekly price of each GTIN code by considering outlet-type (hypermarket or supermarket of a specific chain) and modern distribution chains for the Tuscany region. The dataset consists in 85,345 annual price quotes from the ten Tuscany provincial capitals concerning the eight most important modern distribution chains. In order to illlustrate the potential of the suggested methodology, in this analysis the BHs for Mineral water, Coffee and Pasta are used. The Eurostat-OECD methodology for computing international PPPs has been used, in which it does not consider real weights for items at BH level. Laspeyres and Paasche indexes has been computed by using expenditure share for each product sold in both provinces in the comparison.

$$P_{jk}^{L} = \frac{\sum_{i \in N_{jk}} p_{ik} q_{ij}}{\sum_{i \in N_{jk}} p_{ik} q_{ij}}, \quad P_{jk}^{P} = \frac{\sum_{i \in N_{jk}} p_{ik} q_{ik}}{\sum_{i \in N_{jk}} p_{ij} q_{ik}}, \quad P_{jk}^{F} = \sqrt{P_{jk}^{L} \times P_{jk}^{P}} \tag{3}$$

Then Fisher index are computed. In order to garantee the transitivity property we apply the Elteto-Köves-Szulc (EKS) method:

$$P_{jk}^{GEKS-FISHER} = \prod_{l=i}^{M} \left[P_{jl}^{F} \times P_{lk}^{F} \right]^{1/M} \tag{4}$$

With the aim to obtaining variance estimation of the calculated PPP, the jackknife replications are performed by setting the outlet as PSU and strata to provinces. Results in Table 1 show little variation among provinces.

Table 1 Estimated PPPs for Provinces of Tuscany(FI=1.00). JRR estimates of coefficient of variation in parenthesis.

	Provinces								
BHs	AR	GR	LI	LU	MS	PI	PO	PT	SI
Mineral water	0.9884	0.9990	1.0140	1.0124	1.0234	0.9997	0.9950	1.0005	1.0016
	(*0.36%*)	(*0.65%*)	(*0.71%*)	(*0.80%*)	(*0.51%*)	(*0.37%*)	(*0.41%*)	(*0.52%*)	(*0.72%*)
Coffee	0.9984	1.0313	1.0367	1.0117	1.0380	1.0006	0.9996	0.9985	1.0073
	(*0.67%*)	(*0.73%*)	(*0.58%*)	(*0.54%*)	(*1.19%*)	(*0.57%*)	(*0.72%*)	(*0.48%*)	(*1.67%*)
Dried pasta	1.0027	0.9926	1.0092	1.0060	1.0299	1.0013	1.0018	1.0008	1.0152
	(*0.57%*)	(*0.61%*)	(*0.35%*)	(*0.38%*)	(*0.78%*)	(*0.31%*)	(*0.54%*)	(*0.32%*)	(*0.83%*)

Interestingly, the province of Siena (SI) is the one showing highest variation for two out of three BHs, namely coffee and pasta. Regarding mineral water, the province of Lucca (LU) shows the highest variation followed again by the province of Siena. On the contrary, for each BH the lowest variations are to be found in the provinces of Arezzo (AR), Pistoia (PT) and Pisa (PI).

Communication of Uncertainty of Official Statistics

La comunicazione dell'incertezza delle statistiche ufficiali

Edwin de Jonge and Gian Luigi Mazzi

Abstract Communication of uncertainty of official statistics is of fundamental importance, but is not a common practice. We advocate that uncertainty measures in official statistics should be calculated and communicated and discuss issues in the communication of uncertainty. Best practices in verbal, numerical and visual communication of uncertainty measures in statistics are presented and discussed.
Abstract *La comunicazione dell'incertezza delle statistiche ufficiali ha una importanza fondamentale ma non è pratica comune. Noi riconosciamo che le misure di incertezza nella statistica ufficiale dorebbero essere calcolate e comunicate e discutiamo i problemi di comunicazione dell'incertezza. Inoltre presentiamo e discutiamo le "best practices" nella comunicazione verbale, numerica e visuale delle misure di incertezza in statistica*

Key words: Uncertainty measures, Visualisation, Official Statistics

1 Introduction

Statistics has the aim of producing accurate, precise and reliable measures for a given social, economic and environmental phenomenon. All statistical data should ideally be accompanied by indications of its accuracy, precision and reliability. Usually official statistics are presented and communicated as a singe value without any indication of accuracy, precision and reliability. Official statistics are inherently uncertain since they always include a measurement error which is given by the difference between the true and often latent and unobservable value of the target phe-

nomenon and its estimate produced by statisticians. The European level the Code of Practice Principle 12 explicitly mentions that "Sampling errors and non-sampling errors are measured and systematically documented according to the European standards". Despite this, errors have received little attention and little was done to communicate uncertainty.

This has been noted by [2], [6], [3] and [9], who emphasise as headline statistical estimates, are often presented as point estimates, arguably conveying a misleading degree of reliability, without explicitly expressing underlying and inherent uncertainties. It is important to try to provide an answer to a legitimate question: why are official statisticians ignoring the inherent uncertainty associated to the statistics they are producing? Providing an exhaustive answer is out of scope of this paper but we give two main reasons explaining this conservative approach. The first one reflects that official statisticians are worried that, explicitly acknowledging the presence of uncertainty in their statistics, could lower the reputation and credibility of their institution. The second is the assumption of statisticians that their users do not understand uncertainty and to properly deal with uncertainty without being confused. When dealing with uncertainty in official statistics there are three main aspects which need to be carefully considered and analysed. The first one is represented by the identification of the causes of uncertainty. Manski distinguishes three main source of uncertainty: temporary, permanent and conceptual. The second aspect is the measurement of uncertainty, which can be a challenging endeavour especially when trying to measure independently various types of uncertainty. The third challenging aspect is the communication of uncertainty and to this specific topic the rest of this paper is devoted.

2 Various types of communication

The communication of uncertainty in economic and social statistics is of fundamental importance. Not communicating uncertainty of statistics leads to wrong conclusions about their certitude, which leads to subsequent political, financial, social or economic decisions which are not correctly factoring in those uncertainties. Even more so, it would raise questions *why was a certain statistic revised after some time if it was communicated with certitude in the first instance?* and therefore causes distrust in future publications. Communicating uncertainty in an unclear manner however, can also create negative perceptions in users. Consequently uncertainty measures need to be communicated in a clear, transparent, easily understandable, unambiguous and meaningful manner. Communication tools should guide users to have a correct and positive perception of the uncertainty phenomenon helping them to integrate it in their own analysis or decision process. The way of communicating uncertainty also depends on what kind of uncertainty one is concerned about: *direct* and *indirect*, as [9] argues. Direct uncertainty refers to the uncertainty about a fact, number or scientific hypothesis that can be communicated either in quantitative terms , for instance a probability distribution or confidence interval, likelihood ratios

or verbal indication of its probability. On the other hand, indirect uncertainty refers to the quality of the underlying knowledge that forms a basis for the measured number. This will generally be communicated as a list of caveats about the underlying sources of evidence in a qualitative scale. In this paper we are focusing on communicating direct uncertainty. Literature considers three types of communication: verbal, numerical and visual communication which are not necessarily substitutes but often complementary each other. Following [9] we can say that the appropriate format also depends on the medium of communication.

2.1 Verbal communication

Verbal communication aims at providing users with short, standardised messages giving information on the uncertainty level associated to a specific statistical estimates. Verbal communication is widely used for forecasting, because the verbal terms describe probabilities. In policy when a forecasting estimate is used, it is important to describe the certainty of the estimate with a verbal indication. A well known example of forecasts are the climate analyses and global temperature forecasts of the The Intergovernmental Panel on Climate Change (IPCC). The following terms are used in the communication of the IPCC [8] (table 1):

Virtually certain	>99%
Very likely	90% – 99%
Likely	66% – 90%
About as likely as not	33% – 66%
Unlikely	10% – 33%
Very unlikely	1% – 10%
Exceptionally unlikely	< 1%

Table 1 IPCC verbal uncertainty assessments

The main difficulties limiting the use of verbal communication in official statistics is the constitute by the identification of a clear glossary, consistent across languages, as well as of a standardised set of messages.

2.2 Numerical communication

The most common communication method for uncertainty in official statistics is numerical communication. Often they are sampling error indications, but can also include other sources of uncertainty. Some statistical output is pseudo-accurate: the numerical precision of the number is higher then its statistical precision, e.g. the number of farm chicken in 2019 the Netherlands according to Statistics Netherlands was 100 992 944, which seems overly precise. Rounding a statistical estimate to match its statistical precision is therefore a good practice.

Sampling errors are often expressed in standard errors (SE), which is the standard deviation σ of the sampling distribution. When this approximates the normal distribution the true value x of statistical estimate $\hat{x}$ lies within $[\hat{x} - 1.96 \cdot \mathrm{SE}, \hat{x} + 1.96 \cdot \mathrm{SE}]$ with 95% confidence. The 95% confidence interval is very common in many sciences and official statistics. Other common, but currently less used, uncertainty measures include a Bayesian credible interval and a prediction interval. A credible interval is a summary statistic of a Bayesian data analysis in which the posterior probability distribution of a statistic is estimated. A prediction interval expresses the uncertainty of a prediction, which is conceptually different because there is no true value (yet).

When numerical uncertainty measures are communicated by statistical institutes they are most often not presented together with the statistic but described in a footnote or methodological appendix.

While a confidence interval expressed in percentages gives an indication of the size of the uncertainty interval and therefore its error, it does not communicate the probable range in which the true value lies. A good practice for numerical communication of uncertainty is therefore to present the user an interval with lower and upper bound in the same scale as the statistic it self, e.g., 2.3 ($[2.2, 2.4]$) in stead of $2.3 \pm 5\%$, which also allows for asymmetric interval resulting from an advanced statistical method. Which interval measure is used is for most users less important, for them interval indicates the certainty that the producer of the statistics has found for this statistic.

2.3 Visual communication

Visualisation tools have proven to be a powerful tool for displaying and communicating statistics [14, 10, 12, 11, 13]. The visual perception channel of users of statistics allows for detection of data patterns and abnormalities, such as outliers or missing data with ease [15]. Often visualisation of statistics provides a dense data summary, summarising and compacting many data into one single picture. A properly constructed visualisation shows the main message of the data, trends or other data patterns, but also reveals subtle details. Visualisation techniques are a promising method, allowing to show at the same time statistical data together with the associated uncertainty. this can be achieved by incorporating the uncertainty measures into the visualisation tools. In practice there are two main ways to measure and consequently communicating uncertainty: the use of an interval measure (e.g. confidence interval) and probability distribution (e.g. density distribution of errors).

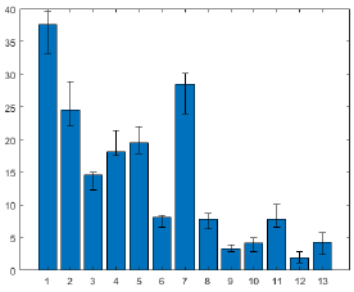

Fig. 1 Bar chart with error bars

Figure 1 shows the most used method in scientific papers of plotting statistical uncertainty: error bar charts.

Each point estimate is visualised with a bar, and the confidence interval is plotted as an interval on top each bar. This is a direct encoding the interval and has the benefits that the visual focus is on the point estimate and that the confidence interval is a detail. It follows the same good practice as for numeric communication, that it shows that range of probable values. The error bar makes it also possible to compare the sizes of the intervals for the different estimates. A disadvantage is that the error bar is visually asymmetric, the lower bound is less visible than the upper bound.

When data are expressed as time series, such as for many macroeconomic indicators, The line chart is the most appropriate and used visualisation tool.

Figure 2 shows the different options to visually add uncertainty to a line chart from the user study in [16].

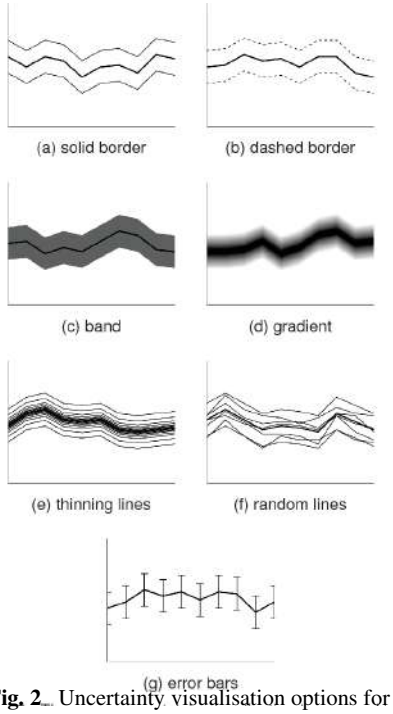

Fig. 2. Uncertainty visualisation options for line charts from [16]

Options a, b, c and g are confidence interval options. All these options ”work” for users, but [9] showed that c) and g) are slightly better in reading off the overall trend of a time series. The paper indicates that the error band is most natural to users and can be used as a good practice for showing time series. When dealing with probability distributions, several methods can use such as diamonds (often used in medical statistics), box and violin plots, giving a more accurate idea of the underlying distribution but not of the uncertainty since the point estimate is missing. We can also use a density plot, which shows the probability of a value or a gradient approach (especially appropriate for time series data) where probability is encoded in transparency, the more likely, the less transparent and more. In the recent year one of the most popularised approach is the fan plot which is designed to show the bounds of several different confidence intervals (often coloured to emphasise the changing probability density going further from the point) and are used by the Bank of England when communicating past and forecasts of future GDP estimates.

3 Conclusions

Uncertainty of official statistics should be communicated in a clear, transparent and understandable manner. Using the best practices for verbal, numerical and visual communication as presented in this paper, should lead to increased and improved publication of uncertainty in official statistics. Contrary to common belief, perception research indicates that common users of statistics have an understanding that measured official statistics have uncertainty and are able to handle communicated uncertainty measures. Not only that uncertainty of statistics is communicated is important, but also how they are communicated.

Key words: official statistics, uncertainty, signal extraction

1 Introduction

Statistical offices and other public agencies producing statistics usually communicate a variety of official economic and social indicators in general as single values (normally corresponding to the central point estimate), without explicitly mentioning the associated inherent and unavoidable uncertainty. While the technical documentation associated with official data often acknowledges the possible presence of errors, little is done to communicate widely such features. While it is difficult to derive a valid scientific or professional explanation for this circumstance, Manski (2019) argues that one possible reason for this status quo lies in the partly political nature of official statistics. He argues that policy makers or other public agencies may be incentivised to express strong certitude in their communication rather than providing further information about the underlying and inherent uncertainty. However, conveying strong certitude about data or economic analysis can be harmful for the development of public policies in multiple ways. If policy makers incorrectly believe that existing statistical analyses provide an errorless description of the current state of the

* Kings College London, george.kapetanios@kcl.ac.uk

† Bocconi University Milan, massimiliano.marcellino@unibocconi.it

‡ Senior Consultant, glmazzi@pt.lu

economy, they will not take into proper account the underlying uncertainty when taking their decisions. Moreover, communicating official statistics with strong certitude leads to further difficulties because of the way that third parties, especially media, distribute this information to a wider audience, namely by largely taking them at face value, which may lead to further miscommunication. On the other hand official statisticians are worried by the possibility that showing that statistics are affected by uncertainty could lower their credibility. Furthermore, they consider that uncertainty, especially when it is relatively high, could confuse or even mislead policy makers and analysts. This explains, even if it does not justify completely, the traditional conservative position taken by official statistical agencies. Nowadays things are starting to move, even if slowly, and the attention to all aspects related to the uncertainty in official statistics is progressively growing up within statistical institutions. In such a promising context, also Eurostat has decided in 2019 to play an active role contributing to the measurement and communication of uncertainty in official statistics by launching a new research project within its methodological framework contract. This Eurostat project labeled "COMmunicating UNcertainty In Key Official Statistics" (Comunikos) aims at:

- review and categorise the various sources of uncertainty in official statistics and identify their impact on the disseminated data;
- review the methods and metrics used in official statistics as well as in other disciplines to measure uncertainties;
- propose new methods and metrics to present uncertainties based on the review of existing sources and methods;
- develop case studies and empirical applications related to both time series and cross-sectional and survey based statistics;
- provide enhanced recommendations and guidance on measuring and communicating uncertainty in official statistics;

The rest of this paper (which is based on the outcome of the Comunikos project) is devoted to the presentation of the method identified to measure uncertainty in time-series based statistics and of a short description of an empirical application.

2 The Methodology

The methodology is based on state space modelling. Such models provide a natural avenue since they permit the presence of unobserved variables that can proxy for the true process that statistical agencies and other policy making bodies are trying to measure. Such models have an added benefit of allowing for the consideration of particular economic structures that can inform the quantification of conceptual uncertainties. The proposed model is a state space representation of the signal extraction problem following the work of Cunningham et al (2012). Using business surveys and other indirect measures, the model allows for an array of measures of each macroeconomic variable of interest. Then, for each variable of interest, the model comprises alternative indicators, a transition law and separate measurement equations describing the latest official estimates. The model is presented in a vector notation, assuming m variables of interest. However, we simplify estimation by assuming block-diagonal structure throughout the model so that the model can be estimated on a variable-by-variable basis for each of the m elements in turn. Let the m dimensional vector of variables of interest that are subject to data uncertainty at time t be denoted by $\mathbf{y}_t$, $t = 1, \ldots, T$. The vector $\mathbf{y}_t$ contains the unobserved true value of the economic concept of interest. The model for the true data $\mathbf{y}_t$ is given by

$$\mathbf{y}_t = \mu + \sum_{i=1}^{q} \mathbf{A}_i \mathbf{y}_{t-i} + \varepsilon_t, \tag{1}$$

$\mathbf{A}_1, \ldots, \mathbf{A}_q$ are $m \times m$ matrices, $\mathbf{A}(L) = \mathbf{I}_m - \mathbf{A}_1 L - \ldots - \mathbf{A}_q L^q$ is a lag polynomial whose roots are outside the unit circle, μ is a vector of constants, $\varepsilon_t = (\varepsilon_{1t}, \ldots, \varepsilon_{mt})'$ and $\mathrm{E}(\varepsilon_t \varepsilon_t') = \Sigma_\varepsilon$, where we denote the main diagonal of Σ_ε by $\sigma_\varepsilon^2 = (\sigma_{\varepsilon_1}^2, \ldots, \sigma_{\varepsilon_m}^2)'$. We further assume that $\mathbf{A}_1, \ldots, \mathbf{A}_q$ are diagonal. Let $\mathbf{y}_t^{t+n}$ denote a noisy estimate of $\mathbf{y}_t$ published by the statistical agency at time $t+n$, where $n = 1, \ldots T-t$. The model for these published data is

$$\mathbf{y}_t^{t+n} = \mathbf{y}_t + \mathbf{c}^n + \mathbf{v}_t^{t+n} \tag{2}$$

where $\mathbf{c}^n$ is the bias in published data of maturity n and $\mathbf{v}_t^{t+n}$ the measurement error associated with the published estimate of $\mathbf{y}_t$ made at maturity n. One of the main building blocks of the model is the assumption that revisions improve estimates so that official published data become more accurate as they become more mature. Reflecting this assumption, both the bias in the published estimates and the variance of measurement errors are allowed to vary with the maturity of the estimate - as denoted by the n superscript. The constant term $\mathbf{c}^n$ is included in equation (2) to permit consideration of biases in the statistical agency's data set. Specifically, $\mathbf{c}^n$ can be modelled as

$$\mathbf{c}^n = \mathbf{c}^1 (1+\lambda)^{n-1}, \tag{3}$$

where $\mathbf{c}^1$ is the bias in published data of maturity $n = 1$ and λ describes the rate at which the bias decays as estimates become more mature $(-1 < \lambda < 0)$. This representation assumes that the bias tends monotonically to zero as the estimates become more mature. The measurement errors, $\mathbf{v}_t^{t+n}$, are assumed to be distributed normally with finite variance. Serial correlation in $\mathbf{v}_t^{t+n}$ is allowed. Concerning the estimation strategy, we mainly use maximum likelihood via the Kalman filter.

3 Application

Our application is based on a dataset containing data for 5 key macroeconomic indicators: Harmonized Index of Consumer Prices (HICP), Industrial Production index (IPI) Retail Trade Volume Index (RTI), Unemployment Rate (UR) and Gross Domestic Product in volume (GDP) for the Euroarea and its 4 major countries: Germany, France, Italy and Spain. Data start in 2000 with vintages available from March 2018 to March 2019 (13 vintages or releases). Then, we have created a quarterly dataset taking for each monthly variable the average of the 3 months of a given quarter. Data were further transformed in quarterly growth rates except for UR which was transformed into a quarterly difference. As a first consideration, the HICP is almost never revised while the RTI is the most often revised indicator among those considered. Over the 2000-2018 sample, the data for GDP show the mean growth rate to have been highest for Spain and lowest for Italy, with the growth rate for the Euroarea, Germany and France being in between, and quite similar to each other. The data for France have the lowest volatility over the period, with the data for the other countries up to twice as volatile. The data for all countries show a skew to the downside, reflecting the great recession, with the downside skew greatest for Germany, and smallest for Spain. Out of the monthly series, IP and RTI are shown to be somewhat more volatile than GDP, even when considered at the quarterly frequency. In broad terms, the patterns across the countries are similar to what is observed for GDP, with the exception of the volatility of RTI growth which turns out to be higher in the case of Spain than for the other countries. In contrast to GDP growth, which has been positive on average over the 2000-2018 sample for all countries, the growth rates of IP and RTI have not been positive on average for all the countries. IP

growth has been negative on average over the sample for Italy, Spain and France, and RTI growth for Italy and Spain, what might be an indication of a shift in activity from industry and retail trade to other parts of the service sector. The UR, finally, has declined on average over the sample in the cases of Germany and the Euroarea, increasing for the cases of Italy and Spain, and unchanged for France. As GDP growth, the changes in the UR are shown to have the lowest volatility over the sample in the case of France. The highest volatility is recorded in the case of Spain, even though the volatility of real GDP growth for that country has been the lowest across the countries. In terms of revisions, the data suggest that the average revision is of the same order of magnitude for the (quarterly) growth rate of real GDP and RTI, while revisions to the IPI growth rate have tended to be somewhat larger on average, at least for the Euroarea, Germany and France. The volatility of the revisions is quite similar across the countries, with exceptions to the upside for IPI for Italy and Spain, and RTI for Germany. When applying our modelling strategy, due to the limited number of releases we set the initial error variance to 1, the parameter beta in serial correlation to -0.2 implying an AR(1) process for v(t+1). Initial bias in the statistical agency's data set and bias decay were both set to zero, as based on an earlier study by Cunningham et al (2012) for UK data. We have experimented with the decay parameter delta, setting it to -0.01 and -0.05 and with the correlation of the measurement errors with the underlying state of the economy. The correlation was set to -0.5; 0 and 0.5 in turn. The results show that delta=-0.05 and rho=-0.5 perform best in describing the revisions in inflation, GDP for all countries and retail trade for all countries but Spain as measured by Mean Squared Error of the final release and the filtered estimate. For industrial production the same combination of variables performs best for Germany and Italy, while for the remaining three countries moving to a slower decay of delta=-0.01 provides better results. In the case of unemployment the no correlation case for delta=-0.05 works best for all countries but Spain for which delta=-0.01. What is interesting to note about those results is that with respect to the correlation of the measurement error, the best-performing specification is the same (rho=-0.5) for the variables expressed as growth rates - GDP, IP and RTI - and another (rho=0.0) for the UR, expressed as a simple difference, and irrespective of the decay parameter (whether delta=-0.05 or -0.01). This supports the notion that variables tend to display different patterns of data uncertainty, and therefore require different treatment for data uncertainty, depending on whether they are stationary or trending.

4 Conclusions

In this short paper, which summarizes an extensive work carried out within the Comunikos project of Eurostat, Kapetanios et al (2020) we considered a state of the art framework for modelling real-time data and quantifying the uncertainty surrounding them. We applied this framework to a post-crisis sample (2000-2018) for the Euroarea and its four largest countries to provide an extensive set of empirical results. The results indicate that the model-based estimate of the true process in terms of mean squared error (MSE) outperforms the most recent published estimate for all the variables considered. The results further illustrate the sensitivity of the performance of the model in terms of the mean squared error (MSE) with respect to the two model parameters, the decay parameter δ, and the parameter capturing the correlation in measurement error, ρ. Overall, the results suggest that the treatment for data uncertainty is both feasible and important, and that the appropriate choice of parameters is quite relevant to achieve the best empirical performance. One aspect that must be given some consideration in applying the methodology is the nature of the variables - trending or stationary - that are being estimated.

Bayesian methods in biostatistics

Network Estimation of Compositional Data

Stima di un Grafo di Dati Composizionali

Nathan Osborne, Christine B. Peterson, Marina Vannucci

Abstract Network estimation for Gaussian data has been extensively studied in the statistical literature. In this paper, we seek to develop a novel method for compositional count data. We use a hierarchical Bayesian model with latent layers and employ spike-and-slab priors for edge selection. For posterior inference, we utilize the expectation maximization algorithm to enable efficient estimation. Through simulation studies, we demonstrate that the proposed model outperforms existing methods in its accuracy of network recovery. We show the practical utility of our model via an application to microbiome data from the Human Microbiome Project.
Abstract *La stima di grafi per dati Gaussiani è stata ampiamente studiata nella letteratura statistica. In questo contributo, proponiamo un nuovo metodo per i dati di conteggio composizionali. Usiamo un modello gerarchico Bayesiano con strati latenti e a priori spike-and-slab per la selezione degli archi. Per l'inferenza a posteriori, si utilizza l'algoritmo EM che consente una stima efficiente. Attraverso studi di simulazione, dimostriamo che il modello proposto supera i metodi esistenti nell'accuratezza della stima del grafo. Mostriamo l'utilità pratica del nostro modello tramite un'applicazione a dati di microbioma dello Human Microbiome Project.*

1 Introduction

In this paper, we propose a Bayesian hierarchical model for compositional data that allows for estimation of network interactions. In the Gaussian setting, the problem of selecting edges in the graph reduces to the estimation of a sparse inverse covariance matrix, since exact zeros in this matrix, which is also known as the precision matrix, correspond to conditional independence relations. In frequentist settings, penalized likelihood methods, such as neighborhood selection and the graphical LASSO, have been proposed. These methods have also been extended to count data by using data transformations or penalized log-likelihood methods. In Bayesian inference, the G-Wishart prior, which is the conjugate prior that imposes exact zeros in the precision matrix, has been explored by several authors for inference of Gaussian graphical models, but poses significant computational challenges and it is not easily scalable. Alternative shrinkage constructions that employ continuous priors on the off-diagonal elements of the precision matrix have been proposed, including the Bayesian graphical lasso, which relies on double exponential priors, or mixture *spike-and-slab* priors [5], for which efficient expectation conditional maximization methods have been recently proposed [4], that allow scalability.

In our approach, we consider multivariate count data, and specifically compositional data that have a fixed sum constraint. We model the data using a Dirichlet-Multinomial likelihood and then introduce a latent layer by modeling the log concentration parameters via a Gaussian distribution. We allow additional covariates to influence the variable counts and account for this through the mean function. We also capture the dependence relationships of the concentration parameters by estimating the inverse covariance matrix via the shrinkage prior of [5]. For posterior inference, we implement an expectation-minimization (EM) algorithm to estimate the model. This allows us to gain flexibility by using a Bayesian model, while still remaining computationally efficient. We test our model on a simulated dataset and see that it outperforms competing models. We apply the model on data from the gut microbiome from the Human Microbiome Project.

2 Model

Suppose we have observed multivariate counts arranged in an $n \times p$ matrix, $\mathbf{X}$, where p is the number of observed variables measured across n samples. We then let the p-vector $\mathbf{X}_i$ correspond to the measurements for observation i, and the matrix entry $x_{i,j}$ correspond to the j^{th} variable measurement for the i^{th} observation. We also observe q covariate measurements for each of the n observations, with these q additional factors possibly influencing the measured counts for each observation. We arrange this covariate data in an $n \times q$ matrix, $\mathbf{M}$.

We are interested in understanding the conditional dependence relationships among the p variables. We adopt a hierarchical model formulation with a latent Gaussian layer, similarly to [6], as

$$\begin{aligned} \mathbf{Z}_i \mid \mathbf{B_0}, \mathbf{M}_i, \mathbf{B}, \Omega &\sim \text{MVNorm}(\mathbf{B_0} + \mathbf{M}_i\mathbf{B}, \Omega^{-1}) \\ \alpha_i &= \exp\{\mathbf{Z}_i\} \\ \mathbf{h_i} \mid \alpha_i &\sim \text{Dirichlet}(\alpha_i) \\ \mathbf{X_i} \mid \mathbf{h}_i &\sim \text{Multinomial}(\mathbf{h_i}). \end{aligned} \tag{1}$$

In this hierarchical formulation, we introduce a latent normal variable $\mathbf{Z}_i$, which is a direct transformation of the concentration parameter α_i and therefore controls the observed counts $\mathbf{X}_i$. This model has several important features: the Dirichlet-Multinomial likelihood for count data, $\mathbf{X}_i$, allows us to account for overdispersion as well as the compositional nature of the data. The dependence among the $\mathbf{Z}_i$ is captured by the inverse covariance matrix, also known as the precision matrix, Ω. We are also able to control for the influence of additionally observed covariates and the abundance of a covariate with the mean term, $\mathbf{B_0} + \mathbf{M}_i\mathbf{B}$.

Prior on $\mathbf{B_0}$ and B We first introduce the priors on the mean elements of $\mathbf{Z}$, which will allow us to control for additional covariates. We put a non-informative prior on each element of $\mathbf{B_0}$, specifically $B_{0_j} \propto 1$. We then consider a horseshoe-like prior on the elements of $\mathbf{B}$, which will encourage the effects of non-influential covariates to be shrunk to zero. Following the work of [1], we say

$$B_{k,j} \mid \mu_{k,j}, \theta_j \sim N(0, \frac{\theta_j}{2\mu_{k,j}}) \text{ , } p(\mu_{k,j}) = \frac{1 - exp(-\mu_{k,j})}{2\pi_\mu^{1/2}\mu_{k,j}^{3/2}}, 0 < \mu_{k,j} < \infty, \theta_j > 0,$$

where $\mu_{k,j}$ is a shrinkage parameter for each individual regression coefficient, and θ_j a global shrinkage parameter for each coefficient related to the j^{th} variable in $\mathbf{Z}$.

Prior on Inverse Covariance Matrix Next we introduce the prior on the precision matrix Ω, which allows us to learn a sparse association network. We consider the prior introduced by [5] as a prior on the precision matrix entries:

$$\begin{aligned} \pi(\Omega \mid \delta, \nu_1, \nu_0, \lambda) \propto \prod_{i<j} \big\{ (1 - \delta_{i,j}) \text{Normal}(\omega_{i,j} \mid 0, \nu_0^2) + \delta_{i,j} \text{Normal}(\omega_{i,j} \mid 0, \nu_1^2) \big\} \cdot \\ \prod_i \text{Exp}(\omega_{i,i} \mid \lambda/2) \mathbf{1}_{\Omega \in M^+}, \end{aligned} \tag{2}$$

where ν_0 and ν_1 are fixed standard deviations, that assume small and large values respectively, and $\delta_{i,j}$ is a latent variable indicating whether or not an edge is present between nodes i and j. The mixture of normals on the off-diagonal precision matrix entries enables the selection of interactions, represented by edges in a network, since non-zero precision matrix entries reflect conditional dependence relationships. Here, entries reflecting conditional independence relations do not equal exactly zero, but get shrunk to close to zero. The diagonal entries are drawn from a

common exponential prior. The final term in equation (2) expresses a constraint to the space of positive definite matrices M^+. This prior is particularly advantageous in our model, as it allows for efficient estimation via the EM algorithm and leads to less bias in graph estimation than the graphical LASSO, as shown by [4].

We complete the modeling by setting the prior on the graph structure, assuming independent Bernoulli distributions on the inclusion of each edge as follows:

$$p(\delta_{i,j} \mid \pi) \propto \pi^{\delta_{i,j}}(1-\pi)^{1-\delta_{i,j}} \text{ , } \pi \mid a_\pi, b_\pi \sim \text{beta}(a_\pi, b_\pi). \tag{3}$$

Model Estimation via EM We define the objective function to maximize as

$$\begin{aligned} F(\Omega, \delta, \pi, \mathbf{Z}, \mathbf{B}, \mathbf{B}_0) =& p(\mathbf{Z} \mid \mathbf{M}, \Omega, \mathbf{B}) p(\Omega \mid \delta, \nu_1, \nu_0, \lambda) p(\mathbf{B} \mid \mu, \theta) p(\mu) \\ & p(\delta \mid \pi) p(\pi \mid a_\pi, b_\pi) p(\mathbf{X} \mid \alpha). \end{aligned}$$

Following the work of [1, 4], we take the expectation of the objective function in terms of δ and $\mu_{k,j}$. This gives an E step of updating

$$\begin{aligned} E_{\delta \mid \Omega, \pi, \mathbf{Z}, \mathbf{B}, \mathbf{B}_0}[\delta_{i,j}] &= p^*_{ij} \equiv \frac{a_{ij}}{a_{ij} + b_{ij}} \\ E_{\delta \mid \Omega, \pi, \mathbf{Z}, \mathbf{B}, \mathbf{B}_0}[\frac{1}{\nu_0^2(1-\delta_{i,j}) + \nu_1^2 \delta_{i,j}}] &= d^*_{ij} \equiv \frac{1 - p^*_{ij}}{\nu_0} + \frac{p^*_{ij}}{\nu_1} \\ E_{\mu_{j,k} \mid .}[\mu_{j,k} \mid \mathbf{B}, \mathbf{Z}, \theta] &= \tilde{\mu}_{j,k} = \frac{1}{2\pi\theta_j^{1/2}}(\frac{\theta_j}{B^2_{j,k}} - \frac{\theta_j}{B^2_{j,k} - \theta_j}) \end{aligned}$$

where $a_{ij} = p(\omega_{i,j} \mid \delta_{i,j} = 1)\pi$ and $b_{ij} = p(\omega_{i,j} \mid \delta_{i,j} = 0)(1-\pi)$. We can think of the parameter p^*_{ij} as an estimate of the posterior probability that the edge i,j is selected in the network. We use these updated values in the M step to update the precision matrix, Ω and standard deviation parameter θ_j.

In the M step, we first update the centering parameters, $B_{0_j} = \frac{\sum_{i=1}^N Z_{i,j} - \mathbf{M}_i \mathbf{B}_j}{N}$. We next update $\mathbf{B}$, updating each column, $\mathbf{B}_j$, and corresponding θ_j independent of each other column. These updates are

$$B_{j,k} = \Big(\frac{M^T M}{\sigma_j} + \text{diag}(\frac{2\tilde{\mu}_{j,k}}{\theta_j})\Big)^{-1}(\frac{M^T Z_j}{\sigma_j}) \text{ , } \theta_j = \frac{1}{q}\sum_{k=1}^{q} 2\tilde{\mu}_{j,k} B^2_{j,k}$$

Note that σ_j is the standard deviation of the j^{th} column of $\mathbf{Z}$, found by using the properties of the multivariate normal distribution shown in equation (1).

We then perform a column-wise update of the precision matrix, Ω. Consider the following notation and block structures:

$$\Omega = \begin{pmatrix} \Omega_{11} & \omega_{12} \\ \omega_{21}^T & \omega_{22} \end{pmatrix}, (\mathbf{Z} - (\mathbf{MB} + \mathbf{B_0}))^T(\mathbf{Z} - (\mathbf{MB} + \mathbf{B_0})) = \begin{pmatrix} \mathbf{S}_{11} & \mathbf{s}_{12} \\ \mathbf{s}_{21} & s_{22} \end{pmatrix}.$$

We can then do a column-by-column update as

$$\omega_{12}^{k+1} = -((s_{22}+\lambda)(\Omega^{k+1})^{-1} + \text{diag}(d_{ij}^*))^{-1})\mathbf{s}_{12}\ ,\ \omega_{22}^{k+1} = \omega_{12}^{k+1}\Omega_{11}^{k+1}\omega_{12}^{k+1} + \frac{n}{\lambda + s_{22}}.$$

The point estimates of π is also updated as $\pi = \frac{(a_\pi + \sum_{i<j} p_{ij}^* - 1)}{(a_\pi + b_\pi + \frac{p(p-1)}{2} - 2)}$.

Finally, the matrix of latent variables can be estimated by finding a point estimate for each entry. This is done by updating each row of the matrix independently. As shown in [6], the objective function to optimize with respect to $\mathbf{Z}$ is

$$\log P(\mathbf{Z} \mid \mathbf{X}, \mathbf{M}, \mathbf{B_0}, \mathbf{B}, \Omega) = -\frac{1}{n}\sum_{i=1}^{n}(\sum_{j=1}^{p}\tilde{\Gamma}(\alpha_{ij} + x_{ij}) - \tilde{\Gamma}(s(\alpha_i) + s(\mathbf{X}_i)) -$$

$$\sum_{j=1}^{p}\tilde{\Gamma}(\alpha_{ij}) + \tilde{\Gamma}(s(\alpha_i)) - \frac{1}{2}\log \mid \Omega \mid + \frac{1}{2n}\sum_{i=1}^{n}(\mathbf{Z}_i - (\mathbf{B_0} + \mathbf{M}_i\mathbf{B}))\Omega(\mathbf{Z}_i - (\mathbf{B_0} + \mathbf{M}_i\mathbf{B})),$$

where $\tilde{\Gamma}$ is the log-gamma function, and $s(x_i) = \sum_{j=1}^{p}(x_{ij})$. To accomplish optimization of each $\mathbf{Z}_i$ we use the limited-memory quasi-Newton (L-BFGS) algorithm, which is a quasi-newton gradient descent method that makes use of the inverse gradient to direct where to search through the variable space.
The parameters are updated by alternating between the E and M steps, updating each parameter in their respective step. Since Ω is updated via a column wise update, in each M step the updates of Ω are repeated until the estimate of Ω for given iteration has converged. For a more detailed derivation of each E and M step refer to [1, 4].

3 Simulated Data

We simulate data to be similar to microbiome data, and follow a simulation set up similar to [6] but use dimensions n = 350, p = 100, and q = 5. We compare the proposed models performance to SparCC, SpiecEasi, and mLDM [2, 3, 6] which are specifically designed for network discovery of microbiome data.

Results in Table 1 show that in all cases the proposed model performs best in terms of TPR and AUC. In all network structures other than a hub structure, the proposed model also does best in F1 and MCC scores. SpiecEasi and mLDM both did well in regards to FPR, but also selected more sparse networks.

4 Human Microbiome Data

Figure 1 shows an estimated network using microbiome data from the Human Microbiome Project. We find that OTUs of the same phyolgenetic family are more likely to be conditionally dependent on each other and also that OTUs of different families have more negative partial correlations, indicating that those are more likely to be in competiton with each other, as also observed by [3, 6]

Table 1 Simulation results shown as averages across 25 different simulated data sets. Band, Hub, Block, and Random refer to the underlying network structure used to generate the data.

Using co-data to empower genomics-based prediction and variable selection

L'uso dei dati complementari per migliorare le previsioni basate su dati genetici e la selezione delle variabili

Magnus M. Münch, Mirrelijn M. van Nee and Mark A. van de Wiel

Abstract Genomics-based prediction is cursed by the dimensionality of the covariates and their collinearity. Fortunately, several sources of complementary data (co-data) are available in the public domain, such as pathway information, p-values from similar studies and genomic annotation. We discuss several types of co-data and how such co-data can be combined to inform the regularization (i.e. the priors) for subsets of the genomics variables in (Bayesian) regression settings. Several priors (and corresponding penalties) are considered, and estimation techniques facilitating efficient computation, such as variational and empirical Bayes, are discussed.
Abstract *La qualità delle previsioni dei modelli per dati genetici è affetta dal problema del dimensionalità e della collinearità presente tra covariate. Fortunatamente, esistono diverse fonti pubbliche di dati complementari (co-data), come pathway data, p-values da studi simili e annotazioni genetiche. In questo lavoro, noi discutiamo diversi tipi di co-data e come tali dati possono essere formalizzati, ad esempio mediante la specificazione di una distribuzione a priori in una regressione Bayesiana. Si studieranno inoltre diverse distribuzioni a priori e le rispettive performance in termini di efficienza computazionale per vari approcci inferenziali quali il variational e empirical Bayes.*

Key words: Co-data, empirical Bayes, variational Bayes, penalized regression

1 Introduction

Clinical research studies the wealth of genomics to predict disease-related outcomes and discover biomarkers of diseases that may be driven by few or many variables. Samples of high-dimensional genomics provide a limited amount of information on the covariates, making prediction and covariate selection difficult. Performance may

Dep. Epidemiology & Data Science, Amsterdam University medical centers, Amsterdam, Netherlands, e-mail: mark.vdwiel@amsterdamumc.nl

be improved when additional information on the covariates, termed *co-data*, is incorporated [8], accessible, for example, from external studies or public repositories.

Ideally, one would like to extract and exploit all relevant information from multiple and various co-data sources. Group-lasso type of methods can handle grouped co-data, penalising covariates in groups to favor group-sparse solutions. Group- and latent overlapping group-lasso [3, 13] form the basis for structured group-lasso penalties like grouped trees [5] and hierarchical groups [12]. As these penalties are parameterised by only one hyperparameter, their flexibility to adapt to the main data is insufficient: non-informative or contradictory grouping information may lead to sub-optimally performing prediction models [8, 2]. Alternative methods like the adaptive lasso [14] exist, but are prone to overfitting, because of the covariate-specific weight that is typically estimated from the same data.

Our focus is on methods that allow co-data-adaptive regularization, in particular methods with a(n) (empirical) Bayesian flavor. We focus on clinical prediction, and therefore on methods that can deal with dichotomous and/or survival response.

2 Co-data

Co-data stands for *co*mplementary *data*, which contains information on the *covariates*; it may originate from any source of information, including data from different or the same samples. In the latter case, it should not include the response labels of those samples, as this may lead to overfitting when training the learner on the main data using co-data adaptive penalties. Below we describe several structures of co-data. Such structures determine the type of penalization induced by the co-data.

i) Non-overlapping groups: the covariates are grouped in non-overlapping groups. An example in clinical genomics are the published gene signatures: a set of genes that is known to play an important role in the development of the disease. This set defines two groups: each gene either belongs to a signature or not; **ii) Overlapping groups:** Pathways are a well-known example of overlapping groups: genes can belong to multiple pathways, which induces overlap between the group defined by the pathways; **iii) Hierarchical or graph-structured groups:** In molecular biology many relations are represented by a graph or hierarchy. If one has exon-level data, a simple hierarchy is: chromosome $\rightarrow$ gene $\rightarrow$ exon. Another example is gene ontology, which represents groups of genes in a directed acyclic graph (DAG). At the top of the hierarchy nodes represent general functions, which are refined in more specific biological functions downwards the DAG; **iv) Continuous co-data:** Some co-data may present itself on a continuous scale. Examples are p-values from external data or correlations with other omics covariates than those used by the learner.

The co-data functionality differs substantially between the methods discussed below. All methods can handle non-overlapping groups, but only some can handle the other co-data structures. In addition, the methods differ in how these are handled, and in the ability to handle *multiple* co-data sources.

3 Regularized regression

Let $\mathbf{y} = (y_1, \ldots, y_n)$ and $\mathbf{X} = (X_{ij})_{i=1,j=1}^{n,p}$ be the response vector and high-dimensional covariate matrix, respectively. We consider regularized regression:

$$\ell(\boldsymbol{\beta}; \mathbf{y}, \mathbf{X}) - f_{\boldsymbol{\lambda}}(\boldsymbol{\beta}), \tag{1}$$

where $\ell(\boldsymbol{\beta}; \mathbf{y}, \mathbf{X})$ is an appropriate log-likelihood for modeling $\mathbf{y}$ and $f_{\boldsymbol{\lambda}}(\boldsymbol{\beta})$ is a penalty function, to be specified for the methodologies below. Alternatively, a Bayesian formulation is pursued, in which case a prior $\pi_{\boldsymbol{\lambda}}(\boldsymbol{\beta})$ plays the role of regularizer. All methods below allow a vector of penalties or hyperparameters $\boldsymbol{\lambda}$, instead of a scalar, where the specific penalty for β_j is modeled by the use of co-data.

4 Co-data informed regression

Group-adaptive ridge regression employs a penalty:

$$f_{\boldsymbol{\lambda}}(\boldsymbol{\beta}) = \sum_{j=1}^{p} \lambda_{g(j)} \beta_j^2, \tag{2}$$

where $g(j) = g$ if $j \in \mathscr{G}_g$, a group based on the co-data, or alternatively $\beta_j \sim N(0, \tau^2_{g(j)})$, with $\tau^2_{g(j)} = C\lambda^{-1}_{g(j)}$. For fixed hyperparameters and suitable constant C, the Bayesian MAP estimate equals the maximum penalized likelihood estimate. Below we discuss two methodologies that employ ridge with empirical Bayes penalty parameter estimation: `GRridge` [8] and `ecpc` [10]. The fully Bayesian method `graper` [11] also handles ridge, and is discussed further on. The crux behind both `GRridge` and `ecpc` is the moment-based empirical Bayes estimation of $\boldsymbol{\lambda}$. Both methods first conventionally estimate a global penalty λ by cross-validation. Then, group penalties are estimated by solving the equations

$$\frac{1}{|\mathscr{G}_g|} \sum_{j \in \mathscr{G}_g} (\hat{\beta}_j^{\lambda})^2 = \frac{1}{|\mathscr{G}_g|} \sum_{j \in \mathscr{G}_g} E[(\hat{\beta}_j^{\lambda})^2],$$

with expectation taken with respect to $\mathbf{y}$ and the prior of β_j, $N(0, \tau^2_{g(j)})$. This renders a linear system of G equations with G unknowns, $(\tau_1^2, \ldots, \tau_G^2)$, denoted by $A\boldsymbol{\tau^2} = \boldsymbol{b}$. Solving this system renders $\boldsymbol{\tau^2}$, so by equivalence, $\boldsymbol{\lambda}$. Overlapping groups are modeled by averaging variances of all groups of which a covariate is a member.

The extension `ecpc` [10] introduces an extra layer of shrinkage on group level. It applies penalised moment-based empirical Bayes estimation for $\boldsymbol{\tau^2}$:

$$\tilde{\boldsymbol{\tau}}^2 = \underset{\boldsymbol{\tau^2}}{\operatorname{argmin}} \, ||A\boldsymbol{\tau^2} - \boldsymbol{b}||_2^2 + f_{pen}\left(\boldsymbol{\tau^2}; \hat{\lambda}_{\tau}\right), \quad \hat{\tau}_g^2 = \max(0, \tilde{\tau}_g^2). \tag{3}$$

The estimate for the hyperpenalty $\hat{\boldsymbol{\lambda}}_{\boldsymbol{\tau}}$ parameterising the penalty function f_{pen} is obtained via a data-driven way of randomly splitting the groups of covariates. The extra level of shrinkage renders a flexible framework as any penalty can be used on the group level, e.g. to shrink group estimates to counter overfitting in the number of groups or to include group structure by using structured penalties on group level. Different co-data sources may demand different penalisation strategies suitable for the type of co-data. The model first estimates group weights independently for each co-data set, using a hypershrinkage strategy suitable for that specific co-data set. Co-data weights are then estimated to integrate multiple co-data by a weighted average.

The following hypershrinkage strategies are allowed: 1) the default L_2 penalty. Such a smooth penalty counters overfitting for an increasing number of groups and handles overlapping, correlated groups. 2) a lasso penalty combined with the default penalty, for group selection; 3) a hierarchical lasso penalty [3, 12], which selects groups under a given hierarchical structure. After selection, the default penalty is used to obtain group weight estimates of the selected groups. This strategy is used to find a well-fitting, data-driven adaptive discretisation of continuous co-data.

Group-regularized elastic net (`gren`) [6] consideres the penalty:

$$f_{\boldsymbol{\lambda}}(\boldsymbol{\beta}) = \lambda_1 \sum_{j=1}^{p} \sqrt{\lambda'_{g(j)}}|\beta_j| + \lambda_2 \sum_{j=1}^{p} \lambda'_{g(j)}\beta_j^2, \tag{4}$$

where the global L_1- and L_2-norm penalization parameters λ_1 and λ_2 determine overall penalization of the features, while the group-specific penalty multipliers $\lambda'_{g(j)}$ adaptively shrink the features based on the prior feature group structure. We use the square root in the L_1-norm such that the feature-specific penalty weights have the same effect on the β_j scale: $\sqrt{\lambda'_g}|\beta_j| = |w_g\beta_j|$ and $\lambda'_g\beta_j^2 = (w_g\beta_j)^2$. As in `GRridge` and `ecpc`, the global penalty parameters λ_1, λ_2 are estimated by cross-validation. The λ'_g, are estimated by maximum marginal likelihood empirical Bayes:

$$\hat{\boldsymbol{\lambda}}' = \underset{\boldsymbol{\lambda}'}{\operatorname{argmax}} \operatorname{ML}(\boldsymbol{\lambda}';\mathbf{y}), \text{ with } \operatorname{ML}(\boldsymbol{\lambda}';\mathbf{y}) = \int_{\boldsymbol{\beta}} \exp[\ell(\boldsymbol{\beta};\mathbf{y},\mathbf{X})]\pi_{\boldsymbol{\lambda}'}(\boldsymbol{\beta})d\boldsymbol{\beta}. \tag{5}$$

The Bayesian prior version of the penalty in (4) is obtained by reparameterising the ridge prior as $\tau_j^2 = (\gamma_j^2 - 1)/(\lambda'_{g(j)}\lambda_2\gamma_j^2)$ and adding an extra layer to the prior [4]: $\gamma_j^2 \sim \text{tr-}\Gamma(1/2, 8\lambda_2/\lambda_1^2, (1,\infty))$, where tr-$\Gamma(k,\theta,(x_l,x_u))$ denotes the truncated gamma distribution with shape k, scale θ, and domain (x_l,x_u). Direct maximisation of (5) requires the repeated numerical calculation of a $p-$dimensional integral, which is unfeasible or computationally prohibitive for many modern problems. Indirect maximisation is achieved by repeated expectation-maximization (EM) updates:

$$\boldsymbol{\lambda}'^{(l+1)} = \underset{\boldsymbol{\lambda}'}{\operatorname{argmax}} E_{\boldsymbol{\gamma}^2|\mathbf{y}}[\log \pi_{\boldsymbol{\lambda}'}(\boldsymbol{\gamma}^2)|\boldsymbol{\lambda}'^{(l)}], \tag{6}$$

where the expectation is with respect to the posterior $p(\boldsymbol{\gamma}^2|\mathbf{y})$. This expectation is difficult to compute due to the unavailability of a closed-form posterior. The posterior is therefore approximated with variational Bayes (VB): $Q(\boldsymbol{\beta},\boldsymbol{\gamma}^2) = q(\boldsymbol{\beta})q(\boldsymbol{\gamma}^2) \approx p(\beta,\boldsymbol{\gamma}^2|\mathbf{y})$. The approximate expectation $E_Q \approx E_{\boldsymbol{\gamma}^2|\mathbf{y}}$ is available in closed-form, and leads to an update (6):

$$\boldsymbol{\lambda}'^{(l+1)} = \underset{\boldsymbol{\lambda}'}{\operatorname{argmax}} \frac{1}{2}\sum_{g=1}^{G} |\mathscr{G}_g| \log \lambda'_g - \frac{\lambda_2}{2}\sum_{g=1}^{G} \lambda'_g d_g^{(l)}, \quad \text{s.t.} \prod_{g=1}^{G} (\lambda'_g)^{|\mathscr{G}_g|} = 1, \quad (7)$$

with $d_g^{(k)} = \sum_{j\in\mathscr{G}_g} E_Q[\gamma_j^2\beta_j^2/(\gamma_j^2-1)|\lambda_g'^{(l)}]$. The constraints ensures that overall penalization is determined by the global penalty parameters λ_1, λ_2. The Bayesian elastic net does not give point estimates of the regression coefficients. To produce such point estimates, we refit the regular, frequentist elastic net with fixed λ_1, λ_2, and λ'_g, as estimated by cross-validation and emprical Bayes, respectively. Similarly to `ecpc`, the `gren` penalty in (5) may be extended to include multiple sources of feature groupings by simply modeling the penalty multiplier as a product within both the L_1- and L_2-norm [6].

Group-adaptive spike-and-slab, `graper` [11], is an hierarchical, full Bayes method that allows differential priors based on co-data groups. In short, the likelihood is either Gaussian or Bernoulli (for dichotomous outcome) and the prior for each regression coefficient β_j is a spike-and-slab:

$$\pi(\beta_j) = \pi_{g(j)}\delta_0 + (1-\pi_{g(j)})N(0,\tau^2_{g(j)}). \quad (8)$$

Hence, both the inclusion probability $\pi_{g(j)}$ and the Gaussian prior variance $\tau^2_{g(j)}$ may depend on the group $g(j)$. Then, π_g and τ_g^2 are endowed with their 'default' priors: a uniform and vague inverse-Gamma distribution, respectively. Much of the elegance of `graper` lies in the variational Bayes estimation strategy. The authors supply two versions: one where the posterior of $\boldsymbol{\beta}$ is approximated by a full factorization, and one where a more realistic, but computationally more demanding, multivariate normal is used. The authors show that the latter is more accurate in several applications. Moreover, they show superior performance to group-agnostic methods like (adaptive) lasso and elastic net, as well as the group-lasso. Finally, they report competitive predictive performances of `GRridge` and `graper` for dense settings (applying `graper` without spike and a Gaussian slab).

5 Discussion

We have discussed several co-data adaptive methods. Of these methods `graper` is the only full Bayes method, which may therefore be superior in terms of uncertainty propagation. This may be particulary attractive when uncertainty of predictions is of interest. In [9] a hybrid alternative to empirical Bayes ridge and full Bayes

ridge is discussed: the overall penalty parameter is endowed with a prior, while co-data-based penalty multipliers are estimated by empirical Bayes. A small simulation study shows that the coverage of the prediction intervals is as least as good as that of the empirical Bayes and full Bayes counterparts.

If the underlying data generating mechanism is truly sparse, `graper` (sparse setting) and `gren` likely outperform the ridge-based methods. Although posterior selection methods for the latter exist [1], `graper` and `gren` may be preferred when a (very) sparse model is desired. By far the most flexible method is `ecpc`: it can seemingly deal with multiple co-data sources of various kinds, and addresses hyper-parameter shrinkage. While `graper` and `gren` can only handle linear and logistic regression, `ecpc` and `GRridge` can also handle penalized Cox regression.

Besides `graper`, other hierarchical Bayes methods, such as [7], may provide an alternative solution to include external information for specific settings. These methods, however, typically do not scale well computationally, and often offer limited flexibility in terms of implementation.

Data integration versus privacy protection: a methodological challenge?

Statistical Disclosure Control for Integrated Data

Controllo statistico della riservatezza di dati integrati

Natalie Shlomo[1]

Abstract The digitalization of all aspects of our society leads to new and integrated data sources offering unprecedented opportunities for research and evidence-based policies. On the other hand, detailed personal information is more easily accessible leading to increased disclosure risks. Traditional statistical disclosure control (SDC) risk scenarios of identity and attribute disclosures and methods for confidentializng statistical data may no longer be sufficient. This has led to statistical agencies placing more control on the release of the data by restricting and licensing access. Guided by government initiatives for open unrestricted access to statistical data, we explore whether the computer science definition of a differentially private perturbation mechanism can be included in the SDC tool-kit. This implies that users of open-access data will have to work with perturbed data.

Abstract *La digitalizzazione in corso nella società offre l'opportunità per la ricerca di utilizzare nuove fonti di dati ottenute tramite integrazione. Ciò porta a un maggior rischio di identificazione. Gli scenari tradizionali di controllo statistico del rischio (SDC) di identificazione personale o di un suo attributo e i corrispondenti metodi per la creazione di dati statistici anonimizzati possono non essere più sufficienti. Ciò ha indotto gli istituti di statistica a porre sotto maggior controllo il rilascio dei loro dati restringendone l'accesso. Le iniziative governative sull'accesso aperto ai dati statistici ci ha indotto a investigare se il meccanismo di pertubazione noto come differential private perturbation tipico nella comunità computer science possa essere incluso fra gli strumenti di SDC. In questo contesto, gli utenti di dati open-access dovranno usare dati perturbati.*

Key words: Differential Privacy, Table Generation, Remote Analysis, Synthetic Data

1. Introduction

Statistical disclosure control (SDC) for traditional forms of statistical data is well established in the literature. These traditional forms of statistical data include microdata from social surveys, magnitude tables from business statistics and frequency tables for whole-population register/census counts (see Hundepool, et al. 2012 for more details). In this paper, we focus on microdata. SDC methods for protecting microdata arising from social surveys include both 'safe data' and 'safe access' approaches. In terms of 'safe data', survey microdata is generally protected by coarsening the quasi-identifiers, deleting sensitive variables, such as low-level geographies, and top-coding sensitive variables such as the size of the household, income and expenditures. Since social surveys typically have very small sample fractions, statistical agencies generally assume that a potential attacker would not have response knowledge, meaning that the attacker would not know if an individual is included in the survey microdata or not. Sampling therefore provides an inherent

[1] Natalie Shlomo, Social Statistics Department, University of Manchester; email: Natalie.Shlomo@manchester.ac.uk

level of protection and is considered an SDC method in itself. In terms of 'safe access', the survey microdata is generally released into data archives or under special licenses so that users need to undergo an application process and state the purpose of their request prior to gaining access to the data. The disclosure risk scenario for survey microdata is the ability of an attacker to link the microdata to a population database on a set of quasi-identifiers, i.e. identity disclosure, to assess whether a data subject in the microdata is unique in the population. A data subject with rare and unique identifying variables is more likely to be a population unique. Therefore, disclosure risk measures for quantifying identity disclosure are typically matching probabilities based on the quasi-identifying variables. Given the large number of variables for each data subject in the microdata, an identity disclosure leads to attribute disclosure where many new variables can be learnt about the data subject. Denoting F_k the population size in cell k of a table defined by identifying variables having K cells and f_k the sample size and $\sum_{k=1}^{K} F_k = N$ and $\sum_{k=1}^{K} f_k = n$, the set of sample uniques, is defined as: $SU = \{k: f_k = 1\}$. The sample uniques are potential high-risk records since they may be population uniques. Individual per-record risk measures in the form of a probability of re-identification are estimated. These per-record risk measures are then aggregated to obtain global risk measures as follows (where I is the indicator function): Number of sample uniques that are population uniques: $\tau_1 = \sum_k I(f_k = 1, F_k = 1)$; Expected number of correct matches for sample uniques (i.e., a matching probability) $\tau_2 = \sum_k I(f_k = 1)\frac{1}{F_k}$).

When the population is unknown, Elamir and Skinner (2006) propose using a Poisson Distribution to estimate the disclosure risk measures with log-linear modelling to estimate population parameters inferred from the observed sample counts. Skinner and Shlomo (2008) developed goodness of fit criteria for determining the optimal log-linear model which produces unbiased estimates of the disclosure risk measures. Shlomo and Skinner (2010) adapt the estimation of risk measures to take into account measurement and perturbation errors. An extension of the probabilistic modelling by Reiter (2005a) accounts for the probability of re-identification weighted by suppositions on attacker knowledge regarding the methods of perturbation. More recently, Manrique-Vallier and Reiter (2012) used mixed membership models to estimate the probability of re-identification.

With the digitalization of all aspects of our society, statistical agencies are able to develop new, integrated and linked data sources offering unprecedented opportunities for research and evidence-based policies. New data sources can contain whole population sectors, such as in big data, and can be combined and integrated statistically through correlation structures. However, with detailed personal information easily accessible from the internet, traditional SDC disclosure risk scenarios are no longer sufficient and statistical agencies are relying more on restricting and licensing data. One disclosure risk scenario that is growing in prominence with new forms of integrated data is inferential disclosure as it encompasses the traditional disclosure risk scenarios of identity and attribute disclosures. Inferential disclosure risk is the ability to learn new attributes with high probability from combining and manipulating datasets. Inferential disclosure can arise if there is a proportion of some characteristic that is very high within a subgroup or a regression model with very high predictive power. In fact, an individual does not even have to be in the dataset in order to disclose information.

Driven by demand from governments to provide open access data alongside the restricted access data, this increased disclosure risk has led to statisticians investigating more rigorous definitions and approaches for protecting the confidentiality of data subjects in microdata. The computer science definition of differential privacy (Dwork, et al. 2006) is currently under research and development on its use in the SDC tool-kit. Differential privacy is a definition of an output perturbation mechanism that states that no one individual can be revealed and all possible outputs must be indistinguishable up to a degree of epsilon with and without the data of one individual. For data to be differentially private, a stochastic perturbation mechanism is applied under certain parametrizations. Traditional approaches of deterministic mechanisms such as sampling and coarsening are not differentially private (Shlomo and Skinner 2012). In Section 2 we define differential privacy and then provide an overview of some open-access data dissemination methods based on protecting outputs in Section 3. We conclude in Section 4.

2. Differential Privacy

Differential privacy was developed by computer scientists as a standard for a perturbation mechanism for protecting outputs in a remote query-based system with the aim to specifically protect against inferential disclosure. See Dinur and Nissim (2003) and an overview book by Dwork and Roth (2014) for more details on differential privacy. In differential privacy, a 'worst case' scenario is allowed for, in which the potential attacker has complete information about all the units in the database except for one data subject of interest. The definition of a perturbation mechanism M satisfies ε-differential privacy if for all queries on neighbouring databases $a, a'\epsilon A$ differing by one individual and for all possible outputs defined as sub-sets $S\epsilon Range(M)$ we have:

$$P(M(a) \in S) \leq e^{\varepsilon}\ P(M(a') \in S) \quad (1)$$

This means that when observing a perturbed output S, little can be learnt (up to a degree of e^{ε}) and the attacker is unable to decipher whether the output was generated from database a or a'. In other words, the ratio $\frac{P(M(a)\epsilon S)}{P(M(a')\epsilon S)}$ is bounded (the probability in the denominator cannot be zero). The solution to guarantee differential privacy in the computer science literature is by adding noise/perturbation to the outputs of the queries under specific parameterizations. The noise is generated from the Laplace Distribution. In addition, a relaxation was proposed leading to the definition of (ε, δ) differential privacy where δ is a small probability of obtaining an unbounded ratio. This extension allows more utility, for example by limiting the extent of the perturbation.

3. Open-access Dissemination Strategies

Since access to microdata, particularly those arising from integrated and linked data sources, is generally licenced within safe data enclaves, open-access options will rely on generating outputs from the microdata through structured web-based internet platforms that return protected (perturbed) outputs in the form of tables and statistics. Another option for open-access data is to produce synthetic data where data is generated from a model based on the sufficient statistics obtained through the original data. We discuss both approaches here.

3.1 Web-based Dissemination

Online flexible table generating servers allow users to define, generate and download their own tables. A good example is the Australian Bureau of Statistics (ABS) TableBuilder for disseminating census tables. In flexible table generating, users access the servers via the internet and define their own table of interest from a set of pre-defined variables and categories typically from drop-down lists. The generated table undergoes a series of ad-hoc SDC checks. If it passes the criteria, it is confidentialized and then downloaded to the user's PC without the need for human intervention. These SDC checks may include, for example, limiting the number of dimensions in the table, minimum population and sparsity thresholds, ensuring consistent and nested categories of variables to avoid disclosure by differencing. One characteristic of the ABS TableBuilder is that for any cell that is generated from census microdata, the perturbation of the cell value will always be the same. Fraser and Wooton (2005) describe the 'same cell-same perturbation' approach where each individual in the microdata is assigned a random number. Any time data subjects are aggregated to form a cell in a table, their random numbers are also aggregated and this becomes the seed for the perturbation. Therefore, the same cell will always have the same perturbation. This reduces the chance of identifying the true cell value through multiple requests of the table and averaging out the perturbations. According to this setting, all possible tables and all possible cells that can be generated in the flexible table generating server are essentially known in advance and hence can be protected under a given privacy budget ε in (1). This is known as a non-interactive mechanism in the theory of differential privacy. Any post-processing of a differentially private output will still be differentially private.

To produce a table for discrete variables (continuous variables may be discretized for the purpose of producing tables), Rinott et al (2018) propose using a differentially private exponential mechanism (McSherry, et al. 2007) based on a utility function: $u(a, b)$ described as follows:

Given a list of all possible cells $k = 1, \dots, K$: $a = (a_1, \dots, a_K) \epsilon A$ choose output $b = (b_1, \dots, b_K) \epsilon B$ with probability proportional to $\exp\left(\frac{\frac{\varepsilon}{2} u(a,b)}{\Delta u}\right)$ where ε is the privacy budget and the scale is defined as: $\Delta \mathrm{u} = \max_{b \in B} \max_{a, a' \in A} |u(a, b) - u(a', b)|$where a and a' are neighboring databases that differ by removing one individual. Δu is known as the sensitivity in the differential privacy mechanism. The utility function is defined through a loss function: $u(a, b) = -l_1 = \sum_{k=1}^{K} |a_k - b_k|$. Under this definition, for a list of internal cells where a data subject appears only once, the sensitivity Δu is 1. If marginal totals are also included and an individual appears several times in the list then Δu will increase. This mechanism is essentially a discretized Laplace distribution and is optimal for the case of perturbing count data with respect to preserving utility. Furthermore, bounding the perturbations such that $|a_k - b_k| \leq m$ for all k leads to (ε, δ)- differential privacy where δ is the probability at the cap m. Shlomo et al. (2019) compared standard SDC methods and differential privacy for a flexible table builder containing survey-weighted counts. The differential privacy mechanism consisted of perturbing the sample counts and then adjusting the survey-weighted cell count according to the average survey weight in the cell. They showed that for the case of internal cells of tables and relatively large sample counts there was less perturbation required under differential privacy and higher utility compared to the SDC approaches.

It is now recognized that differential privacy for protecting frequency tables can be a viable technique in the SDC tool-kit at statistical agencies. Open questions remain and are subject to further research. Whilst the use of the non-interactive differential privacy mechanism will avoid depleting a privacy budget under multiple generation of tables, how to set this budget and determine the sensitivity of the mechanism given the large-scale dissemination of tables containing internal and marginal cells need careful consideration. In addition, policy makers need to understand the consequences of the privacy parameters ε and δ. Moreover, there is a need to go beyond the flexible table generating server towards a remote analysis server where users can query a dataset for exploratory analysis, measures of association and regression modelling and in return receive a confidentialized output under the differentially private mechanism, smoothed histograms and sequential boxplots for scatterplots and residual analyses.

3.2 Synthetic Data

In recent years, there have been initiatives to produce synthetic microdata as public-use files that preserve some of the statistical properties of the original microdata. This type of open data allows researchers to plan their research questions and data analysis and prepare their code prior to gaining access to the licenced restricted data. In addition, these data can be used for teaching purposes. The data elements are replaced with synthetic values generated from an appropriate probability model that is developed through the sufficient statistics of the original data. Similar to imputation techniques, the synthetic data is generated through a posterior predictive distribution. See Reiter (2005b) and references therein for more details of generating synthetic data. The synthetic data can be implemented on parts of data so that a mixture of real and synthetic data is released although this means that a thorough disclosure risk assessment is needed prior to releasing such data. In practice, it is very difficult to capture all conditional relationships between variables and within sub-populations. If models used in a statistical analysis are sub-models of the model used to generate data, then the analysis of multiple synthetic samples should give valid inferences. The subject of using differential privacy in the production of synthetic data is still undergoing research. One early application for generating synthetic data using a differential privacy mechanism that is embedded in the Bayesian Multinomial-Dirichlet model is the US Census Bureau 'On the Map' available at http://onthemap.ces.census.gov/. It is a web-based mapping and reporting application that shows where workers are employed and where they live according to the Origin-Destination Employment Statistics from the US Census 2001. More information is given in Abowd and Vilhuber (2008). New research is ongoing where differentially private noise is added to the estimating equations used to generate synthetic data through the sequential regression modelling approach. In addition, the regression models are adapted to ridge regression which bounds the parameter space. Early results show that adapting the sequential regression modelling approach to the differentially private standard does not have a significant utility loss compared to the standard regression approaches.

4. Discussion

In recent years, with increasing opportunities for linking and integrating data, statistical agencies are relying more on restricting access to such data due to their inability to ensure the confidentiality of statistical units. However, with government

initiatives for more open and accessible data, statistical agencies are exploring alternative means for disseminating statistical data through web-based applications and synthetic data. Given the rising concerns of inferential disclosure under these new dissemination strategies, this has led to fruitful collaborations between statisticians and computer scientists and initial research on whether the formal 'by-design' privacy guarantee of differential privacy can be embedded in the SDC tool-kit. However, perturbative methods of SDC come at a cost in that researchers will have to cope with the perturbation when carrying out statistical analysis which may require more training. Under differential privacy, the parameters of the privacy mechanism are not secret and can be used to correct statistical analysis of perturbed data and this provides a large incentive for including differential privacy into the SDC tool-kit.

The Integrated System of Statistic Registers: first steps towards facing privacy issues

Il Sistema Integrato dei Registri: primi passi per affrontare i problemi di privacy

Mauro Bruno and Roberta Radini[1]

Abstract The Italian Integrated System of Statistical Registers (ISSR) provides coherent and high quality data that support all the steps of statistical production, ranging from the extraction of frames to aggregated data for dissemination. The ISSR processes personal data on a large scale, such data can refer to populations with strong privacy and confidentiality restrictions. In this paper, we will briefly describe how we can enrich the data architecture of ISSR with privacy preservation solutions. In particular, the system ISSR must be equipped with a privacy-preserving statistical analysis system that: (i) performs privacy-preserving access on the input parties by controlling elaborations that can be performed by the computing parties, and (ii) decides which results can be published to which result parties.

Abstract *Il Sistema Integrato dei Registri italiano (SIR) fornisce dati coerenti e di alta qualità che supportano tutte le fasi della produzione statistica, che vanno dall'estrazione di frame a dati aggregati per la diffusione. Il SIR elabora i dati personali su larga scala, tali dati possono fare riferimento a popolazioni comportando rischi di forti restrizioni sulla privacy e sulla riservatezza. In questo documento, descriveremo brevemente come possiamo arricchire l'architettura dei dati del SIR con soluzioni di tutela della privacy. In particolare, il SIR deve essere dotato di un sistema di analisi statistica che preservi la privacy: (i) eseguendo l'accesso in modalità "privacy-preserving" alle parti di input e controllando le elaborazioni che possono essere eseguite dalle strutture di calcolo e (ii) decidendo quali risultati possono essere pubblicati e a quali parti fanno riferimento.*

Key words: Integrated System of Statistical Registers, Privacy, Ontologies

[1] Mauro Bruno, Istat; mbruno@istat.it
Roberta Radini, Istat; radini@istat.it:

1 Background

In 2016, Istat launched a modernization program with the aim to redesign the statistical production chain, moving from a silos-based model to a process-oriented approach. Within this transformation, a major choice was the centralization and organization of the statistical information from administrative sources and surveys in an integrated system of registers, called the Italian Integrated System of Statistical Registers (ISSR).

The main purpose of the ISSR is to provide to the production processes coherent and high quality data to be used in all the production steps, from extraction of frames for the selection of samples to aggregated data for dissemination and information for statistical research on new issues.

The integrated system of registers is obtained from processing of personal data on a large scale, also concerning particular categories such as minors, disabled people or in general populations with particular privacy and confidentiality restrictions. In view of the unquestionable value in obtaining important statistical outputs, the integrated system of registers must be equipped with particular policies for the protection of the privacy, defined as the right of an individual or business to keep information about them from being disclosed. Personal privacy is recognised and upheld by the European Union as a fundamental human right [1].

In this paper, we will briefly describe how we can enrich the data architecture of ISSR with privacy preservation solutions. In particular, the system ISSR must be equipped with a privacy-preserving statistical analysis system that: (i) performs privacy-preserving access on the input parties by controlling elaborations that can be performed by the computing parties, and (ii) decides which results can be published to which result parties.

1.1 Integrated System of Statistical Registers (ISSR)

The Italian Integrated System of Statistical Registers (ISSR) is a 'micro data' repository that guarantees: i) homogeneous management process of domain specific registers, ii) statistical, conceptual and physical integration of the statistical units contained in each register. The registers that compose the ISSR refer to the core themes of statistical production, i.e. Individuals, Families and Cohabitations, Economic/Institutional Units and Places. Moreover, the relationship among the themes allows it to be called "Integrated System" [2, 3, 4].

The design of ISSR data architecture is compliant with modern semantic integration approaches, with a strong emphasis on active metadata guiding the access to the system. More precisely the whole data architecture (see **Figure 1**) can be split into three layers: all registers, ISSR and data consumption, defined by all type of publication or analysis outputs.

ISSR offers flexibility and agility to retrieve on-the-fly data from all registers, overcoming the limitations of older approaches such as ETL and data replication. Currently, the System is composed by four sub-layers: 1) Physical Integration that

combines data, using the unit identification code, 2) Integrated Micro Layer that selects, integrates and transforms data, then exposing them as views, 3) Macro-data Layer provides aggregated data to users to conduct analyses or business intelligence activities, 4) Semantic level provides access to data via Ontology Based Management System (ODBM) to micro and macro data [5].

The Ontologies is a formal, shared and explicit representation of the conceptualization of the domain of interest expressed through the formal language, which makes it "machine-actionable", allow representing metadata “coupled” with data. Therefore, in this system the metadata are not limited to a “documentation” role but allow governing the data integration step by ensuring the high quality of integrated data. Moreover, ontologies allow the access to the data and the accesses management. This functionality can be a component to handle some Output privacy issues as described below in *Use Case 2*.

In the 2th sub-layers, Integrated Micro Layer, we need to implement solutions that solve or mitigate input privacy issues, as described in the *Use Case 1*.

1.2 Input and Output privacy: Techniques

In this section, we introduce input and output privacy core concepts. In literature, the term Input Privacy refers to a set of methods and technologies that allow to perform processing without accessing or deriving any input value provided, nor accessing intermediate values or statistical results during the processing of data other than output established for processing [6].

Input Privacy techniques allow processing registers linked data without accessing directly to the data of each register, thus reducing liability and simplifying compliance with data protection regulations. Secure computation techniques, which process data while it remains encrypted or obfuscated from regular access, allow achieving this goal. Input privacy techniques are generally used when a party wants to share data with other parties, without providing access or sharing its information. Concerning the ISSR, its input sources are the statistical registers and privacy measures have to be put in place in order to enforce privacy on computations that involve multiple registers.

Another class of techniques to preserve privacy is Output Privacy. Such class guarantees that the published results do not contain identifiable input data beyond what is allowable by Input Parties.

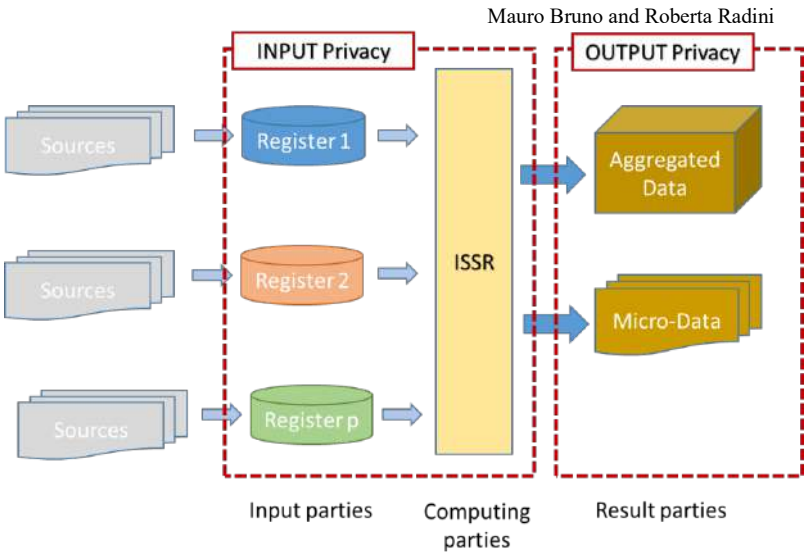

Figure 1: *ISSR privacy*

Following the general description provided above in **Figure 1** we identify the parties involved in the ISSR and the 'boundaries' of input and output privacy.

In the following subsections, we will describe two applications of input and output privacy techniques in the context of ISSR. 'Use Case 1' describes how input privacy techniques allow merging two or more registers in a single archive, in compliance with data protection regulations. 'Use Case 2' describes the access the ISSR to obtain a non-aggregated or aggregated output combining differential privacy with ontology-based access to information.

Use Case 1: Input Privacy

Suppose we want to perform analyse the employment conditions of individuals with disabilities with respect to the municipality of residence. This analysis requires linking the basic *Register of individuals* with the selection of the disabled, enriched with the information of the municipality of residence and the *Register of Labor*, which records the job positions of the selected individuals.

In this scenario, access to register data could be ontology-driven. Ontologies allows defining concepts and relationships between concepts, therefore allow identifying queries - or more general analysis - that can have strong impact on privacy of individuals. In addition, these analyses allow defining possible harm to individuals.

The use of input privacy techniques such as (Full) Homomorphic Encryption (HE, FHE) [7] are extremely onerous from a computational perspective, thus limiting for the number of operations that can be performed. Therefore, ontology-driven accesses could determine in which cases processing according to input privacy.

We can define, through ontologies, confidential and sensitive the information about disabilities and potentially discriminating if combined with information on their employment.

The link of two registers using privacy-preserving record linkage techniques is described in [8]. This type integration is classified as Private Set Intersection with Analytics (PSI-A) [9]. Each register has an owner internal at Istat; the analysis can be executed by one of owners or a third party (internal at Istat). In order to avoid the disclosure of sensitive information during the linkage process, we need sophisticated techniques. We will examine HE and FHE, a family of encryption schemes with a special algebraic structure that allows computations to be performed directly on encrypted data without requiring a decryption key. In particular, Full Homomorphic Encryption allows both additions and multiplications to be performed on encrypted data.

Use Case 2: Access Privacy

Suppose we want to perform analyses relating to the residential individuals in small areas (sub municipality). This analysis requires linking the basic *Register of individuals* with the selection of residential people, enriched with the information of the addresses or the sub municipality areas of residence and the *Register of Places,* which records the geographic identification.

As described in previous case, the use of the ontologies can guide in the definition of risky concepts and dangerous with respect to privacy relationships between multiple concepts.

We can define through the ontologies the relationship between individuals and the residential address or area as a risky information and that can determine the damage of location of the people and therefore define required the use of privacy input techniques to the access to this information.

A second level of use of ontologies can be to intercept people with a set of characteristics that can make them re-identifiable.

Besides the use of ontologies, we are investigating the use of output privacy techniques belonging to Differential Privacy. Differential Privacy is an approach used to quantify and limit the number of information about individuals in a database that leak out releasing the result of an aggregate calculation on that database.

Trusted Smart Surveys: a possible application of Privacy Enhancing Technologies in Official Statistics

Trusted Smart Surveys: una possibile applicazione delle tecnologie di miglioramento della privacy nella statistica ufficiale

Fabio Ricciato, Kostas Giannakouris, Albrecht Wirthmann, Martina Hahn

Sommario In this discussion paper we outline the general concept of Trusted Smart Surveys as a possible use-case for the application of Privacy Enhancing Technologies (PET). Central to the Trusted Smart Survey paradigm is the notion of *extracting output information without revealing the input data*. This can achieved by leveraging PET to compute the final desired information — a statistical indicator or and aggregate table — without centralising the individual data from the respondents. Together with additional mechanisms for ensuring transparency, auditability and public control over the whole process these technologies can help to scale up public trust in new survey models, hence promoting participation, and in this way contribute to improve accuracy and relevance of official statistics.

Sommario *In questo contributo viene delineato il concetto delle* Trusted Smart Surveys *intesa come una possible applicazione delle moderne tecnologie di miglioramento della privacy (PET). Un elemento centrale di questo paradigma è il concetto che il risultato di una computazione possa essere estratto senza rivelare i dati in ingresso. In questo modo, le tecnologie PET consentono di ottenere l'informazione desiderata — ad esempio un indicatore statistico oppure una tavola di valori aggregati — senza centralizzare i dati individuali dei partecipanti. Insieme ad altri meccanismi tesi a garantire la trasparenza, la verificabilità e il controllo sull'inte-*

ro processo, queste tecnologie possono aiutare a rafforzare la fiducia da parte del pubblico nei nuovi modelli d'indagine, promuovendo una maggiore partecipazione, contribuendo cosi a migliorare l'accuratezza e la rilevanza delle statistiche ufficiali.

Key words: Trusted Smart Survey, Trusted Smart Statistics, Privacy Enhancing Technologies, Official Statistics.

1 From traditional surveys to Smart Surveys

The traditional survey model based on paper questionnaire is based on a batch of questions (questionnaire) presented to the respondent, by a human interviewer, during a single survey session. Such questionnaire-based interaction model has not changed with telephone-based and computer-assisted interviews. Instead, leveraging the smartphone (via a mobile app) allows for several important changes to the survey model. First, the so-called *response burden* can be diluted over much longer intervals, even months or years, with a continuous flow of questions presented at very low rate in the background of the respondent's normal activities. Second, the *active data* generated in response to explicit queries may be complemented by and combined with *passive data* collected automatically by sensors onboard the smartphone (e.g. GPS, accelerometer, etc.) or acquired from other devices within the personal sphere of the respondent (e.g., home appliances, Internet-of-Things devices), again contributing to reduce the response burden (e.g., automatic diary). Third, the human interviewer can be replaced by an Artificial Intelligence (AI) assistant. The combination of these elements enable the design of *context-aware* survey models where *timing and content* of the presented questions are decided dynamically based on *context* information as inferred based on the sensor data. For example, a question of the kind "*It seems you are travelling today: is this trip mainly intended for work or for leisure?*" might be posed during the trip instead of the more traditional "*How many business trips did you perform in the previous 6 months?*" In other words, the combined use of AI and passive data allow to decide dynamically *when* and *what* question to ask. Furthermore, questions can request explicit action and non-textual response, for example taking photos or recording sound ("*Can you please take a photo of your surrounding environment?*").

What we have outlined insofar is basically the concept of *Smart Surveys*. Through the smartphone app, Statistical Offices (SO) have the possibility to establish a continuous, long-term dialogue with each respondent. Furthermore, they have the opportunity to feed back individualised reports to the respondent, to disseminate selected figures and statistics of special interest for particular groups, and to better communicate the importance of official statistics. In this way, the bi-directional dialogue between the SO and the respondent may become even more interactive.

Such fundamental change of paradigm is enabled not only by the availability of mobile technologies, but also by the fact that continuous interaction with mobile apps is considered rather normal nowadays. It is not only a matter of exploiting

new digital technologies, but also leveraging the *new digital behaviours* and *new digital attitudes* that citizens have developed through the use of such technologies. In the private sector, marketing strategies are increasingly relying on continuous low-intensity interaction with customers via mobile apps, and in principle similar practices (with appropriate adaptations) may be adopted by public institutions for public interest purposes, including by statistical offices to produce better official statistics. That does not mean that SOs are called to emulate marketing practices from the commercial sector. Rather on the contrary, SOs have the opportunity to pioneer new models of data use based on their constituent principles of transparency, openness, independence and democratic control, and to *show the way* to other public institutions (but also to the private sector) as to how the collectivity can (re)gain democratic control over its data. In so doing, SO should remain critical and vigilant of the possible negative consequences and unintended effects, not least the risk of distorting — or anyway influencing excessively — the social phenomena they aim at measuring. Taking a critical design approach, SO can design new survey models that ripe the potential benefits of the new (data, technologies, behaviours, attitudes) while minimising the potential risks. In the remainder of this short contribution we propose an initial reflection on one of several aspects related to the design of a suitable Smart Survey model, namely the issue of *trust*.

2 From Smart Surveys to *Trusted* Smart Surveys

The *smart survey* model is considerably more intrusive in the life of the participant than the traditional survey model: it would allow SO to plug into a much richer, wider and deeper set of data about the individual respondent and his/her activities, with much greater level of detail and for longer times. The rising awareness by the public about the dystopian risks of mass surveillance would make such model difficult to accept (if at all desirable) unless a set of convincing safeguards are put in place to offset the risks of any possible data misuse — against the individuals, groups and the whole collectivity — and to guarantee a level of transparency and *trustworthiness* that is commensurate to the risks.

Trust is a complex issue where aspects of *trust in the process*, *trust in the input data* and *trust in the output statistics* are closely intermingled and reciprocally inter-dependent. If the respondents fear negative consequences resulting from participating in Smart Surveys, they will not provide their truthful data (or provide no data at all) and the resulting final figures will be poorly representative of reality. In this way, lack of trust in the process causes lack of trust in the input data and therefore in the final statistics. To stir a virtuous cycle of trust, SOs must provide strong trust guarantees on the whole survey process in the first place.

As the survey model evolves from traditional to smart, additional guarantees must be provided, also based on new technological means. The success of a well designed Smart Survey model requires SOs to put in place (and convincingly communicate to the respondents and to the general public) a set of strong mechanisms to ensure

by design public control on *what information is extracted* from such data, *how* (methodology), *why* (purpose) and *by whom*. This requires the deployment of a coherent combination of “soft" measures (i.e. legal provisions, organisational processes, practices) and “hard" measures (i.e. technological solutions) that are adequate to the new scenario[1]. Putting in place a coherent set of strong safeguards is what qualifies the *Trusted* Smart Survey model, i.e., an augmentation of the Smart Survey concept by technological and non-technological elements aimed at increasing the degree of *trustworthiness of data use*.

3 Design principles: an initial proposal

Designing a Trusted Smart Survey model is a task that involves multiple dimensions: it is matter of *trustworthiness engineering* where security, privacy, organisational and communication elements must be blended together, each of them entailing hardware, software and *humanware* aspects. To this aim, it is important to establish a common terminology and a clear set of design principles and requirements in the first place. A key aspect of the Trusted Smart Survey paradigm, and more in general of the whole Trusted Smart Statistics concept [1], is a shift of focus from *data collection* to *data use*. This implies that the central pivot of the whole engineering process is the *combination of DATA and CODE* — not merely DATA.

Generally speaking, given a collection of input data $\boldsymbol{x}$ and pre-defined function $\boldsymbol{f}$, statistical production entails the computation of the output $\boldsymbol{y} = \boldsymbol{f}(\boldsymbol{x})$. The *function* $\boldsymbol{f}$ denotes here any generic algorithmic workflow (or statistical methodology) described by a pre-defined sequence of mathematical operations of arbitrary complexity. The most complete and non-ambiguous description of a complex function $\boldsymbol{f}$ is by means of a computer program, i.e., software code. A computation instance, or *query*, is therefore associated to the application of CODE $\boldsymbol{f}$ to DATA $\boldsymbol{x}$, hence to the DATA-CODE pair $\langle \boldsymbol{x}, \boldsymbol{f} \rangle$. Both elements may be centralised at a single machine administered by a single entity, or distributed among multiple machines possibly administered by different entities. In the envisioned model of Trusted Smart Survey the individual data of each participant remain local to the participant's private space (e.g., her personal device or private cloud space). The code execution is split between the participant's machine, for the local pre-processing of individual data (“micro" processing), and an institutional or inter-institutional infrastructure supporting secure private computation of aggregate values (“macro" processing) through PET. Such PET infrastructure might possibly comprise multiple machines administered by different organisations, as e.g. with Secure Multi-Party Computation (SMPC), or it may reduce to a single machine controlled jointly by multiple institutions, e.g., based on Trusted Execution Environment (TEE) combined with

[1] While a set of measures is already in place to ensure trustworthiness of statistical production and protection of personal data collected from traditional sources, such measures need to be scaled up and strengthened in order to cope with new, more intrusive non-traditional kinds of data sources.

mechanisms for multi-party authorisation. Whatever PET solution is adopted, it is important to avoid concentrating control into a *single point of trust*.

Paraphrasing a famous quote: "*DATA is neither good nor bad; nor is it neutral*" (the original version had "technology" instead of "data" [2]). In fact, the discourse about what is ethically desirable vs. undesirable — hence operationally allowed or disallowed, technically enabled vs. disabled — would be more clearly scoped if centered specifically on the DATA-CODE pair $\langle \boldsymbol{x}, \boldsymbol{f} \rangle$, rather than solely on DATA $\boldsymbol{x}$. It is possible to envision data governance models wherein the legal right *and the technical possibility* of applying a particular CODE on a particular set of DATA is decoupled from who holds the data. Keeping data holding and data usage as distinct issues is indeed a pivotal aspect in the discourse.

Based on the above considerations, we list below a possible set of design principles for the future Trusted Smart Survey model. Our goal here is to present an initial proposal serving as starting point for a critical discussion within the statistical community. With the caveat above, we propose to consider the following design principles:

1. For a generic respondent i, the individual data element $\boldsymbol{x}_i$ remains private to the respondent and is never disclosed as such to any single other entity — DATA are closed and remain stored at their respective sources.
2. The source code of $\boldsymbol{f}$ is always made openly available for public scrutiny *before* and *after* performing the computation, in order to allow for ex-ante and ex-post checks — CODE is open.
3. The final result of the computation $\boldsymbol{y}$ (query output) is made available to the SO but not automatically released to the public — access to the query output remains restricted to authorised SO.
4. Before execution, the source code of $\boldsymbol{f}$ must be approved by a pre-determined set of ex-ante controllers.
5. The execution of every query must be logged in a secure way and made accessible to ex-post controllers. Each log must contain all appropriate meta-data, including an unmodifiable pointer to the exact code version that was executed and detailed information as to who had access to the computation result.
6. Technical and organisation means are adopted to ensure that the binary (executable) code run on the data corresponds to the (source) code $\boldsymbol{f}$ that was preliminarily approved by *all* ex-ante controllers (e.g., code authentication).
7. Technical and organisation means are adopted to ensure that the information stored in every log corresponds truthfully to the query execution.

The role of ex-ante or ex-post controller may be taken by any entity (institution, organisation, association, etc.) bearing a legally recognised interest related to the query. To illustrate, consider the example that entity A is mandated to ensure methodological quality (the code $\boldsymbol{f}$ is appropriate and fit for the purpose), entity B cares that the prospective output to be computed by $\boldsymbol{f}$ is ethically acceptable, and entity C is concerned that the same output does not cause harm to some legitimate private business. One possible way to reassure and gain support by all entities is to assign to all such entities a *shared, non-exclusive* ex-ante controller role. Similar conside-

rations apply for the assignment of ex-post controller roles. We do not claim here that each and every entity with some interest in the computation has automatically the right to act as controller. However, the PET infrastructures must allow to flexibly configure ex-ante and ex-post controller roles to different entities as needed in each specific use-case. In other words, having such feature in place at the software and hardware level allows to flexibly engineer the process and governance model at the *humanware* level, and to assign shared, non-exclusive controls to the relevant and legitimate stakeholders.

Note that Principle (3) foresees that access to the computation output $\boldsymbol{y}$ may still be restricted to the SO. This provision allows to execution of computation function $\boldsymbol{f}$ for which the output $\boldsymbol{y}$ still yields some residual risk of personal re-identification. In this case, it is responsibility of the SO to apply the usual Statistical Disclosure Control (SDC) checks in post-processing before releasing the final statistics to the public. Alternatively, Differential Privacy (DP) mechanisms may be embedded in the computation function $\boldsymbol{f}$. Depending on the specific use-case, both variants can be considered. In summary, referring to the notions of Input Privacy and Output Privacy (see e.g. to [3] for a discussion), the whole chain from raw input data until final statistics must compose an Input Privacy solution (e.g., SMPC or TEE) with a solution for Output Privacy (SDC or DP).

The above principles imply that *(i)* the computation function $\boldsymbol{f}$ is defined beforehand, and *(ii)* the whole statistical production process is fully automatised and represented in machine-readable code. These conditions are not problematic in the statistical *production* stage, but may be somewhat critical for *research* and *methodological development* where some degree of manual data exploration is unavoidably needed. To cope with such situation, a slightly modified set of design principles could be formulated, where some items are loosened (e.g., ex-ante checks) while others are strengthened (e.g., ex-post checks) in order to maintain adequate control while allowing for the necessary degree of flexibility during manual exploration.

Designing adaptive clinical trials

Optimal designs for multi-arm exponential trials

Disegni ottimi per prove cliniche a risposte esponenziali

Rosamarie Frieri and Marco Novelli

Abstract Most of the randomized clinical trials for treatment comparisons have been designed to obtain a balanced allocation among the treatments. This is mostly due to the so-called universal optimality of balance. However, with several treatments the balanced allocation may not be efficient and could be strongly ethically inappropriate, in particular for phase III-trials. In [3], taking into account the exponential model, the target allocation maximizing the power of Wald test under a suitable ethical constraint has been derived. In this paper, we further explore the operating characteristics of such allocation through a comparison with other targets proposed in the literature, showing that the constrained optimal target exhibits good performances in terms of inferential precision and ethical demands.

Abstract *La maggior parte degli studi clinici randomizzati per il confronto tra trattamenti sono stati disegnati per ottenere un'allocazione bilanciata tra i gruppi. Questo è dovuto principalmente alla cosiddetta ottimalità universale del bilanciamento. Tuttavia, in presenza di molti trattamenti, l'allocazione bilanciata potrebbe risultare inefficiente e fortemente non etica, in particolare nelle prove cliniche di Fase III. In [3], considerando risposte esponenziali, è stata derivata l'allocazione ottimale che massimizza la potenza del test di Wald basato sui contrasti, sotto un appropriato vincolo etico. In questo articolo, verranno approfondite le caratteristiche operative di tale allocazione anche attraverso un confronto con le altre allocazioni proposte in letteratura, allo scopo di valutare la sua efficienza rispetto a criteri di natura sia etica che inferenziale.*

Key words: unbalanced allocations, efficiency, power of the Wald test, ethics

1 Introduction

In randomized clinical trials two competing goals, i.e. individual vs. collective ethics, have to be balanced. Indeed, the need to allocate more patients to the best available treatment (individual ethics) usually conflicts with the rigourous pursuit of scientific knowledge obtained with high inferential precision (collective ethics). So far, the vast majority of randomized clinical trials have been designed to achieve a balanced allocation among treatment groups, thanks to the optimal properties of balance especially in terms of estimation accuracy (see [6]). However, adopting equal allocation in the presence of several treatments could be neither efficient - since it is different from the optimal design for hypothesis testing (see [2, 3]) - nor ethical, especially in the context of phase-III trials, where the need to care for the well-being of the subjects involved in the trial is of primary importance. To overcome this trade-off, target allocations depending on a metric that accounts for treatment effects and/or their variabilities have been proposed, in order to obtain a valid compromise between ethical demand and inferential precision (see [1, 5]). Generally, these allocations depend on the unknown model parameters and can be targeted by suitable response adaptive randomization procedures, namely sequential allocation rules that, making use of the information accrued along the trial, change the assignment probabilities at each step in order to skew allocations toward the superior treatment. Recently, taking into account the problem of testing statistical hypothesis in normal homoscedastic trials, Baldi Antognini et. al. in [2] proposed an optimal target which maximizes the power of the Wald test of homogeneity, subject to an ethical constraint reflecting the effectiveness of the treatments. Moreover, Frieri and Zagoraiou in [3] derived a constrained target for exponential outcomes that are particularly relevant for oncological trials with survival endpoints. In this paper, we explore in depth the operating characteristic of the allocation derived in [3] through a comparison with other targets proposed in the literature. Our results show that the constrained optimal target guarantees very good performance in terms of statistical power, estimation precision, and ethical demands.

2 Framework and notation

In this work, clinical trials in which each subject is sequentially allocated to one of $K \geq 2$ available treatments are considered. Let δ_{kj} be the treatment assignment indicator such that $\delta_{kj} = 1$ when patients j is assigned to treatment $k\,(k = 1, \ldots, K)$ and 0 otherwise, with $\sum_{k=1}^{K} \delta_{kj} = 1$. The experimental outcome of the corresponding patient, Y_j, is assumed to be exponentially distributed with $E(Y_j|\delta_{kj} = 1) = \mu_k$, the treatment effect, and $V(Y_j|\delta_{kj} = 1) = \mu_k^2$ its variance. At each stage n, let $\boldsymbol{\pi}_n = (\pi_{1n}, \ldots, \pi_{Kn})^\top$, with $\pi_{kn} = n^{-1} \sum_{j=1}^{n} \delta_{kj}$ and $\sum_{k=1}^{K} \pi_{kn} = 1$, be the vector collecting the treatment assignment proportions up to that point, and $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_K)^\top$ the vectors of treatment effects. In what follows, without loss of generality, we adopt

the-larger-the-better scenario, that is an higher response is more desirable for the patient's care, and we will work under the non-restrictive assumption that $\mu_1 \geq \mu_2 \geq \cdots \geq \mu_K$, i.e. the best performing treatment is labelled as the first one and the worst as the Kth one.

Here, the inferential focus is on the treatment contrasts, so letting $\mathbf{A}^\top = [\mathbf{1}_{K-1}| -\mathbf{I}_{K-1}]$, where $\mathbf{1}_p$ and $\mathbf{I}_p$ represent the p-dim vector of ones and the identity matrix, we denote by $\boldsymbol{\mu}_c = \mathbf{A}^\top \boldsymbol{\mu} = (\mu_1 - \mu_2, \ldots, \mu_1 - \mu_K)^\top$ and $\hat{\boldsymbol{\mu}}_{cn} = (\hat{\mu}_{1n} - \hat{\mu}_{2n}, \ldots, \hat{\mu}_{1n} - \hat{\mu}_{Kn})^\top$ the vector of contrasts wrt the first treatment and their MLEs, respectively. Under well-known regularity conditions, $\hat{\boldsymbol{\mu}}_{cn}$ is strongly consistent and asymptotically normal, i.e. $\hat{\boldsymbol{\mu}}_{cn} \xrightarrow{a.s.} \boldsymbol{\mu}_c$ and $\sqrt{n}(\hat{\boldsymbol{\mu}}_{cn} - \boldsymbol{\mu}_c) \xrightarrow{d} \mathrm{N}(\mathbf{0}_{K-1}, \mathbf{A}^\top \mathbf{M}^{-1} \mathbf{A})$, where $\mathbf{M} = \mathbf{M}(\boldsymbol{\mu}|\boldsymbol{\pi}) = \mathrm{diag}\left(\mu_i^{-2}\pi_i\right)_{i=1,\ldots,K}$ is the Fisher information matrix associated with $\boldsymbol{\mu}$. Finally, let us define by $\boldsymbol{\rho} = (\rho_1, \ldots, \rho_K)^\top$, with $\rho_k \geq 0$ and $\sum_{k=1}^K \rho_k = 1$, the desired target allocation proportion, that can be obtained through suitable optimization problems.

The experimental strategy adopted to obtain the optimal target depends on the objective of the trial. When the aim is to maximize the inferential precision in the estimation of the treatment contrasts, Sverdlov and Rosenberger in [7] derived the tr_A optimal target by minimizing $\mathrm{tr}[\mathbf{A}^\top \mathbf{M}^{-1} \mathbf{A}]$, i.e.

$$\rho_1^A = \frac{\mu_1 \sqrt{K-1}}{\mu_1 \sqrt{K-1} + \sum_{i=2}^K \mu_i} \quad \text{and} \quad \rho_k^A = \frac{\mu_k}{\mu_1 \sqrt{K-1} + \sum_{i=2}^K \mu_i} \text{ for } k = 2, \ldots, K. \quad (1)$$

It is easy to show that $\rho_i^A \geq \rho_{i+1}^A \iff \mu_i \geq \mu_{i+1}$ for $i = 1, \ldots, K-1$ so this target, for exponential outcomes and under the-larger-the-better scenario, is ethical. On the side of hypothesis testing instead, a typical problem in multi-arm trials is to test the null-hypothesis of equality of treatment effects, i.e. $\boldsymbol{\mu}_c = \mathbf{0}_{K-1}$, where $\mathbf{0}_{K-1}$ is the $(K-1)$-dimensional vector of zeros. The target allocation maximizing the power of the Wald test of homogeneity is $\boldsymbol{\rho}^* = (\mu_1/(\mu_1+\mu_K), 0, \ldots, 0, \mu_K/(\mu_1+\mu_K))^\top$ (see [3]), which is clearly inappropriate for both statistical and ethical reasons. To avoid empty treatment arms, Zhu and Hu in [9], adopting the same framework in [8], set an optimization problem in which the power of the test is maximized subject to a constraint on the lower bound of the minimum number of subject assigned to each treatment. More specifically, the ensuing target $\boldsymbol{\rho}^Z$ should satisfy $\rho_i^Z \geq T$ for $i = 1, \ldots, K$, where $T \in [0, 1/K]$ is selected by the user. The target $\boldsymbol{\rho}^Z$ is available in closed form (which is not reported here for brevity, see [9]), however, it is only defined when $\mu_1 = \cdots = \mu_s > \mu_{s+1} \geq \ldots \geq \mu_{K-g} > \mu_{K-g+1} = \cdots = \mu_K$, for some positive integers s and g such that $s + g < K$. Notice that this framework does not include the configurations of the parameters in which $s + g = K$, i.e. $\mu_1 = \cdots = \mu_j > \mu_{j+1} = \cdots = \mu_K$ for $j = 2, \ldots, K-1$.

Finally, Frieri and Zagoraiou in [3], by adopting a multipurpose design methodology, derived the optimal allocation maximizing the power of Wald test subject to an ethical constraint reflecting the efficacy of the treatments. The ensuing constrained optimal target maximizing the non centrality parameter $\phi(\boldsymbol{\rho}) = n \cdot \mu_c^\top [\mathbf{A}^\top \mathbf{M}^{-1} \mathbf{A}]^{-1} \mu_c$ of the multivariate Wald test subject to $\rho_i \geq \rho_{i+1}$ for $i =$

$1,\dots,K-1$ is

$$\boldsymbol{\rho}^C = \begin{cases} (1-(K-1)x, x, \dots, x)^\top & \text{if } x < K^{-1}, \\ \boldsymbol{\rho}^B & \text{if } x \geq K^{-1}, \end{cases} \tag{2}$$

where $\boldsymbol{\rho}^B$ is the balanced allocation and

$$x = \frac{\frac{1}{\mu_1}\sum_{k=1}^{K}\left(\frac{1}{\mu_k}-\frac{1}{\mu_1}\right)^2}{\sum_{k=1}^{K}\left(\frac{1}{\mu_k}-\frac{1}{\mu_1}\right)\sum_{k=1}^{K}\left(\frac{1}{\mu_k^2}-\frac{1}{\mu_1^2}\right)}.$$

Note that in the presence of a cluster of superior treatments $\mu_1 = \dots = \mu_s > \mu_{s+1} \geq \dots \geq \mu_{K-g} > \mu_{K-g+1} = \dots = \mu_K$ all targets $\boldsymbol{\rho}^C = (\rho_1^C, \dots, \rho_s^C, x, \dots, x)^\top$ such that $\sum_{i=1}^{s}\rho_i^C = 1-(K-s)x$ and $s+g<K$ are optimal. Instead, when $s+g=K$ every allocation such that $\sum_{i=1}^{s}\rho_i^C = 1-(K-s)x = \mu_1/(\mu_1+\mu_K) = 1-\sum_{i=s+1}^{K}\rho_i^C$ is optimal.

3 Comparisons of optimal allocations for the exponential model

In this section, we compare the statistical performances of the previously introduced designs, that is $\boldsymbol{\rho}^A, \boldsymbol{\rho}^B, \boldsymbol{\rho}^C$ and $\boldsymbol{\rho}^Z$, in terms of the normalized power, $E_P(\boldsymbol{\rho}) = \phi(\boldsymbol{\rho})/\phi(\boldsymbol{\rho}^*)$ and the tr_A efficiency, $E_{tr_A}(\boldsymbol{\rho}) = \frac{\mathrm{tr}[\mathbf{A}^\top\mathbf{M}^{-1}(\boldsymbol{\rho}^A)\mathbf{A}]}{\mathrm{tr}[\mathbf{A}^\top\mathbf{M}^{-1}(\boldsymbol{\rho})\mathbf{A}]}$. As a measure of ethics, we consider the ratio between the total expected outcome and its maximum value, that is $E_E(\boldsymbol{\rho}) = \mu_1^{-1}\sum_{i=1}^{K}\mu_i\rho_i$. Figure 1 summarizes the operating characteristics of the targets for $\mu_2 = 10, \mu_3 = 9$ and $\mu_4 = 8$, as μ_1 varies from 15 to 35. As far as the statistical power is concerned, for values of μ_1 close to μ_2, $\boldsymbol{\rho}^Z$ with $T = 0.1$ shows the highest power efficiency while, as μ_1 increases (greater than 25) the best performance in terms of $E_P(\cdot)$ is achieved by $\boldsymbol{\rho}^C$ in (2), whose power is always increasing wrt μ_1. Note that, this property is not shared by all the targets. The $\boldsymbol{\rho}^A$ target in (1), the balanced one and $\boldsymbol{\rho}^Z$ for $T = 0.15$ and $T = 0.2$ always present lower power than $\boldsymbol{\rho}^C$. In terms of ethical demand, $\boldsymbol{\rho}^C$ outperforms all the competitors with a gain wrt the second best ($\boldsymbol{\rho}^Z$, $T = 0.1$) up to 7%. The ethical efficiency of $\boldsymbol{\rho}^C$ - as also confirmed by other studies omitted here for brevity - is slightly decreasing for values of μ_1 close to μ_2 and tends to increase as μ_1 grows. A similar behaviour is retrieved only for $\boldsymbol{\rho}^A$, whereas all the remaining targets have decreasing ethical efficiency as μ_1 increases. In terms of estimation precision, the second best is $\boldsymbol{\rho}^Z$ with $T = 0.15$ for $\mu_1 < 26$, while the same target with $T = 0.1$ shows a value of E_{tr_A} approaching 1 as μ_1 grows. The constrained target $\boldsymbol{\rho}^C$ exhibits an estimation efficiency almost constant wrt μ_1 with a value always greater than 0.93. In general, the balanced design shows the lowest efficiency in all the measures considered, while the performances of $\boldsymbol{\rho}^Z$ strongly depends on the subjective choice of T.

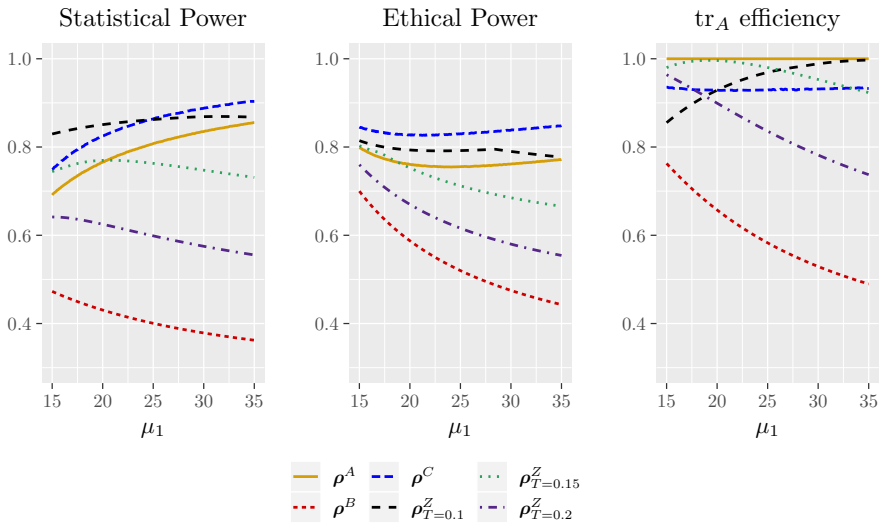

Fig. 1 Efficiency measures for $\boldsymbol{\rho}^A$, $\boldsymbol{\rho}^C$, $\boldsymbol{\rho}^B = (0.25, 0.25, 0.25, 0.25)^\top$, and $\boldsymbol{\rho}^Z$ for $T = 0.1, 0.15$ and 0.2 where $\mu_1 \in [15, 35]$, $\mu_2 = 10$, $\mu_3 = 9$ and $\mu_4 = 8$.

In Table 1, we present some examples in which groups of treatments with the same efficacy are considered . We can notice that $\boldsymbol{\rho}^C$, which coincides with the balanced design in scenario *(a)*, skews the allocations to the best performing treatment as the differences between μ_1 and the other treatment effects increases. In all the configurations considered, $\boldsymbol{\rho}^C$ leads to the highest power while keeping the ethical and the estimation efficiency always greater than 92.3% and 91.5%, respectively.

Scenario	$\boldsymbol{\mu}$	$\boldsymbol{\rho}$	$E_P(\boldsymbol{\rho})$	$E_E(\boldsymbol{\rho})$	$E_{tr_A}(\boldsymbol{\rho})$
(a)	$(12, 12, 12, 10)^\top$	$\boldsymbol{\rho}^A = (0.379, 0.219, 0.219, 0.183)^\top$	0.670	0.970	1
		$\boldsymbol{\rho}^C = \boldsymbol{\rho}^B$	0.818	0.958	0.915
		$\boldsymbol{\rho}^Z$	-	-	-
(b)	$(12, 12, 10, 10)^\top$	$\boldsymbol{\rho}^A = (0.394, 0.227, 0.189, 0.189)^\top$	0.975	0.936	1
		$\boldsymbol{\rho}^C = (0.318, 0.227, 0.227, 0.227)^\top$	1	0.923	0.969
		$\boldsymbol{\rho}^B$	0.992	0.917	0.898
		$\boldsymbol{\rho}^Z$	-	-	-
(c)	$(12, 10, 10, 10)^\top$	$\boldsymbol{\rho}^A = (0.409, 0.197, 0.197, 0.197)^\top$	0.928	0.902	1
		$\boldsymbol{\rho}^C = (0.545, 0.152, 0.152, 0.152)^\top$	1	0.925	0.932
		$\boldsymbol{\rho}^B$	0.682	0.875	0.881
		$\boldsymbol{\rho}^Z$	-	-	-

Table 1 Behaviour of $\boldsymbol{\rho}^A$, $\boldsymbol{\rho}^C$ and $\boldsymbol{\rho}^B = (0.25, 0.25, 0.25, 0.25)^\top$ in presence of groups of treatments with the same efficacy.

As discussed in Section 1, it is worth noticing that the target proposed by Zhu and Hu [9] cannot be computed for some parameters configurations, e.g. scenarios *(a), (b), (c)* of Table 1. This drawback can strongly affect its applicability.

Notice also that in clinical trials comparing $K > 2$ treatments the definition of ethics is not unequivocally determined and the requirement of being ethical by skewing more patients to the superior treatment may sometimes be misleading (see [3]). The structure of the ethical constraint $\rho_i \geq \rho_{i+1}$ for $i = 1, \ldots, K-1$ in $\boldsymbol{\rho}^C$ ensures that the target has its components ordered accordingly to the magnitude of the treatment effects. In general, this property is not shared by the considered targets: for example the $\boldsymbol{\rho}^A$ allocation in (1) assigns more patients to the reference treatment, which in our set-up coincides with the best treatment. However, if for example we consider $\boldsymbol{\mu} = (10, 12, 12, 12)^\top$, then $\boldsymbol{\rho}^A = (0.325, 0.225, 0.225, 0.225)^\top$. Moreover, if we adopt $\boldsymbol{\rho}^Z$ with $T = 0.1$ in a configuration close to scenario *(a)*, e.g. $\boldsymbol{\mu} = (12.1, 12, 11.9, 10)^\top$ then the ensuing target is $\boldsymbol{\rho}^Z = (0.357, 0.1, 0.1, 0.443)^\top$. In both examples the highest proportion of patients is receiving the less effective drug showing that these targets may be inappropriate from an ethical viewpoint.

The results of Figure 1, Table 1 and the discussion above, show that the constrained optimal target $\boldsymbol{\rho}^C$ represents a valid trade-off between statistical power, inferential precision and ethical demand.

Education: students' mobility and labour market

From measurement to explanatory approaches: an assessment of the attractiveness of the curricula programs supplied by Italian universities

Dalla misurazione all'analisi delle determinanti: una valutazione dell'attrattività dei Corsi di Studio in Italia

Isabella Sulis and Silvia Columbu and Mariano Porcu

Abstract The aim of this study is to define the attractiveness of degree programs supplied by Italian Universities using data provided by the National Student Archive (NSA) on a cohort of students enrolled at the universities in a.y. 2017-18. For this sake, micro data on students university mobility choices have been summarized at field of study level in each of the Italian University by defining several indicators of degree programs attractiveness. A classification of universities based on the attractiveness of the fields of study they offer have been advanced which relies on a robust definition of mover and which takes into account multiple aspects of the investigated phenomena. The resulting data set has been investigated using Multilevel Latent Profile Analysis to identify profiles of universities and degree programs.

Abstract *Il lavoro analizza l'attrattiva dei corsi di laurea attivati nelle Università italiane utilizzando i dati forniti dall' Anagrafe Nazionale Studenti relativi alla coorte di immatricolati nell'a.a. 2017-18. I micro dati sulle scelte di mobilità degli studenti sono stati aggregati a livello di corso di studio delle singole università attraverso la definizione di diversi indicatori di attrattività. La scelta di usare indicatori multipli per la definizione di un indice di attrattività ha consentito di avanzare una classifica delle università, in termini di attrattività dei corsi di studio attivati nell'offerta curriculare, che si basa su una definizione robusta di studente in mobilità e che tiene conto di molteplici aspetti complementari. L'utilizzo della Multilevel Latent Profile Analysis ha permesso di identificare profili di università in base all'attrattività dei rispettivi corsi di laurea.*

1 Introduction

The study of the capability of universities of attracting students from other geographical areas has become a topic of great relevance in the last years, since it is strictly linked with the reputation of the universities and their perceived quality in the public opinion [2, 3, 9], with the depopulation of the youth and educated people from the less developed areas of the country and the related brain drain phenomenon [6, 7, 5, 1, 8, 9, 10, 4]. This study aims to measure the attractiveness of Italian universities focusing on degree programs they supply and addressing the following research questions: (i) How Italian degree programs can be classified according to their capability to attract students? (ii) Which are the main profiles that arise of universities and degree programs in terms of attractiveness? We operationalize attractiveness using multiple indicators and we adopted a multilevel latent profile analysis for shaping profiles of universities and degree programs characterized by different levels of attractiveness. For this sake micro data provided by the National Student Archive (NSA) on a cohort of students enrolled in # 1540 bachelor degrees of # 80 Italian Universities in a.y. 2017-18 has been adopted and individual student mobility choices have been summarized for each university at field of study level (degree program) by defining six indicators of attractiveness which are function of the number of incoming movers, the distance from their city of residence and their status of free or forced movers.

2 Data

We use the micro data provided by the NSA related to a cohort of freshman enrolled in 2017/18 and the information on the two surveys AlmaLaurea on graduated in 2015 in order to build up a data set of Italian bachelor degree programs. The micro data provided by NSA have been summarized (averaged) at degree program level for each university to sketch profiles in terms of socio-demographic background of their students. The distribution of students and degree programs by disciplinary field is listed in Table 1. We use a robust definition of mover by considering as student in mobility only those students who attend a university outside their region (for regional mobility) or the province (for provincial mobility) of residence and who take more than 90 minutes to reach their municipality of residence from the university.

Moreover, we identified free and forced mover students. Namely we classified as free movers only those students who had the possibility to attend the degree programs where they enrolled in their province of residence and chose to move. In this way we overcome issues related to considering as movers, students coming from bordering areas or universities which offer a limited number of degree programs. Six indicators have been considered in order to operationalize the attractiveness dimension of bachelor degree programs offered by Italian universities: 1) the number of incoming robust regional mover students in each degree program over the num-

ber of enrolled students in each degree program (`INCIDENCER`); 2) the number of incoming robust provincial mover students in each degree program over the number of enrolled students in each degree program (`INCIDENCEP`); 3) the number of incoming robust regional movers attracted by a degree program of a given university on the total number of regional movers in the specific study field (classe di laurea) of the degree program in Italy (`QUOTEMOVERR`); 4) the number of incoming robust provincial movers attracted by a degree program of a given university over the total number of regional movers in the specific study field (classe di laurea) of the degree program in Italy (`QUOTEMOVERP`); 5) the number of free movers coming from other regions (without applying the condition of the 90 minutes travel time) over the total number of enrolled students (`FREEMOVERR`); 6) the average travel time of students coming from other regions using the travelling time between municipalities estimated by ISTAT (`AVERAGETRAVEL`)[1]. The average values of the indexes and their standard deviations (see Table 2) show a remarkable variability of the six indicators across the four geographical macro-areas and within the macro-areas. This clearly highlight the divergences between Centre-North and South universities not only in the capability to attract students but also in the type of mover students attracted (free versus forced movers) and in the extension of their catching area in the national framework. The dimensionality of the selected attractiveness indicators has been assessed using Principal Component Factors Analysis on the standardized indicators. Results clearly suggest the presence of a dominant factor which explains about 72% of the common variance.

[1] For this last indicator we had to impute values for incoming and outgoing mover students in Sardinia and Sicily (less than 3% of the population) as the Istat database provides for the two islands only the travel time for between municipalities within region movements.

3 Modelling Approach

Multilevel Latent Profile Analysis [12] has been used to jointly classify universities and degree programs in Level-2 and Level-1 latent classes and to sketch profiles for both. The number of lower and higher level classes has been defined on the basis of the improvement in the goodness of fit measures, heterogeneity in the classes and interpretability of the results [11]. By indicating with $j = 1,\ldots,n_k$ the 1540 degree programs on which the analysis refers to (Level-1 units) and with $k = 1,\ldots,K$ the 80 universities (Level-2 units) in which degree programs are clustered, the vector $\boldsymbol{y}_{kj}$ of observed values for units kj is explained by defyning two discrete latent variables U (defined by $h = 1,\ldots,H$ latent classes) and V (defined by $m = 1,\ldots,M$ classes), respectively at Level-1 and Level-2 units. A 2-level latent profile model is described by two equations representing respectively the level-2 and the level-1 membership. That is at second level

$$f(y_k) = \sum_{h=1}^{H} P(v_k = h) \prod_{j=1}^{n_k} f(\boldsymbol{y}_{kj}|v_k = h),$$

with $P(v_k = h)$ membership probability of Level-2 units to profile h, and at first level

$$f(\boldsymbol{y}_{kj}|v_k = h) = \sum_{m=1}^{M} P(u_{kj} = m|v_k = h) \prod_{i=1}^{I} f(y_{kji}|u_{kj} = m, v_k = h),$$

where $P(u_{kj} = m|v_k = h)$ is the conditional membership probability of first level units to profile m, given the belonging in level-2 class h, and y_{kji} is the value of the indicator i ($i = 1,\ldots,I$) for unit kj. We assume that $f(y_{kji}|u_{kj} = m, v_k = h)$ is normally distributed with mean μ_{jmkh} and variance σ^2_{jmkh}).

4 Results

On the basis of these aspects, four Latent Classes have been identified to profile degree programs attractiveness and three Latent Classes to differentiate between universities, as Table 3 shows. The profiles of the latent classes at Level-1 (Table 3 (a)) have been drawn looking at the differences in the expected values of the indicator items (expressed in z-score) between degree programs belonging to different classes. Namely the degree programs in LC2 have on average a value of the z-score equal to -0.96, thus it detects *Low attractive degree programs*, whereas degree programs in LC4 have an average z-score equal to 1.53, thus it identifies *High attractive degree programs*. LC3 and LC2 with values equal to -0.61 and 0.05 detect respectively *Medium-Low attractive* and *Medium attractive* degree programs. The value of the Wald test statistics show that the average values of the indicators significantly differ between LCs. At Level-2 three profiles of Universities arise on the basis of the proportion of degree programs classified in each Level-1 category (Table 3 (b)). *Low* attractive universities have about 50% of the degree programs classified in the *Low* attractive LC at Level-1, *Medium* attractive universities have about 68% of degree programs classified as *Medium-Low and Medium* attractive, whereas *High* attractive universities have 53% of degree programs classified as *High attractive*.

5 Conclusion

Main findings clearly suggest the clustering of universities and degree programs in lower and higher level latent classes with different intensity of the underlying latent trait. Latent classes at Level-1 and Level-2 are well differentiated at both levels of analysis. Further analyses focused on the e determinants of class assignment are still in progress.

Pull factors for university students' mobility: a gravity model approach

Il gravity model per la individuazione dei fattori di attrazione per la mobilità studentesca

Giovanni Boscaino and Vincenzo Giuseppe Genova

Abstract Migration phenomena are characterised by flows that are typically multilateral. Often an outgoing flow corresponds to one or more incoming flows, which counterbalances it. When the balance is negative, socio-economic problems can arise. Italy has been afflicted for years by a particular type of unilateral migration: student mobility. Thousands of students leave the South to study in the Centre-North, driven by the better socio-economic conditions of those areas, and by more prosperous job prospects. Since this flow is not followed by a return one, nor by other incoming flows, the historical, socio-economic gap between North and South is widened. Taking advantage of the big dataset concerning the cohorts of students enrolling in Italian universities, made available by the Ministry of Education, we adopted the viewpoint of gravity models to investigate the social, economic and educational aspects of universities and destination areas that can make mobility attractive, studying them also over time.

Abstract *I fenomeni migratori sono caratterizzati da flussi tipicamente multilaterali: ad un flusso in uscita ne corrisponde uno o più in entrata che ne bilancia il saldo. Ma accade a volte si assiste a flussi sbilanciati, con saldo molto negativo conducendo a problemi socio-economici. L'italia da anni è afflitta da un particolare tipo di migrazione unilaterale: la mobilità studentesca. Migliaia di studenti abbandonano il Sud per studiare al Centro-Nord, attratti dalle migliori condizioni socio-economiche. Poiché tale flusso non è poi seguito da uno di ritorno, né da un altro in entrata, lo storico divario socio-economico tra il Nord e il Sud è amplificato. Sfruttando il dataset delle coorti degli studenti che si iscrivono alle università italiane, fornito dal MUR, per indagare gli aspetti socali, economici e formativi delle università e delle aree di destinazione che possono rendere appetibile la mobilità, studiandoli anche nel tempo, secondo l'approccio del gravity model.*

Key words: Student mobility, gravity model, mobility pull factors

1 Introduction

The critical role of a university for the development of a territory is widely accepted in the literature. Its importance is due mostly to two factors. First, universities play a core role in the level of education in the area in which they are situated. This importance is amplified where there is a knowledge-based economy, for which human capital is of primary importance and the labour market requires highly qualified people [9]. Second, Perry & Wiewel [12] introduced the notion of *university as urban developer and regenerator*, having positive, direct and indirect effects to the environment around. If it can attract students, then income will be created from them, due to the increase in both population and demand of consumer goods. In Italy, since the 90's students' mobility has brought a significant national concern for the socio-economic future of the Country. Specifically, students from the southern regions tend to move toward the northern ones, and this phenomenon is seen as a perpetual mechanism of the regional disparities and the existing dualism between the southern and northern regions of Italy [1]. From the origin region perspective, students' migration may severely hamper the regional potential in many ways. First of all, when students move from one region to another one, they have to be financially supported by their families, creating a transfer of capital to the destination ones. Second, the origin regions could lose their best students and so the best human capital for their future growth, since students are more likely to find a job in that region. If graduates do not come back to their home regions, these regions will have less human capital, losing the ability to attract external investments, that together with their economy, will be negatively affected. In the academic year 2016-2017, compared to the 685,000 southerners enrolled at the University, 25.6% study at a University in the Centre-North. The share of residents in the Centre-North studying in the South is only 1.9%. The net migration balance is about 157,000 units, and is constantly increasing. Students who emigrate for study purposes make up about 0.7% of the resident southern population [5]. The empirical evidence shows how, when we consider the entire range of working life, the rate of Return On Investments in human capital in the southern regions is about half of that observed in the "richest" regions of the Center-North (Piedmot, Lombardy and Emilia-Romagna, [6]). Besides, students' choice regarding where to study often depends on the (perceived) "quality" of the training offered by the university. In Italy, the largest regions usually offer the broadest range of topics, becoming an attractive pole for the migratory flow of students. It emerges rather clearly the presence of a market failure [8]. The economic theory suggests how there should be market equilibrium characterised by investments smaller than the optimal ones, or sub-optimal choices in terms of "quality" of universities or courses that fit better the students' needs. The study carried out by Dotti et al. [9] shows that, although the quality of a university and its characteristics play a central role in the decision process of a student, the characteristics of the labour market in a specific region must be taken into account as well. They point out that in the southern regions there are not universities which attract students living more than 200 kilometres of distance, and the number of registrations of a university is linked to the job prospects of students, so to the expected number of job offers.

Amendola & Restaino [7] focus the attention to the determinants and characteristics of the mobility process from and toward Italy. They show that the number of students interested in spending part of their academic education abroad is steadily increasing. This is not a surprise, given that students who choose to study abroad earn much in terms of life experience, intercultural competencies and quality of studies, being more and more willing to learn and/or to strengthen their competencies and knowledge. The study carried out by Camillo et al. [11] on Italian graduates who work abroad, shows that more than 80% of graduates interviewed five years after getting their degree would make the same choice because they were very satisfied and would not go back in Italy. So, it seems that the Italian labour market is not able to increase the value of human capital generated by Italian universities. Students' enrolment has decreased significantly, especially after the economic crisis of 2008, while the students' migration from the South to the other regions of the Country has increased. This phenomenon has created further inequalities within the Country and a cultural and socio-economic loss for the South of Italy. The study presented in this paper aims to explore the determinants of students' mobility in Italy. In particular, the focus is on the pull factors of the destination universities and areas. We have considered information coming from institutional statistics about universities' and city areas characteristics, seeking for some aspects that can motivate students to abandon the South.

2 Methodology

In literature, the Gravity Models approach is one of the most adopted to study migration flows from an origin to a destination place. The main idea behind the Gravity Model is the Newton gravity law: a gravity model assumes that flow (the attraction force) is proportional to the sizes of origin and destination (of bodies' masses) but inversely proportional to the distance of these two places (bodies). In its general form a gravity model can be expressed as $N_{ij} = G\frac{Y_i Y_j}{d_{ij}}$ where, considering mobility flows, N_{ij} is the number of people move from area i to area j; G is a constant; Y_i is the number of people in area i; Y_j is the number of people in area j; d_{ij} is the distance between countries i and j. Under a modelling approach previous equation can be expressed by logarithmic transformation:

$$\ln(N_{ij}) = \beta_0 + \beta_1 \ln(Y_i) + \beta_2 \ln(Y_j) + \beta_3 \ln(d_{ij}) + \varepsilon_{ij} \quad (1)$$

In literature many reformulation of Eq. 1 were proposed, in particular authors proposed to substitute the d_{ij} with variables that act as detractors, *e.g.* the travel costs. For example, concerning students' mobility, Beine *et al.* [2] argued that students' mobility could be affected by migration costs and the size of the network at the destination. According to them, the network at the destination is defined as migrants from the origin city living at the destination and this network can facilitate migration flows. Indeed previous migrants are likely to provide assistance and information

to those students decide to migrate in the city j, reducing migration costs [2, 3]. The goal of our analysis is to study the determinants of students' mobility and the possible effects of the migration chain. When students move because they are advised and invited by friends or relatives living in the destination area, we are in the presence of a migratory chain [4]. According to Beine *et al.* [2], we decided to analyse students' mobility following a Gravity Model approach with mixed effects on clusters of Sicilian municipalities (clusters of origin), and on the provinces of "out of Sicily" universities (provinces of destination). Clusters come from [10]: 38 clusters grouping the 390 Sicilian municipalities, based on economic, commercial and geographical proximity aspects, and the spoken language (Italian vs local dialects). In our analysis we assume the response variable is $N_{ij|k} \sim NB(\mu_{ij|k}, \sigma_{ij|k})$, where $N_{ij|k}$ is the number of outgoing students from cluster i to university's province j conditioned to the $k-th$ covariate profile. Under these assumptions the model is:

$$\ln(\mu_{ij|k}) = \ln(N_{i|k}) + \alpha_{ij} + V_i\phi + X_j\beta + Z_u\gamma + \theta_{ij}\ln(M_{iju}) + \varepsilon_i + \omega_j \qquad (2)$$

where $N_{i|k}$ is the total number of freshmen of the i cluster of Sicilian municipalities, α_{ij} is the intercept, V_i is the vector of student's characteristics in the cluster i, X_j are socio-economic covariates of the provinces of destination, Z_u are covariates related to the characteristics of university u, and M_{iju} are students of previous years from cluster i that study at university u in the province j. ϕ, β, and γ are vectors of unknown regression parameters and θ_{ij} is the network effect. $\varepsilon_i \sim N(0, \sigma^2)$ is the cluster of origin random effect, and $\omega_j \sim N(0, \sigma^2)$ is the province of destination level random effect. As the aim of this analysis is to evaluate pull factors in students' mobility, we decided to include in the model socio-economic covariates and universities covariates that can act as pull factors. Another goal of this analysis is to measure the migration chain effect in students' mobility. In this first approach, we decided to use as migration chain effect the network measure proposed in [3], that is expressed by θ in eq. 2. Our idea is if a chain migration effect in Italian university students there exists, the parameter θ should be positive and significant.

3 Results and comments

The model in Eq. 2 was estimated for data coming from the Italian Ministry of Education. In particular, data regards individual information about two cohorts (2014 and 2017) of the population of the Italian freshmen followed up to graduation. Many variables are available: socio-demographic (Gender, Area of study, High School Finale Grade, and Diploma Type), life quality of the province of destination (Unemployment rate, House Price, Free time indicator, Public order indicator), and university characteristics (Scholarship, Indicators of Services, Structures, and Communication). The baseline profile is a student with high school grade $[60-70]$, from scientific high school, that enrol at a Degree Course of the humanistic area, with quantitative covariates. For sake of simplicity and pages limit, the estimates of the

four models are reported in Table 1. Concerning the baseline profile, the expected number of outgoing students, for the cohort 2014, is grater for those students choose a non-humanistic area, and in particular the expected number of outgoing students for male seems to be greater in the social area and for female in the scientific area. Looking at the cohort 2017 (last two columns) we notice that outgoing male students prefer the scientific area and females the health one, *ceteris paribus*. In the 2017 cohort, instead, male students with lower mobility are those choose the social area and females the scientific area, maybe due to the labour market in the destination provinces which could have determined the degree courses choice.

Table 1 Model estimates by gender and cohort, standard errors in parenthesis.

Scholarships	0.011 (0.00)	0.001 (0.00)	0.015 (0.00)	0.005 (0.00)
Structures	0.002 (0.00)	0.000 (0.00)	0.015 (0.01)	0.006 (0.01)
WEB	-0.011 (0.01)	-0.002 (0.00)	0.030 (0.01)	0.000 (0.01)

Furthermore, regardless the gender and the cohorts, looking at the high school grade, the higher the grade, the bigger the expected number of outgoing students and this result could be in according to the idea that families let move their children if they are very talented and motivated. Instead, we can see differences due to the high school diploma. Indeed, the expected number of outgoing students is lower for students have not a Scientific lyceum diploma, and this result suggests the students with a higher mobility profile come from the Scientific and Classical Lyceum. Looking at pull factors related to the areas and the universities of destination, Table

1 highlights that the unemployment rate at the destination seems to play a role in the student mobility: indeed, regardless the cohort and the gender the higher the rate, the lower the expected number of outgoing students. In addition, such an effect is higher for male students than females, and it does not show great differences between the two years. Moreover, the more accessible the scholarships are at the enrolment, the higher the number of students that chose an "out of Sicily" university is. Also, the effect related to the scholarship seems to change according to gender. With respect to the migration chain effect in students' mobility, the explanatory variable M_{iju} (defined as students that from cluster of origin i move to province of destination j to study at university u in previous years) highlights a migration chain if it will be positive and significant (as explained in section 2). Looking at Table 1, such effect seems exist and it's highly significant, and as expected this result could suggest migration chain plays a role in student mobility. Also, this result seems to be similar and stable with respect to the gender and over time.

Spatial autoregressive gravity models to explain the university student mobility in Italy

Modelli gravitazionali spaziali autoregressivi per spiegare la mobilità studentesca in Italia

Silvia Bacci, Bruno Bertaccini, Chiara Bocci

Abstract We investigate the mobility of Italian academic students among geographical areas (i.e., provinces) to attend university. The study relies on data collected by the Italian National Student Registry and concerns students enrolled in the academic year 2011–2012 in a bachelor degree program or a five-years degree program of any Italian university. The methodological approach we adopt is based on the analysis of the flows of students among provinces through spatial autoregressive gravity models. The gravity component of this type of models accounts for the deterrence effect due to the distance among province of origin and province of destination. Instead, the spatial autoregressive component is introduced to capture homogenous behaviours among contiguous geographical areas. In particular, we focus on alternative ways to specify the spatial weight matrix that characterises the spatial autoregressive component of the models at issue.

Abstract *Oggetto di questo contributo è l'analisi della mobilità degli studenti universitari italiani tra aree geografiche (province) per frequentare l'università. Lo studio si basa su dati raccolti dall'Anagrafe Nazionale Studenti e riguarda gli immatricolati ad un corso di laurea triennale o a ciclo unico nell'anno accademico 2011-2012 in un qualsiasi ateneo italiano. L'approccio metodologico adottato è basato sull'analisi dei flussi di studenti tra province tramite un'idonea specificazione di un modello gravitazionale spaziale autoregressivo. La componente gravitazionale del modello tiene conto dell'effetto deterrente dovuto alla distanza tra provincia di origine e provincia di destinazione. La componente autoregressiva spaziale viene, invece, introdotta per catturare comportamenti omogenei tra aree geografiche contigue. Una particolare attenzione è posta sulle possibili specificazioni della matrice dei pesi spaziali, caratterizzante la componente autoregressiva spaziale dei modelli in oggetto.*

1 Introduction

Mobility of academic students across a country (inter-regional mobility) to attend university has important consequences on the economic development of the geographical areas involved, as the migration for study reasons is often just a precursor of the migration for job reasons and students that move away from home to take a degree tend not to return at the end of the academic studies. This phenomenon is particularly remarkable in Italy where many students living in the South are attracted by university courses offered in the North of Italy. Some recent contributions in such a setting are [6], [7], [14].

In the present contribution we are interested in detecting homogenous geographical areas having a similar behaviour in terms of student mobility. More in detail, we investigate the possibility of aggregation of: (i) geographical areas of origin on the basis of their tendency to "send out" young people living there to attend university and (ii) geographical areas of destination where academic campus are located on the basis of their tendency to attract students from outside. The study deals with the first-level mobility, that is the transition from the high-school to the bachelor (or five-years) degree. Hence, the focus is on the flows of students from the place of residence to a university located elsewhere, with provinces considered as the territorial unit of reference.

The statistical methodology we adopt is based on the Spatial Auto-Regressive (SAR) gravity models.

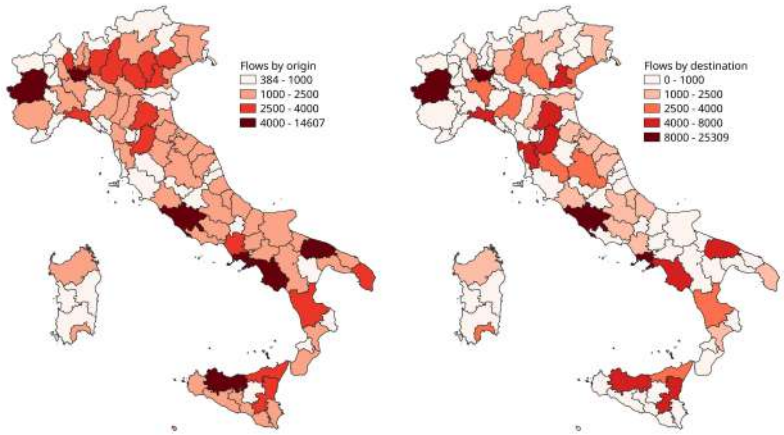
The class of gravity models (for a review see [1] and [13]) is typically adopted to explain incoming and outgoing flows (of migrants, goods, workers, and so on) between geographical areas (e.g. countries). In the higher education field, gravity models are useful to explain the flows of students across territories and/or universities; examples of gravity models applied to the university context are given by [12], [3] and [6]. In addition, some spatial components may be introduced to take into account the spatial correlation between flows [10], after having controlled for observable characteristics of the origins and destinations.

The data used in the study comes from the Italian National Student Registry (in Italian, Anagrafe Nazionale Studenti - ANS), which is an administrative database that monthly registers and monitors the careers of university students enrolled in any degree program in a public or private university located in Italy.

2 Data

Analyses are carried on freshmen enrolled in the academic year 2011–2012 in a bachelor degree program or a five-years degree program (i.e., degree program that usually lasts five or six years), defined according to Law 509 of 1999 and Law 270 of 2004, of any Italian higher education institution, with the exclusion of on-line universities. The set of students amounts to 207,388 distributed in 71 universities and 102 provinces (note that a certain number of universities have campus dislocated on several provinces). The biggest universities are the University of Rome "La Sapienza" (5.3%), Bologna (5.0% of students) and Neaples "Federico II" (5.0%). The 28.9% of universities is located in the North-West of Italy, the 21.5% in the North-East, the 23.1% in the Centre, the 19.5% in the South of Italy and the remaining 7.0% in the Islands (i.e., Sicily and Sardegna). A more detailed description of the data at issue together with some assessments of the capability of attraction and retention of students by universities is provided by [2].

Around one-half (48.6%) of freshmen enrolled in a bachelor or five-years degree program comes from a province different from the one where he/she lives. Obviously, in certain cases the migration is "forced" because the higher education offer of several provinces is completely absent or strongly limited (see Fig. 1). For this reason, the study of flows needs to take into account the distinction between forced migrant students and free migrant students [9] or, similarly, the distinction between provinces that supply a complete and varied offer of bachelor degree programs and provinces with a limited or absent offer.



(a) (b)

Fig. 1 Number of outgoing students by province of residence (panel a) and number of incoming students by province of destination (panel b).

3 The SAR gravity model

The gravity model we rely on is formulated as [8]

$$\log Y_{hi} = \beta_0 + \gamma_t \log d_{hi} + \log \vec{x}'_{Oh}\vec{\beta}_O + \log \vec{x}'_{Di}\vec{\beta}_D + e_{hi}, \tag{1}$$

with Y_{hi} denoting the flow of students from the origin h to the destination i, with h representing the province of residence and i the province where is located the university attended by the student. Moreover, d_{hi} is the road distance in kilometers between h and i: as the distance between h and i increases, we should observe a reduction in the flows towards i. Vectors $\vec{x}_{Oh}$ and $\vec{x}_{Di}$ collect characteristics of the origin h and destination i, respectively, that affect outgoing and incoming flows, such as the type of higher educational offer supplied (e.g., complete and varied, limited, absent). Moreover, β_0 is the constant term and γ_t, $\vec{\beta}_O$, and $\vec{\beta}_D$ are the regression coefficients associated with the distance and the other characteristics of the origin and the destination; e_{hi} is the error term. Considering n provinces, the model analyses all flows for n^2 origin-destination pairs of provinces. The $n \times n$ flow matrix contains intra-provincial flows in its main diagonal and inter-provincial flows in its off-diagonal elements; it is vectorised by stacking the columns to form an $n^2 \times 1$ vector of log-flows contained in $\vec{y}$. Hence, model (1) may be written in matrix notation as

$$\vec{y} = \vec{\beta}_0 + \vec{\gamma}\vec{d} + \vec{X}_O\vec{\beta}_O + \vec{X}_D\vec{\beta}_D + \vec{e}, \tag{2}$$

where $\vec{d}$ is the $n^2 \times 1$ vector of log-distances $\log d_{hi}$, $\vec{X}_O = \vec{X} \bigotimes \vec{1}_n$ and $\vec{X}_D = \vec{1}_n \bigotimes \vec{X}$, with $\vec{X}$ being the $n \times p$ matrix of the provinces' p characteristics. To take simple the notation we assume the same covariates for origin and destination provinces, but this assumption is not necessary. In practice, the Kronecker product $\bigotimes$ repeats the same values of the n provinces to create a matrix of covariates associated with each origin ($\vec{X}_O$) and each destination ($\vec{X}_D$).

The gravity model (2) assumes independence among the origin-destination flows. It is possible to relax this assumption to account for different types of spatial dependence between geographical areas [10, 11]. In detail, the SAR gravity model is specified as follows

$$\vec{y} = \vec{\beta}_0 + \rho_O\vec{W}_O\vec{y} + \rho_D\vec{W}_D\vec{y} + \rho_{OD}\vec{W}_{OD}\vec{y} + \vec{\gamma}\vec{d} + \vec{X}_O\vec{\beta}_O + \vec{X}_D\vec{\beta}_D + \vec{e}, \tag{3}$$

with $\vec{W}_O = \vec{W} \bigotimes \vec{1}_n$, $\vec{W}_D = \vec{1}_n \bigotimes \vec{W}$, and $\vec{W}_{OD} = \vec{W} \bigotimes \vec{W}$, where $\vec{W}$ is the $n \times n$ spatial weight matrix that accounts for the neighbour relationships between the n provinces. The coefficients ρ_O, ρ_D, and ρ_{OD} measure the strength of the origin-based, destination-based and origin-to-destination-based dependence, respectively. In other words, these correlation coefficients denote how larger flows from origin h to destination i are accompanied by: larger flows from neighbours of h to i (ρ_O), larger flows from h to neighbours of i (ρ_D), larger flows from neighbours of h to neighbours of i (ρ_{OD}). Note that the model specification could include one or more of the spatial components.

4 Specification of the spatial weight matrix $\vec{W}$

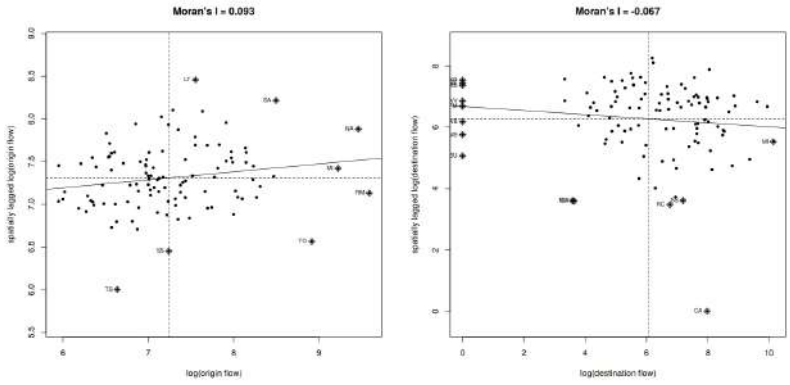
The specification of a SAR gravity model requires a suitable definition of the spatial weight matrix $\vec{W}$. We can adopt two main approaches to define the elements w_{hi} of $\vec{W}$: (i) taking into account actual geographical relations or (ii) considering socio-economic similarities. Note that, whatever the definition of $\vec{W}$ matrix is, elements on the principal diagonal are set to 0 by definition.

Point (i) represents the traditional approach to the definition of $\vec{W}$. Typical choices are given by:

- contiguity matrices of order 1 (i.e., we consider only areas that share a border) or higher (i.e., we also consider neighbours of neighbours): $w_{hi} = 1$ if area h and area i are contiguous (of order 1 or higher), and 0 otherwise;
- k-nearest neighbours: $w_{hi} = 1$ if i is one of the k-nearest areas to h, and 0 otherwise;
- distance-based neighbours: $w_{hi} = 1$ if i is within a specified distance from h, and 0 otherwise;
- inverse distance: $w_{hi} = 1/d_{hi}$.

A different perspective is adopted under point (ii), where the elements of $\vec{W}$ are defined according to measures of similarity alternative or complementary to the geographical ones. The recent literature proposes the use of socio-economic variables that characterise the substantial (not necessarily geographical) neighbourhood among areas; for instance, [5] use a distance between areas based on a quality of life indicator.

Preliminary results obtained using contiguity matrices of order 1 are displayed in Figure 2, where the spatial autocorrelation Moran's index is plotted both for outgoing flows (panel a) and for the incoming flows (panel b).



(a) (b)

Fig. 2 Moran's index plot for the outgoing flows (panel a) and the incoming flows (panel b).

The Moran's index outlines weak (although significant) spatial correlation between flows of students from different provinces, with a few provinces having a leverage effect. In order to better investigate the spatial correlation structure of data at issue, the future work will be focused on the evaluation of alternative specifications of the spatial weight matrix $\vec{W}$, mainly based on socio-economic similarities (point (ii) above) in order to detect groups of provinces sharing a common behaviour in terms of propensity to send out students to attend university elsewhere and/or to attract students from other provinces.

Environmental Statistics (GRASPA-SIS)

A Time Clustering Model for Spatio-Temporal Data

Un modello di clustering temporale per dati spazio-temporali

Clara Grazian and Gianluca Mastrantonio and Enrico Bibbona

Abstract Clustering methods are ubiquitous in many areas of science: ecology, environmental sciences, microbiology, linguistics, transport models, etc. Model-based methods, like mixture models, allow to quantify the uncertainty on the clustering, however extensions to data showing specific types of dependence, as spatio-temporal data, present some hidden difficulties. In this work, we propose an approach to identify clusters in spatio-temporal data and study their evolution over time; the method is invariant with respect to the ordering of the clusters and to the choice of the reference cluster.

Abstract *Metodi di clustering possono essere trovati in ogni area della science: ecologia, science climatiche, microbiologia, linguistica, trasporti, etc. Metodi basati su modelli, come i modelli mistura, permettono di quantificare l'incertezza sulla struttura di clustering, ma l'introduzione di strutture di dipendenza particolari, come quelle caratteristiche dei dati spazio-temporali, presentano alcune difficoltà nascoste. In questo lavoro, proponiamo un approccio per identificare cluster in dati spazio-temporali e studiare la loro evoluazione nel tempo; il metodo è invariante rispetto alla scelta dell'ordine dei gruppi e del grouppo di riferimento.*

Key words: logistic-normal process, hidden Markov models, coregionalization, invariance

1 Introduction

Clustering analysis is one of the main tasks in statistics and applied statistics; some examples can be find in the task of characterising the number and the features of animal behaviours from tracking trajectories, identifying the genetic characteristics of regional flora which increase the probability of survival in presence of pollution, or defining levels of resistance to antibiotics of bacteria. In this respect, mixture models represents a flexible tool to define a probability distribution for the problem of clustering. The natural temporal extension to mixture models is defined by the class of hidden Markov models (HMMs) [7].

Although HMMs are very popular and applied in various settings, the Markov structure can be too restrictive in some situations. One typical example is the dependence of the allocation to each group to external variables or processes. A possible solution would be to introduce covariate information that models the probabilities, however this type of information is not always available and the strucutre of this dependence can be too complex to be easily defined in a model. Another problem of HMMs is that the probabilities to belong to each cluster are time-independent: this is a strong assumption that is rarely satisfied. Finally, the full set of clusters should be present in all the temporal window of observation, while it could be reasonable to assume that some clusters can appear and disappear in specific moments, in particular if the time framework is large. The main reason why the HMM is so widely used lies on its efficiency and ease of implementation.

We propose a model where the clustering probabilities are time-dependent and depend on the particular locations of the data. These is achieved by assuming that the vector of probabilities is marginally distributed as a logistic-normal model (*LogitN*) [1] and the structured temporal dependence is induces by a Gaussian process obtained through the coregionalization method [2]. The logitN distribution was proposed by [1] as a distribution for compositional data, i.e. vectors of positive probabilities with the sum-to-one constraint. With respect to the Dirichlet distribution, which is usually introduced to model compositional data, the logitN distribution has the advantage that relates the vector of probabilities to a latent Gaussian random variable. The structure of the simplex, where the probabilities are defined and which is imposed by the sum-to-one constraint, imposes that in a vector of K elements, only $(K-1)$ are free to vary, while the K-th is deterministically determined; this element is usually defined the *reference element*.

Since there is no reason to choose any group as the reference one, inference should not depend on this choice; however, the introduction of a coregionalization in the Gaussian process involved in the Gaussian latent variable can change the marginal distribution of the elements of the probability vector; a solution to this problem is usually reached by introducing simplifying assumptions.[5] assumes independence between the $K-1$ process and spatio-temporal correlation functions, while [3] and [6] assume dependence between the vectors but only a common functional form for the spatial correlation is used for all regimes.

In this work, we propose a method which is invariant with respect to the choice of the reference element and to the choice of the ordering of the groups.

2 A LogitN representation of the temporal clustering

Let $\{t_1, t_2, \ldots, t_T\} \equiv \mathscr{T}$ be the set of observed time points and let $\mathbf{x}(\mathbf{s}) = \{\mathbf{x}_t(\mathbf{s})\}_{t\in\mathscr{T}}$ be the data observed at locations $\mathbf{s} \in \mathbb{R}^2$. Let $\mathbf{z}(\mathbf{s}) = \{z_t(\mathbf{s})\}_{t\in\mathscr{T}}$ with $z_t(\mathbf{s}) \in \{1,2,\ldots,K\} \equiv \mathscr{K}$, and $f(\cdot)$ be a generic density, with parameter of location ξ_k and scale Ω_k. We assume that the data come from a mixture-type model based on (possibly multivariate) normal densities:

$$f(\mathbf{x}(\mathbf{s})|\mathbf{z}\{\xi_k, \Omega_k\}) = \prod_{t\in\mathscr{T}} f(\mathbf{x}_t(\mathbf{s})|\xi_{z_t(\mathbf{s})}, \Omega_{z_t(\mathbf{s})}), \tag{1}$$

$$\mathbf{x}_t(\mathbf{s})|\xi_{z_t(\mathbf{s})}, \Omega_{z_t(\mathbf{s})} \sim N_2(\xi_{z_t(\mathbf{s})}, \Omega_{z_t(\mathbf{s})}). \tag{2}$$

It is necessary to define the distribution of the allocation variable $\{z_t(\mathbf{s})\}_{t\in\mathscr{T}}$ in such a way that it can describe the dynamic evolution of the clustering probabilities. The most popular model used in this setting is the hidden Markov model, which assume that

$$z_{t_i}(\mathbf{s})|z_{t_{i-1}}(\mathbf{s}), \{\pi_{k,k'}\}_{k,k'\in\mathscr{K}} \sim \sum_{k\in\mathscr{K}} \pi_{z_{t_{i-1}},k}(\mathbf{s})\delta_k, \tag{3}$$

with $z_{t_0} = 1$ and where δ_k is the Kronecker delta function, i.e. the evolution is governed by the Markov property. The mixing probability $\pi_{t,k}(\mathbf{s})$ is the probability that the location $\mathbf{s}$ belongs to component k at time t and are defined in such a way that $\pi_{t,k}(\mathbf{s}) > 0$ and $\sum_{k=1}^{K} \pi_{t,k}(\mathbf{s}) = 1$ for each $\mathbf{s}$ and t.

The cluster probabilities $\{\pi_{t,k}(\mathbf{s})\}_t$ are allowed to vary across space and time. In particular, we want to introduce dependence among them such that observations close in space or time are more likely to be allocated to the same cluster than observations which are more distant from each other. In order to work on the dependence structure, the standard approach involves to work on a transformation of the probabilities

$$\pi_{t,k}(\mathbf{s}) = \frac{e^{\omega_{t,k}(\mathbf{s})}}{1+\sum_{j=1}^{K-1} e^{\omega_{t,j}(\mathbf{s})}}, \quad k \neq K. \tag{4}$$

From (4), it is evident that there is an identification problem, since the vector of probabilities is invariant by adding a constant c to all the $\omega_{t,k}(\mathbf{s}) \in \mathbb{R}$, then an identification constraint is needed; it is usual to set one of the $\omega_{t,k}(\mathbf{s})$ to zero, e.g. $\omega_{t,K}(\mathbf{s}) = 0$ for all $t \in \mathscr{T}$ and $\mathbf{s} \in \mathbb{R}^2$.

The $(K-1)$-dimensional vector $\omega_t(\mathbf{s}) = (\omega_{t,1}(\mathbf{s}), \ldots, \omega_{t,K-1}(\mathbf{s}))'$ is assumed to be a realization of a time structured Gaussian process

$$\omega_t(\mathbf{s}) = (\mathbf{I}_{K-1} \otimes \mathbf{X}_t(\mathbf{s}))\,\beta + \mathbf{A}\eta_t(\mathbf{s}) \tag{5}$$

where $\mathbf{X}_t(\mathbf{s})$ is a vector of p (possible) time-dependent covariates, β are $(K-1)p$ regressors, $\mathbf{A}$ is an $(K-1)\times(K-1)$ matrix and $\eta_t(\mathbf{s}) = (\eta_{t,1}(\mathbf{s}), \ldots, \eta_{t,(K-1)}(\mathbf{s}))'$, where $\eta_{\cdot,k} = \{\eta_{t,k}\}_{t\in\mathscr{T}}$ is a realization of a Gaussian processes with zero mean and isotropic and stationary correlation functions $C_k(|t-t'|;\psi_k)$. Moreover, $\eta_t(\mathbf{s})$ as a function of space are independent-in-time spatially correlated errors distributed

accordingly to a Gaussian process with zero mean and with spatial covariance function, given by a isotropic correlation function $C_k(|\mathbf{s}-\mathbf{s}'|;\theta_k)$, where θ_k describes the decay rate of the correlation as a function of the distance between locations. The dependence structure of the Gaussian process induces a dependence on the compositional vectors. Since marginally ω_t is normally distributed with mean $(\mathbf{I}_{K-1}\otimes\mathbf{X}_t(\mathbf{s}))\,\beta$ and covariance matrix $\Sigma=\mathbf{AA}$, then $\pi_t(\mathbf{s})=(\pi_{t,1}(\mathbf{s}),\dots\pi_{t,K-1}(\mathbf{s}))'$ is *LogitN* distributed:

$$\pi_t(\mathbf{s}) \sim LogitN((\mathbf{I}_{K-1}\otimes\mathbf{X}_t(\mathbf{s}))\,\beta,\Sigma).$$

The term $(\mathbf{I}_{K-1}\otimes\mathbf{X}_t(\mathbf{s}))\,\beta$ rules the mean of the processes, while $\mathbf{A}$ introduce dependence between the $\omega_{\cdot,k}(\mathbf{s})=\{\omega_{t,k}(\mathbf{s})\}_{t\in\mathscr{T}}$, i.e. if $\mathbf{A}$ is diagonal the $\omega_{\cdot,k}(\mathbf{s})$ are independent; finally, $\eta_t(\mathbf{s})$ models the structured temporal dependence. The covariance between $\omega_t(\mathbf{s})$ and $\omega_{t'}(\mathbf{s})$ is given by

$$\Sigma_{t,t'}=\mathbf{AC}_{\eta,|t-t'|}\mathbf{A}'$$

where $\mathbf{C}_{|t-t'|}$ is a $(K-1)\times(K-1)$ diagonal matrices with i-th diagonal elements equal to $C_i(|t-t'||;\psi_i)$.

The sum-to-a-constant constranint of compositional vectors introduces some difficulties in the modelling of the clustering probabilities, since

$$\mathrm{Cov}(\pi_{t,k}(\mathbf{s}),\pi_{t,1}(\mathbf{s})+\cdots+\pi_{t,k}(\mathbf{s})+\cdots+\pi_{t,K}(\mathbf{s}))=0$$

and, therefore,

$$-\mathrm{Var}(\pi_{t,k}(\mathbf{s}))=\sum_{\substack{j=1\\k\neq j}}^{K}\mathrm{Cov}(\pi_{t,k}(\mathbf{s}),\pi_{t,j}(\mathbf{s})).$$

The left hand side is negative except for the trivial case when $\pi_{t,k}(\mathbf{s})$ is a constant.

[1] and following works pointed out that a more consistent measure of dependence between compositional elements can be measure as

$$\tau_{ij,kl}(t,t')=\mathrm{Cov}\left(\log\frac{\pi_{t,i}(\mathbf{s})}{\pi_{t,k}(\mathbf{s})},\log\frac{\pi_{t',j}(\mathbf{s})}{\pi_{t',l}(\mathbf{s})}\right),\ i,j,k,l\in 1,\dots,K,$$

that are the covariance between all possible combinations of log-ratios; it has to be noticed that the elements of compositional vectors provide information about the relative value of the components (i.e. ratios) instead of their absolute values. Moreover there is a one-to-one correspondence between the composition data and the log-ratios then the covariance may be expressed in terms of log-ratios without modifying the statistical problem or losing information.

The measure of dependence $\tau_{ij,kl}(t,t')$ is related to the covariances of the Gaussian variables ω_t through the fact that

$$\log\frac{\pi_{ti}(\mathbf{s})}{\pi_{tk}(\mathbf{s})}=\log\frac{\exp(\omega_{ti}(\mathbf{s}))}{\exp(\omega_{tk}(\mathbf{s}))}=\omega_{ti}(\mathbf{s})-\omega_{tk}(\mathbf{s})\qquad\forall i,k\in\mathscr{K},$$

and then

$$\begin{aligned}\tau_{ij,kl}(t,t') = \mathrm{Cov}(\omega_{ti}(\mathbf{s}),\omega_{t'j}(\mathbf{s})) + \mathrm{Cov}(\omega_{tk}(\mathbf{s}),\omega_{t'\ell})(\mathbf{s}) \\ - \mathrm{Cov}(\omega_{ti}(\mathbf{s}),\omega_{t'\ell})(\mathbf{s}) - \mathrm{Cov}(\omega_{tk}(\mathbf{s}),\omega_{t'j}(\mathbf{s}))\end{aligned} \tag{6}$$

Equation (6) highlights an important interpretation problem: the structure of $\tau_{ij,kl}(t,t')$ changes if they involves the last components of the compositiona vector.

It is easy to see [1] that a *LogitN* process has independent components in term of log-ratios at time lag $|t-t'|$, i.e. $\tau_{ij,kl}(t,t') = 0$ for arbitrary i, j, k and l, only if the covariance matrix between $\omega_t(\mathbf{s})$ and $\omega_{t'}(\mathbf{s})$ can be written as

$$\Sigma_{t,t'} = \begin{pmatrix} a_1 + a_K & a_K & \dots & a_K \\ a_K & a_2 + a_K & \dots & a_K \\ \dots & \dots & \dots & \dots \\ a_K & a_K & \dots & a_{K-1} + a_K \end{pmatrix}.$$

It is then easy to see that independent ω's, i.e. diagonals $\Sigma_{t,t'}$, does not imply independence between the elements of π. In general, the dependence structured assumed for $\omega_{t,k}(\mathbf{s})$ is not automaticcaly transferred to the vector of probabilities $\pi_{t,k}(\mathbf{s})$.

2.1 A new parametrization

A new parametrization which allows an easier interpretation of the parameters is now proposed.

It is possible to model the Gaussian variable defined without imposing the identifiability constraint:

$$\gamma_t(\mathbf{s}) = (\mathbf{I}_K \otimes \mathbf{X}_t(\mathbf{s}))(\beta_1,\beta_2) + \mathbf{A}^*\eta_t(\mathbf{s}) \tag{7}$$

where $\gamma_t(\mathbf{s})$ is a K dimensional process, aand $\mathbf{A}^*$ is a $K \times K$ matrix, β_1 is a $p(K-1)$-dimensional vector, β_2 is a p dimensional vector and $\eta_{.k}(\mathbf{s}) \sim GP(0, C_k(|t-t'|;\psi_k))$, where $C_k(|t-t'|;\psi_k)$ is a covariance function that dependes on parameters vector ψ_k. At time t, the covariance matrix of $\gamma_t(\mathbf{s})$ is $\Sigma^* = \mathbf{A}^*(\mathbf{A}^*)'$. Moreover, $\eta_{.k}(\mathbf{s}) \sim GP(0, C_k(|\mathbf{s}-\mathbf{s}'|;\theta_k))$, where $C_k(|\mathbf{s}-\mathbf{s}'|;\theta_k)$ is a covariance function that dependes on parameters vector θ_k.

Similarly to (5), the compositional vector is defined by using the $\gamma_t(\mathbf{s})$

$$\pi^*_{t,k}(\mathbf{s}) = \frac{e^{\gamma_{t,k}(\mathbf{s})}}{\sum_{j=1}^K e^{\gamma_{t,j}(\mathbf{s})}} = \frac{e^{\gamma_{t,k}(\mathbf{s})-\gamma_{t,K}(\mathbf{s})}}{\sum_{j=1}^K e^{\gamma_{t,j}(\mathbf{s})-\gamma_{t,K}(\mathbf{s})}}, \quad k = 1,\dots,K.$$

In order to deal with the identifiability problem, we subtract the value $\gamma_{t,K}(\mathbf{s})$ to all the components of $\gamma_t(\mathbf{s})$, instead of setting to zero one of the them:

$$\pi^*_{t,k}(\mathbf{s}) = \frac{e^{\gamma_{t,k}(\mathbf{s})-\gamma_{t,K}(\mathbf{s})}}{\sum_{j=1}^{K} e^{\gamma_{t,j}(\mathbf{s})-\gamma_{t,K}(\mathbf{s})}}, \quad k = 1,\dots,K.$$

We have then created a link between the two parametrizations, and the parameters of (5) can be derived by the ones of (7):

$$\mathbf{A} = [\mathbf{A}^*]_{1:(K-1),1:K} - [\mathbf{A}^*]_{K,1:K},$$

where with notation $[\cdot]_{\cdot,\cdot}$ we select the sub-matrix with given indexes; simlarly,

$$\beta = \beta_1 - \mathbf{1}_{K-1} \otimes \beta_2,$$

and, finally,

$$[\Sigma^*]_{1:(K-1),1:(K-1)} + \mathbf{1}_{K-1}[\Sigma^*]_{K,K}\mathbf{1}'_{K-1} - [\Sigma^*]_{1:(K-1),K}\mathbf{1}'_{K-1} - \mathbf{1}_{K-1}[\Sigma^*]'_{1:(K-1),K},$$

where $\mathbf{1}_c$ is a c-dimensional vector of elements equal to one. Given this link, it follows that $\pi_{t,k}(\mathbf{s}) = \pi^*_{t,k}(\mathbf{s})$ for any $k = 1,\cdots,K$ and $t = 1,\cdots,T$.

The process $\gamma_t(\mathbf{s})$ provides more interpretable results: the set of log-ratio variances are easy to compute since

$$\tau_{ij,kl}(t,t') = \mathrm{Cov}\left(\gamma_{t,i} - \gamma_{t,k}, \gamma_{t',j} - \gamma_{t',l}\right);$$

now all the $\tau_{ij,kl}(t,t')$ have the same structure, solving the inconsistencies shown in equation (6).

3 Conclusion

We have introduced a new model to describe and predict spatio-temporal trajectories characterised by a clusters. This approach introduces a latent representation which allows to maintain the assumption on the dependence structure among the clustering probabilities. It represents a generalisation of the approach proposed in [4] in order to introduce the possibility of spatial dependence in the clusters.

Areas of application are hugely variable: environmental sciences, animal movements, epidemiology, economics, genomics, among many others.

Reconstruction of sparsely sampled functional time series using frequency domain functional principal components

Ricostruzione di serie temporali funzionali scarsamente campionate utilizzando componenti principali funzionali nel dominio delle frequenze

Amira Elayouty, Marian Scott and Claire Miller

Abstract In this paper, we present a useful application of the recently developed time-varying Functional Principal Components (FPCs) to the analysis of non-stationary Functional Time Series (FTS) that commonly occurs in high-frequency environmental data. The time-varying FPCs (Elayouty, 2017) adapt to the changes in the auto-covariance structure and vary smoothly over frequency and time by taking into account (i) the temporal dependence between the functional observations and (ii) the changes in the covariance/variability structure over time. This makes them an attractive option for a number of analyses including the assessment of stationarity, the clustering of functional curves as well as the reconstruction of sparsely sampled functional data in a dynamic FTS context. The performance of the time-varying FPCs in reconstructing sparsely sampled FTS has been assessed here by a simulation study.

Abstract *In questo paper, presentiamo un'applicazione delle Componenti Principali Funzionali (CPF) tempo-varianti, di recente sviluppo, all'analisi delle serie temporali funzionali non stazionarie che tipicamente si osservano su dati ambientali raccolti ad alta frequenza. Le CPF tempo-varianti si adattano a cambiamenti nella struttura dell'auto-covarianza e variano in modo smooth nel tempo e nello spettro delle frequenze prendendo in considerazione (i) la dipendenza temporale tra le osservazioni funzionali e (ii) le variazioni nel tempo nella struttura di varianza-covarianza. Questo rende le CPF un'opzione interessante per una serie di analisi*

1 Introduction

Current sensor technology enables environmental monitoring programs to record measurements at high-temporal resolutions over long time periods, for processes which are in reality continuous in time. Examples include water quality measurements from automatic monitoring buoys/sensors recorded every 2 minutes over time or temperature recordings from thermistor chains at different depths in a lake over time. Unfortunately, statistical modelling and analysis as well as feature extraction from these environmental High-Frequency Data (HFD) are challenging due to the persistent and dynamic dependence structure over the different timescales (Elayouty et al. 2016) that can even become more problematic with the presence of missing measurements. Functional Time Series (FTS) analysis and its recent developments (Hormann and Kokoszka, 2012; Hormann et al. 2015; Elayouty, 2017) provides an appropriate framework for the analysis and feature extraction from these HFD, taking into consideration these challenges.

Frequency domain Functional Principal Components (FPCs) that vary smoothly over time, taking into account both the temporal correlation and the non-stationarity in the series, have been recently developed by Elayouty (2017). These time-varying FPCs proved useful to the exploration and analysis of dynamic FTS that commonly manifest in environmental data. Testing for second-order stationarity and clustering of individual curves in a FTS are two typical applications of these timevarying FPCs (Elayouty, 2017). This paper presents an application of these FPCs to the reconstruction of sparsely sampled dynamic FTS, assessed through their performance in a simulation study.

2 Frequency domain time-varying FPCs

In FTS, data are viewed as realizations of a functional stochastic process $\{X_k(t) : k \in \mathbb{Z}, t \in \mathscr{T}\}$, with k denoting the discrete time parameter e.g. day and t being the continuous time parameter defined on $\mathscr{T}$ e.g. intra-day. The time-varying FPCs evaluate the Spectral Density (SD) of the FTS process at each time point k. An eigen-decomposition of the SD is then performed at each time point k to extract

the frequency domain eigenfunctions, under the assumption that the process varies smoothly over time. The time-varying FPCs accommodate the varying autocorrelation structure in a FTS through the decomposition of the SD which, unlike the lag-0 covariance, contains information on the whole family of lag-h covariances (Hormann et al., 2015).

As only a limited number of replicates are available at each time point k, the local lag-h covariances and spectral densities are estimated by smoothing the sample lag-h covariances over time using a weight kernel $w_s(.)$ with smoothing parameter s,

$$\hat{V}_{k,h} = \frac{1}{\sum_{k' \in \mathbb{Z}} w_s(|k-k'|)} \sum_{k \in \mathbb{Z}} w_s(|k-k'|) X_{k'} \otimes X_{k'+h}. \tag{1}$$

where $w_s(.)$ is a monotonically decreasing weight function of the distance $|k-k'|$ regardless of the lag h, ensuring that the highest weights are assigned to the pairs $(X_k, X_{k'})$ near the target point k. The neighbourhood contributing to the covariance estimation is determined by the choice of the kernel and smoothing parameter.

After estimating $\hat{V}_{k,h}$, the local SD is estimated at each time point k by:

$$\hat{F}_{k,\theta} = \frac{1}{2\pi} \sum_{h \in \mathbb{Z}} \hat{V}_{k,h} \exp(-\mathrm{i}h\theta), \quad \theta \in [-\pi, \pi], \tag{2}$$

and the local eigenvalues $\hat{\lambda}_{k,m}(\theta)$ and eigenvectors $\hat{\varphi}_{k,m}(\theta)$ of $\hat{F}_{k,\theta}$ are computed. The local frequency domain FPCs $\{\hat{\phi}_{kml}(t) : l \in \mathbb{Z}\}$ are then obtained via the inverse Fourier transform of $\hat{\varphi}_{k,m}(\theta)$.

3 Reconstruction of sparsely sampled FTS

Although sensor data often come in large volumes they may involve periods of missing data as a result of temporary breakdown in equipment or in transmission of data. Imputing or reconstructing these missing periods with a better accuracy is of interest to develop a complete picture of the phenomenon. Obtaining the frequency domain functional PCs at each time point k requires a full data set. For this reason a naive simple imputation method, using the average for instance, can be used to provide initial values for the missing periods. After that the time-varying FPCs $\{\hat{\phi}_{kml}(t) : l \in \mathbb{Z}\}$ are obtained and used subsequently to filter the original FTS across a number of lags and leads l to obtain the m^{th} local dynamic FPC scores at k by: $\hat{Y}_{m,k}^{(k)} = \sum_{l=-L}^{L} \int_{t \in \mathscr{T}} X_{k-l}(t) \hat{\phi}_{kml}(t) dt$. All (complete or sparsely sampled) curves can thus be approximately reconstructed based on these scores, using q-term (smooth) time-varying FPCs, $q < \infty$, as follows:

$$\hat{X}_k(t) \approx \sum_{m=1}^{q} \sum_{l=-L}^{L} \hat{Y}_{m,k+l}^{(k)} \hat{\phi}_{kml}(t), \quad \forall k. \tag{3}$$

This procedure can then be re-iterated to achieve better results.

4 Results and Discussion

An extensive simulation study was conducted to assess the performance of the proposed time-varying FPCs versus the stationary dynamic FPCs (Hormann et al, 2015) in reconstructing sparsely sampled FTS, under a variety of non-stationary data-generating processes. For each of the scenarios 200 FTS were simulated and for each FTS a random collection of curves constituting $\nu \in (10,35)\%$ of the total number of curves in the series are made incomplete. For each randomly chosen incomplete curve, a block of $\tau \in (35,60,100)\%$ of the discrete data, representing the realisations of the curve at a set of finite time points, are made missing. Naive imputations of the missing values are used as initial values before applying the FPCA.

The results of the simulation study indicated that, in basically all missing data patterns, the missing data were better recovered using the time-varying FPCs (see Fig 1). The performance of FPCs has been measured in terms of the normalised mean squared errors (NMSE) between the initially simulated complete curves and the reconstructed ones using the stationary dynamic FPCs and the time-varying FPCs with different values of the smoothing parameter allowing for different levels of smoothness. As the smoothing parameter decreases the NMSE decreases, reflecting the necessity of using local FPCs in case of non-stationary FTS. It can also be noted that the variation in NMSE between the 200 replications is systematically smaller for the time-varying FPCs.

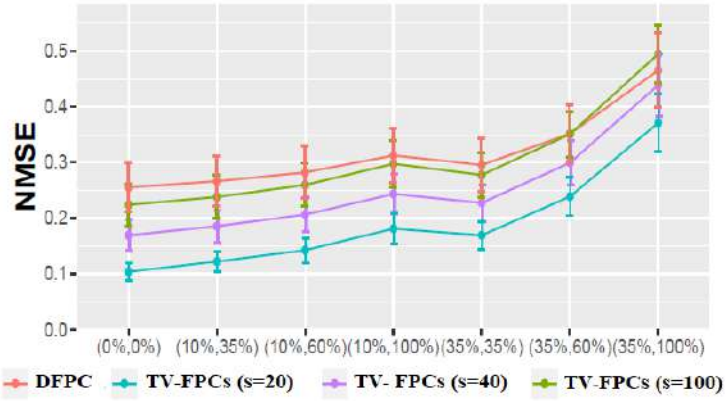

Fig. 1 Average NMSE between the originally simulated curves and their recovered versions using the first dynamic (red) and the first smooth dynamic FPCs with a smoothing parameter $s = 20$ (turquoise), 40 (purple), 100 (olive) based on the simulation results under the different levels of sparsity specified by $(\nu,\tau)\%$. The vertical bars represent one standard deviation from the mean NMSE.

5 Conclusion

Time-varying FPCA proved useful for reconstructing sparsely sampled curves in dynamic FTS with an increased accuracy compared to the dynamic FPCA by Hormann et al. (2015). This accuracy can even be improved through iteratively repeating the same procedure.

Methods for High Dimensional Compositional Data Analysis

Algorithms for compositional tensors of third-order

Algoritmi per tensori composizionali di terzo ordine

Violetta Simonacci

Abstract The PARAFAC-ALS procedure for estimating CP parameters on tridimensional tensors is sensitive to data collinearity. This inefficiency is especially problematic if collinearity is paired with other issues such as data of large dimensions and difficulties in establishing correct model rank. When dealing with compositional data, i.e. positive values with a covariance bias, multicollinearity is inherent by definition, and it is preserved also if the data is transformed in log-ratios by means of the *clr* function. For this reason, alternative estimating procedures may be considered, such as INT and INT-2. These dual-step methods use the properties of the SWATLD and ATLD algorithms during initialization to overcome ALS inefficiency while still providing least squares results. Their comparative performance is tested in an extensive simulation study on collinear data.

Abstract *La procedura PARAFAC-ALS per la stima dei parametri CP su tensori tridimensionali è sensibile alla collinearità dei dati. Questa inefficienza è particolarmente problematica se la collinearità è accoppiata ad altre difficoltà come dati di grandi dimensioni e difficoltà nello stabilire il corretto rango del modello. Quando si trattano dati composizionali, valori positivi con covarianza vincolata, la multicollinearità è data per definizione e viene preservata anche se i dati sono trasformati in logaritmi dei rapporti attraverso la trasformazione clr. Per questo motivo, è possibile prendere in considerazione procedure di stima alternative, come INT e INT-2. Questi metodi a doppia fase utilizzano rispettivamente le proprietà delle procedure SWATLD e ATLD durante l'inizializzazione per sopperire alle inefficienze del PARAFAC-ALS pur fornendo risultati in termini di minimi quadrati. Le loro prestazioni comparative sono testate in un ampio studio di simulazione su dati collineari.*

1 Introduction

Third order tensors of compositional data are positive data charachterized by spurious correlations and organized along three indexes (individuals, variables, occasions). These tensors, especially when large, can be quite difficult to model. Compositional data are generally treated as log-ratio coordinates in order to get to rid of their biased structure [2]. The preferred log-ratio transformation for both two and three-way exploratory analysis [1, 9, 6] is the centered log-ratio transformation (*clr*) which preserves full multicollinearity of the data, i.e. one redundant dimension in the variable space.

Multicollinearity does not present a major issue when bilinear SVD-based methods are applied, however it can become problematic for the estimation of the CANDECOMP/PARAFAC (CP) model [3, 7]. This decomposition is an adaptation of bilinear SVD to higher orders which guarantees a unique solution under mild condition by imposing the restriction that the same latent structure is found throughout samples. For this reason, it represents the preferred modeling tool for data with a true trilinear structure. In this sense it can be differentiated from the Tucker3 procedure [12], an unrestricted high order version of bilinear models which does not provide unique outputs, thus, can prove difficult to interpret.

CP uniqueness comes at the price of estimating issues, which become more likely in case of large data, such as slow convergence and degeneracy. In particular both permanent or temporary degenerate solutions may occur. This latter case is detected when an iterative estimating algorithm encounters bottlenecks or swamps: it starts converging towards a degenerate solution, slows down excessively but eventually emerges from the swamp and finds the real optimal point. Degenerate solutions are generally recognizable by the fact that two factors appear highly correlated but with opposite signs. Abnormal convergence can be caused by bad-initialization, wrong rank selection (the dimensionality of the model does not match the real underlying one), data and factor collinearity.

Many algorithms have been proposed in the literature to fit the CP model, all with different performances with respect to these difficulties. In general, unless specific data conditions require it, the preferred option is PARAFAC-ALS (ALS), the procedure originally proposed in [7]. This is because of a key advantage: its Loss of Fit (LoF) function monotonically decreases, thus convergence is stable and results are found in the least squares sense.

Nonetheless, this algorithm is quite slow at converging on large data sets and it is sensitive to bad initial values, wrong rank and data collinearity. This last weakness, pointed out in [8], is particularly relevant for compositions because it makes the algorithm underperform on *clr*-coordinates especially for large tensors.

In particular it was observed in [5] that multicollinearity appears to slow down the algorithm more than usual, and when it is paired with over-specification it may also make it quite difficult for the procedure to find the correct results. As a solution it was proposed to use an alternative estimation process, an integrated procedure called INT, which adds a Self-Weighted Alternating Tri-Linear Decomposition (SWATLD) initialization step to ALS in order to overcome its deficiencies. This

is because SWATLD, proposed by [4], is somewhat complementary to ALS in the sense that it is robust in presence of wrong model specifications, collinearity and it is fast at converging. However, it is less stable and precise, so it constitute only an ideal initialization step.

INT was introduced for compositions but it was thoroughly tested only on non-collinear data [11].

Starting from INT another procedure was also implemented later on in [10], called INT-2, where the initialization step is no longer carried out by SWATLD but by means of the Alternating TriLinear Decomposition (ATLD) proposed by [13]. This second version was not developed for dealing with collinearity but for modeling large data-sets, as ATLD is a more efficient version of SWATLD albeit less precise. It was never tested for compositions, however it has good potential to work well because it is fast and robust to collinearity.

In this perspective the purpose of this work is to find the best algorithmic alternative for large tensors of *clr*-transformed data between INT, INT-2 and ALS by evaluating which one is preferable in terms of accuracy and efficiency. Multicollinearity, especially when associated with large dimensions and wrong factorization can severely impair estimation of the CP model and recognizing the best way to address this issue can be of great interest, especially with the increasing dimensionality of data sets in all fields of research.

2 Methods

2.1 Third-order tensors of compositions

A third order tensor $\mathscr{T} \in \mathbb{R}^{n\times m\times p}$ with generic element t_{ijk} is a data structure arranged along three dimensions or modes identified as first-mode with index $i = 1,\ldots,n$, second-mode with index $j = 1,\ldots,m$ and third mode with index $k = 1,\ldots,p$. Usually it is shaped like a cube containing the measurement of n individuals over m variables at p occasions along the vertical, horizontal and depth dimensions respectively.

If one of the three indices is fixed while the other ones are free to vary, $\mathscr{T}$ can be partitioned in three different sets of second-order tensors, referred to as slabs: frontal slabs $\mathbf{T}_{(k)}^{(n\times m)}$ with $k = 1,\ldots,p$, vertical slabs $\mathbf{T}_{(j)}^{(n\times p)}$ with $j = 1,\ldots,m$ and horizontal slabs $\mathbf{T}_{(i)}^{(p\times m)}$ with $i = 1,\ldots,n$. Slabs can be juxtaposed so that $\mathscr{T}$ is unfolded along only two dimensions and treated as a matrix. Specifically we have three unfolded tensors which are usually considered: $\mathbf{T}_{A}^{(n\times mp)}$, $\mathbf{T}_{B}^{(m\times np)}$ and $\mathbf{T}_{C}^{(p\times mn)}$.

If two of the indexes are fixed, the third order tensor can also be subdivided in rank-one tensors, known as fibers. Specifically there are $n\times p$ horizontal fibers or rows $\mathbf{t}_{ik}(1\times m)$, $m\times p$ vertical fibers or columns $\mathbf{t}_{jk}(1\times n)$ and $n\times m$ "depth" fibers or tubes $\mathbf{t}_{ij}(1\times p)$.

A third order tensor presents a compositional structure if its generic row $\mathbf{t}_{ik} = [t_{i1k},\ldots,t_{ijk},\ldots,t_{imk}]$ consists of positive values characterized by a covariance bias: $cov(t_{i1k},t_{i2k}) + cov(t_{i1k},t_{i3k}) + \ldots + cov(t_{i1k},t_{imk}) = -var(t_{i1k})$. The m elements of a compositional row are denoted as parts because they describe the portions of a whole and do not vary independently from each other, i.e. $\sum_{j=1}^{m} t_{ijk} = \kappa$ where κ is a constant representing a generic total.

The variability of such row-vectors can be fully explained only in relative terms, by referring to ratios amongst them, thus the value of κ is irrelevant and can be scaled to one. When compositions are analyzed in absolute scores frontal slices are perfectly collinear and their covariance matrix is singular.

The compositional problem can also be explained form a geometric stand point: the biased structure translates into one dimension of the row-vector being redundant, thus the sample space of the generic row composition $\mathbf{t}_{ik}$ is not $\mathbb{R}_{+}^{m}$ but rather the unit-simplex $\mathbb{S}^{m-1}$. This vector space is characterized by its own geometric rules called Aitchison geometry. In order to project compositions onto real space and apply standard multilinear tools, they can be transformed in the log-ratios amongst vector parts.

In exploratory analysis the most used transformation is the centered log-ratio (*clr*). The *clr* function provides a correspondence between $\mathbb{S}^{m-1}$ and $\mathbb{R}^m$ and considers the logarithms of the ratios between each part and the geometric mean of the full composition. Each frontal slab $\mathbf{T}_{(k)}^{(n\times m)}$ is transformed in $\mathbf{Z}_{(k)}^{(n\times m)}$ with generic element $z_{ijk} = t_{ijk}/g(\mathbf{t}_{ik})$, with $g(\mathbf{t}_{ik}) = \prod_{j=1}^{m} t_{ijk}$.

This transformation is symmetric and isometric, however, it maintains a redundant dimension, thus the condition of perfect multicollinearity of frontal slabs is not eliminated.

2.2 Compositional CP algorithms

A third-order tensor of *clr*-coordinates $\mathscr{Z} \in \mathbb{R}^{n\times m\times p}$ can be decomposed by means of the CP model, which is based on the concept of polyadic decomposition.

A tensor is in polyadic form when it is represented as the linear combination of $1,\ldots,f,\ldots$F rank-one tensors. For a tridimensional tensor of *clr*-coordinates we have:

$$\mathscr{Z}^{n,m,p} = \sum_{f=1}^{F} \mathscr{D}_f = \sum_{f=1}^{F} \mathbf{a}_f \circ \mathbf{b}_f \circ \mathbf{c}_f \quad \text{with} \sum_{j=1}^{m} b_{jf} = 0 \quad \forall \quad 1,\ldots,f,\ldots\text{F} \tag{1}$$

The generic rank-one tensor $\mathscr{D}_f$ is the result of a triad, namely the outer product of the corresponding generic vectors $\mathbf{a}_f \in \mathbb{R}^n$, $\mathbf{b}_f \in \mathbb{R}^m$ and $\mathbf{c}_f \in \mathbb{R}^p$, which indicate the factors of the first, second and third mode respectively. Each factor in every mode is related to only one factor in the other modes, i.e. it belongs to only one triad. These factors can be arranged as columns of loading matrices $\mathbf{A} = [\mathbf{a}_1,\ldots,\mathbf{a}_f,\ldots,\mathbf{a}_F] \in \mathbb{R}^{n\times F}$, $\mathbf{B} = [\mathbf{b}_1,\ldots,\mathbf{b}_f,\ldots,\mathbf{b}_F] \in \mathbb{R}^{m\times F}$ and $\mathbf{C} = [\mathbf{c}_1,\ldots,\mathbf{c}_f,\ldots,\mathbf{c}_F] \in \mathbb{R}^{p\times F}$.

If the total number of factors F corresponds to the tensorial rank of $\mathscr{Z}$, that it is the minimal number of real underlying constructs which fully describe the information in the array, this decomposition is known as rank decomposition.

The CP model aims to model a tensor with noise contamination $\mathscr{Z} = \hat{\mathscr{Z}} + \mathscr{E}$, where $\mathscr{E}$ is the tensor of errors, by providing its rank decomposition without modeling excessive noise. The CP model is generally written using a frontal slab notation in the following manner:

$$\mathbf{Z}_{(k)} = \hat{\mathbf{Z}}_{(k)} + \mathbf{E}_{(k)} = \mathbf{A}\mathbf{D}^{(k)}\mathbf{B}^t + \mathbf{E}_{(k)} \quad k = 1, \ldots, p \tag{2}$$

Here the diagonal matrices $\mathbf{D}^{(i)}$, $\mathbf{D}^{(j)}$ and $\mathbf{D}^{(k)}$ contain the ith, jth and kth rows of the first-, second- and third-mode factor matrices respectively while $\mathbf{E}_{(i)}$, $\mathbf{E}_{(j)}$ and $\mathbf{E}_{(k)}$ are the horizontal, lateral and frontal slices of $\mathscr{E}$.

One of the problems connected with this procedure, however, is that the rank of a tensor is hard to establish in advance, thus, when estimating parameters, F is often chosen so that $F > R$ and a rank decomposition is not reached. This case is called over-factoring and results in the CP model being over-specified, which may create problems in the estimation process, leading to degenerate solutions.

The first and most used algorithm for fitting the CP model is ALS. which carries out least-squares optimization steps based on the following loss function:

$$\min_{\mathbf{A},\mathbf{B},\mathbf{C}} = \sum_{k=1}^{p} \|\mathbf{Z}_{(k)} - \hat{\mathbf{Z}}_{(k)}\|^2 = \sum_{k=1}^{p} \|\mathbf{Z}_{(k)} - \mathbf{A}\mathbf{D}^{(j)}\mathbf{B}^t\|^2 \tag{3}$$

The symbol $\|\cdot\|$ is used to represent the Frobenius norm.

Since this algorithm is sensitive to data collinearity, intrinsic to *clr*-coordinates, and it is quite slow, thus hardly preferable for large data-sets, other procedures are considered for comparison: i) INT developed to address collinearity issues but not fully tested in this framework and ii) INT-2 developed for efficiency but could also perform well on compositions.

INT is articulated in two optimization steps: an initialization phase in which SWATLD is used to overcome collinearity and over-factoring issues, and a second step in which ALS is used to refine the solution to obtain least-squares results.

SWATLD properties which make it robust to these difficulties are directly determined by the fact that instead of one, it uses three loss function and that the focus is on extracting the trilinear information.

For a full presentation of INT and of its estimation steps refer to [11].

In the other procedure considered, INT-2 [10], ATLD is used rather than SWATLD to initialize estimation, for the rest it is analogous to INT. ATLD has similar properties to SWATLD when it comes to overcoming deficiencies and it is also based on three loss functions. ATLD is however more efficient than SWATLD but way less stable in its final results.

3 Experimental design and results

The aim of this study is to understand which algorithm is best suitable for large tensors of compositional data. For this purpose the performance of the status quo algorithm, standard ALS, is compared with the two alternative procedures, INT and INT-2, developed for multicollinear and for large tensors respectively. A Monte Carlo design is thus implemented in which the algorithms are tested on large tensors of artificial data sets with three dimensionality: $n = m = p = 50$, $n = m = p = 100$, $n = m = p = 150$ and varied degrees of factor congruence and noise contamination. Performance is tested in terms of efficiency (CPU time, number of iterations employed, number of bottlenecks encountered) and of accuracy (congruence with real solution and MSE). Both the rank decomposition and the over-specification case are considered

Preliminary results show that ALS clearly undeperformes with respect to both INT and INT-2. In particular this latter procedure appears to be the best performing option for efficiency and accuracy in over-factoring.

High-dimensional regression with compositional covariates: a robust perspective

Metodi di regressione per high-dimensional data con covariate composizionali: una prospettiva robusta

Gianna Serafina Monti and Peter Filzmoser

Abstract In this contribution we propose a robust approach to high-dimensional regression with compositional covariates. The proposed procedure is based on a class of shrinkage estimators for least trimmed squares regression in combination with elastic-net penalty. We illustrate the effectiveness of our methods by an application to a human microbiome data set with the aim to robustly predict the body mass index as a function of the gut microbiome composition.

Abstract *In questo contributo presentiamo un approccio robusto ai metodi di regressione penalizzata per la selezione automatica delle variabili nel caso in cui la matrice del disegno abbia una natura composizionale. La procedura proposta é basata su una regressione di tipo LTS (least trimmed squares) in combinazione con una penalizzazione di tipo elastic-net. Al fine di illustrare l'efficacia del metodo proposto, viene presentata un'applicazione all'analisi del microbiota intestinale umano, strettamente connesso alle abitudini alimentari e agli stili di vita, al fine di stimare in modo robusto l'indice di massa corporea .*

linear regression with compositional covariates cannot be applied; but even without the constraint, standard regression models on the original compositions are not meaningful.

In the seminal work of Aitchson and Bacon-Shone (1984), a regression model for compositional data was proposed, known as log-contrast model. In this model the response variable is a linear combination of log-ratios of the original compositions. Let y be a response vector of dimension $n \times 1$ and $\mathbf{X}_{n\times p}$ a design matrix of compositional covariates, w.l.o.g. expressed with constant sum 1, thus each row lies in the unit simplex $\mathcal{S}^p = \{x_{ij} : x_{ij} > 0 \text{ and } \sum_{j=1}^{p} x_{ij} = 1\}$. The linear log-contrast model has the following structure

$$y = \mathbf{Z}^p \beta_{\setminus p} + \varepsilon, \tag{1}$$

where $\mathbf{Z}^p = \{\log(x_{ij}/x_{ip})\}$, $j = 1, \ldots, p-1$, is the additive log ratio transform matrix of dimension $n \times (p-1)$, with the pth component as reference, and $\beta_{\setminus p} = (\beta_1, \ldots, \beta_{p-1})$ is the regression coefficient vector, and ε is the error component, usually assumed normally distributed around zero, with constant variance σ^2. The model (1) can be expressed in a symmetric form (Lin et al., 2014) introducing a constraint on the coefficient vector:

$$y = \mathbf{Z}\beta + \varepsilon, \quad \sum_{j=1}^{p} \beta_j = 0, \tag{2}$$

where $\mathbf{Z} = \{\log(x_{ij})\} \in \mathbb{R}^{n\times p}$, and $\beta = (\beta_1, \ldots, \beta_p)$.

Considering a high-dimensional setting, Lin et al. (2014) proposed a variable selection procedure and estimation for model (2):

$$\hat{\beta} = \arg\min_{\beta} \left(\frac{1}{2n} \|y - \mathbf{Z}\beta\|_2^2 + \lambda \|\beta\|_1 \right), \quad \text{subject to } \sum_{j=1}^{p} \beta_j = 0, \tag{3}$$

where $\lambda > 0$, is the regularization parameter and $\| \|_2$ and $\| \|_1$ indicate the ℓ_2 and ℓ_1 norm, respectively.

Altenbuchinger et al. (2017) combined the variable selection problem and estimation for model (2) with the elastic-net regularization (Friedman et al., 2010):

$$\hat{\beta}_{zeroSum} = \arg\min_{\beta} \left(\frac{1}{2n} \|y - \mathbf{Z}\beta\|_2^2 + \lambda \left(\frac{1-\alpha}{2} \|\beta\|_2^2 + \alpha \|\beta\|_1 \right) \right), \quad \text{subject to } \sum_{j=1}^{p} \beta_j = 0, \tag{4}$$

where α is a tuning parameter for the compromise between the ℓ_2 and ℓ_1 penalty. Model (4) is known as *zeroSum elastic-net regression*, to emphasize the constraint of the regression coefficients in conjunction with the elastic-net regularization.

2 Robust and sparse regression models for compositional data

With the aim to explore sparse relationships between a response variable and a set of covariates in a high-dimensional setting, Alfons et al. (2013) proposed a robust estimator by adding an ℓ_1 penalty on the coefficient estimates to the least trimmed squares (LTS) estimator (Huber and Ronchetti, 2009), leading to the sparse LTS estimator:

$$\hat{\beta}_{sparseLTS} = \arg\min_{\beta} \left\{ \sum_{i=1}^{h} r^2_{(i)}(\beta) + h\lambda \|\beta\|_1 \right\}, \tag{5}$$

where $r^2_{(i)}$ are the order statistics of the squared residuals, and $\lfloor (n+p+1)/2 \rfloor \leq h \leq n$, and $\lfloor . \rfloor$ means rounding down to the nearest integer. Sparse LTS regression is equivalent to detecting the subset of h observations whose least squares fit produces the smallest (penalized) sum of squared residuals. The authors demonstrated the robustness of the estimator (5) to multiple regression outliers, as well as to leverage points.

Kurnaz et al. (2018) extended the work of Alfons et al. (2013), they combined the sparsity of the elastic-net (EN) procedure with the robustness of LTS regression. They proposed the trimmed (EN)LTS estimator, based on the idea of repeatedly applying the non-robust classical estimators to data subsets only. The (EN)LTS estimator is defined by:

$$\hat{\beta}_{(\mathrm{EN})LTS} = \arg\min_{\beta} \arg\min_{H \subseteq \{1,2,\ldots,n\}: |H|=h} \left(\frac{1}{2h} \|y - \mathbf{X}\beta\|_2^2 + \lambda \left(\frac{1-\alpha}{2} \|\beta\|_2^2 + \alpha \|\beta\|_1 \right) \right), \tag{6}$$

A constrained penalized LTS regression estimator for (EN)-type penalized regression is proposed here as follows,

$$\hat{\beta}_{RobzeroSum} = \arg\min_{\beta} \arg\min_{H \subseteq \{1,2,\ldots,n\}: |H|=h} \left(\frac{1}{2h} \|y - \mathbf{Z}\beta\|_2^2 + \lambda \left(\frac{1-\alpha}{2} \|\beta\|_2^2 + \alpha \|\beta\|_1 \right) \right)$$
$$\text{subject to } \sum_{j=1}^{p} \beta_j = 0\,, \tag{7}$$

which conveys the zero-sum constraint typical of compositional covariates. We refer to model (7) as *RobzeroSum elastic-net regression*, to combine the constraint of the regression coefficients with the elastic-net regularization in a robust way. In the following we will only consider the special case with $\alpha = 1$. An extensive simulation study, not reported here for space constraints, demonstrates its robustness in presence of outliers in the data.

2.1 Parameter selection

We suggest to perform a (10 fold) cross-validation procedure, over an appropriate grid of values for λ, to determine the optimal value of the elastic-net regularization in (7). Thus the regression coefficient estimates are calculated in correspondence of λ which minimizes the CV-error.

3 An application to human gut microbiome

The study of human microbiome, i.e. the collection of all microorganisms found in the human body, including bacteria, viruses, and fungi, is crucial in the understanding of the roles that symbionts play on human health, and their impacts on a number of diseases. We applied the proposed model to a cross-sectional study of the association between diet and gut microbiome composition (Wu et al., 2011). In this study, fecal samples from 98 healthy individuals were collected and the DNA samples were analyzed by the 454/Roche pyrosequencing of 16S rRNA gene segments of the V1-V2 region. The resulting microbiome database, produced by high-throughput sequencing of 16S rRNA, is a matrix of counts of clustered sequences, known as operational taxonomic units (OTUs), that depict bacteria types. Only the relative abundances have a meaning, as the number of sequencing reads varied a lot across samples (Weiss et al., 2017), thus microbiome data have essentially a compositional nature. Due to the high proportion of zero counts in the OTU table, we considered, among the 78 taxa at genus level, only those with an abundance $\geq 0.2\%$ in at least one sample and those which appeared in more than 10% of the samples, resulting in a matrix of dimension $n \times p = 98 \times 37$. Zero counts were replaced by the minimum non-negative observed count. We fitted RobzeroSum elastic-net regression to predict BMI response as a function of a subset of the most important taxa.

To measure the prediction accuracy of the RobzeroSum model and the zero-Sum model, we calculated the trimmed-squared prediction error $||y - \mathbf{Z}\hat{\beta}(\hat{\lambda}_{CV})||_2^2/h$ (trimming level equal to 0.1). The RobzeroSum model achieved a value of 6.91 and performs clearly better compared to the zeroSum model with a value of 11.37. This can also be seen from the two scatter plots of the measured versus predicted BMI values reported in Figure 1.

To determine the statistical strength of the selected taxa, we performed a classical nonparametric bootstrap of the units (Hastie et al., 2015). Figure 2 (left) reports the estimated regression coefficients, $\hat{\beta}_j(\hat{\lambda}_{CV})$, for the selected taxa. Thick lines and thin lines represent $\hat{\beta}_j(\hat{\lambda}_{CV}) \pm SE$, and $\hat{\beta}_j(\hat{\lambda}_{CV}) \pm 2SE$ respectively, where the SE is estimated through the trimmed standard deviation of the 1000 bootstrap realizations. Figure 2 (right) reports the proportion of times each coefficient is zero in the 1000 bootstrap realizations. We found that Clostridium is significantly negatively correlated with BMI, as obtained by Lin et al. (2014). Furthermore the major part of the selected taxa belongs to the Firmicutes phylum, confirming the strictly dependence of the BMI with this phylum.

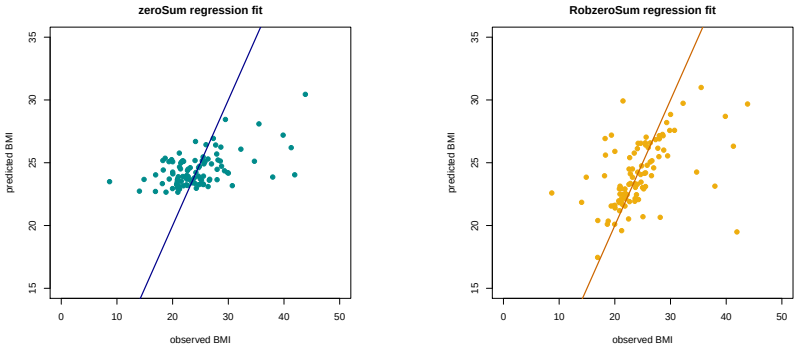

Fig. 1 Left: Scatter plot of the fitted values for the BMI response variable according to the zeroSum regression model estimates. Right: Scatter plot of the fitted values for the BMI response variable according to the RobzeroSum regression model estimates.

Three-way compositional analysis of energy intensity in manufacturing

Analisi composizionale a tre vie dell'intensità energetica nel settore manifatturiero

Valentin Todorov and Violetta Simonacci

Abstract Both the scientific and political communities agree that significant reductions in CO2 emissions are necessary to limit the magnitude and extent of climate change and of course the energy efficiency is one of the most interesting issues analyzed by economists and policy makers within this debate. Different measures of energy efficiency in manufacturing can be defined but broadly this is the ratio of the production output to the energy input, usually disaggregated by industry. We create a global data set of energy intensity in manufacturing and analyze its structure by country, time and industry applying parallel factor analysis (CP). Since we are interested in the structure of the energy intensity, the absolute values are no more relevant for the analysis and the nature of this data set is compositional which requires specific adaptation of the methodology and suitable software.

Abstract *La comunità scientifica e il mondo politico concordano sul fatto che la riduzione dell'emissione di CO2 è necessaria per limitare il cambiamento climatico, quindi un efficiente uso dell'energia è tra gli aspetti più trattati dagli economisti e dai politici nell'affrontare tale tema. Nella produzione manifatturiera sono definite diverse misure di efficienza energetica, ma in generale il rapporto tra consumo energetico e output, disaggregato per settore, è tra i più usati. Considerando i paesi, gli anni e i settori merceologici, un dataset sull'intensità energetica nel settore manifatturiero è stato costruito e studiato con l'analisi dei fattori paralleli (CP). Tuttavia, l'analisi dell'intensità energetica in valore assoluto non è l'aspetto più rile-*

vante da studiare, inoltre, la natura di tali dati è composizionale e quindi richiede un'adeguata metodologia e software.

Key words: energy intensity, manufacturing value added, PARAFAC, compositional data

1 Introduction

Energy efficiency is one of the key emissions reduction policy tools and is becoming a top priority in energy policies. If energy is used more efficiently, this can contribute to steadier and potentially higher economic growth since the amount of energy required per unit of output can be reduced. This reduction will subsequently lead to a reduced product price. Energy intensity is measured by the amount of energy used to produce one unit of economic output. It is the inverse of energy efficiency: less energy intensity means more energy efficiency. To calculate the energy intensity the amount of energy used (in physical terms, kilotons of oil equivalent, or *ktoe*) is divided by a measure of the produced output in monetary terms. Energy intensity in manufacturing is measured by dividing the energy consumed by the manufacturing value added. Many studies of energy efficiency are related to the analysis in one or few countries and do not consider the issue globally. Kepplinger et al [7] analyzes the energy efficiency in manufacturing industry using mixed-effect models, but is limited to the aggregated level. Cantore [2] studies the energy efficiency in developing countries for the manufacturing sector using the Fisher Ideal Index but covers only around 20 countries.
Data on manufacturing value added at annual frequency are available from the UNIDO INDSTAT database and data on energy consumption can be obtained from the International Energy Agency (IEA). Using the data from these data sources in the present paper we will analyze the structure of energy intensity of the manufacturing industry across countries, time and industries. The outline of the paper is as follows. The next Section 2 briefly introduces the concept of compositional data and its relevance for parallel factor analysis (CP). Section 3 describes the data and presents the results of the analysis. The last section concludes and outlines topics for further research.

2 CP and compositional data

Compositional data as defined by Aitchison [1] are strictly positive multivariate observations that carry only relative information, i.e. the only relevant information is contained in ratios between parts of a composition. Compositional data with a given constant sum constraint are represented in the simplex sample space, S^D, which consists of D-part compositions

$$S^D = \{x = (x_1, \ldots, x_D)^\top; x_j > 0, j = 1, \ldots, D; \sum_{i=1}^{D} x_i = \kappa\} \tag{1}$$

where κ is an arbitrary constant (κ equals 100 for the case of percentages and 1 for proportions). On the simplex the compositional data follow a specific geometry, called Aitchison geometry. This means that standard statistical methods relying on the Euclidean geometry in real space cannot be applied to capture the multivariate structure. Therefore, to enable the application of multivariate statistical methods on compositional data is necessary first to transform the data to the usual Euclidean geometry. Several transformation for this purpose were introduced and it depends on the analysis which of them to use. A simple and popular transformation is the centered log-ratio transformation defined as follows:

$$clr(x) = \left\{ ln\frac{x_1}{g(x)}, \ldots, ln\frac{x_D}{g(x)} \right\}^\top \tag{2}$$

where $g(x)$ is the geometric mean of all parts in the composition. The most important property of the *clr* transformation is that it preserves the distances among data, i.e. it presents an isometry between the Aitchison geometry and the Euclidean geometry.

The CP model [see 3, 5] decomposes the 3-way data array $\underline{X}$ into three loading matrices A $(I \times F)$, B $(J \times F)$, C $(K \times F)$ with F components (using the same number of components for each mode). The CP model can be written formally as

$$X_A = AI_A(C \otimes B)^\top + E_A, \tag{3}$$

where X_A, I_A $(F \times FF)$ and E_A $(I \times JK)$ are the original array, the superdiagonal three-way identity array and the error array, all matricized with respect to the mode A. The symbol $\otimes$ represents the Kronecker product between two matrices. To estimate the optimal component matrices the residual sum of squares

$$||E_A||^2 = \sum_{i=1}^{I}\sum_{j=1}^{J}\sum_{k=1}^{K}(x_{ijk} - \hat{x}_{ijk})^2 = \sum_{i=1}^{I}||x_i - \hat{x}_i||^2 = \sum_{i=1}^{I} RD_i^2$$

is minimized. Three-way models are usually fitted by an iterative procedure based on *PARAFAC-ALS (ALS)*. In the case of compositional data the rotational invariance of the ALS algorithm is important since it allows the application of any logratio transformation with the isometry property [see 4, where CP was considered for the first time in compositional context].

The computations in this paper were carried out using the R package **rrcov3way** [8]. It provides functions for classical and robust three-way modeling using Tucker3 and CP. These functions can be applied on both compositional and non-compositional data selecting the appropriate transformation.

3 Energy intensity in manufacturing

The data on energy consumption is obtained from the world energy balances database compiled by IEA [6]. It comprises data for more than 180 countries, 68 products and 98 flows in the period 1960-2017 in ktoe. From the products we select only the total and from the flows—the 11 flows pertaining to manufacturing (see Table 3). Manufacturing value added at annual frequency, disaggregated by industry, is available from the UNIDO INDSTAT database (`http://stat.unido.org`) for a large number of countries for the period 1963 to 2017 (at different level of detail, but we will use the 22 ISIC Revision 3 divisions). The data can be downloaded in current USD. Combining these two data sets in order to calculate the energy intensity by country poses a number of challenges. The first issue that we observe is that many countries, at least for a given period, do not disaggregate the data properly by flow but put everything into the category INONSPEC, therefore we exclude from the analysis data where the value in INONSPEC is 90% or more of the total or there are less than 5 flows with nonzero value. The discrepancy between the 11 IEA flows and the 23 ISIC Revision 3 divisions is obvious from Table 3—it was necessary to combine several ISIC divisions into one flow but also several flows together (BASICMET=NONFERR+IRONSTL). When considering only the relative nature of data, we do not need to convert the current US dollars into constant US dollars. Both data sets are compositional (sum up to a total energy consumption in manufacturing or total manufacturing value added, respectively). We can take their ratios for every flow (to obtain the energy intensity by flow), and further continue with the statistical processing in *clr* coordinates. After linking the two data sets together and removing countries where either energy consumption or value added is missing as well as removing obvious inconsistencies, we remain with 40 countries, 10 aggregated flows for the period 2000 to 2015 (16 years). This results in a three-dimensional array with dimensions $40 \times 10 \times 16$. We could start the analysis by applying principle component analysis (PCA) to the data year by year, and then present the results in a sequence of compositional biplots, but will be skipping this step for the sake of saving space. Also, if we want to get the complete picture about the development in a larger time frame, we should apply a CP model. It is

Flow	ISIC R3	ISIC Description
FOODPRO	15, 16	Manufacture of food, beverages and tobacco
TEXTILES	17, 18, 19	Manufacture of textiles, wearing apparel; dressing and dyeing of fur Tanning and dressing of leather
WOODPRO	20	Manufacture of wood and of products of wood and cork
PAPERPRO	21, 22	Manufacture of paper and paper products; Publishing
CHEMICAL	24	Manufacture of chemicals and chemical products
NONMET	26	Manufacture of other non-metallic mineral products
BASICMET	27	Manufacture of basic metals
MACHINE	28, 29	Manufacture of fabricated metal products; Machinery and eq.
	30, 31, 32	Manufacture of office eq.; Electrical machinery and apparatus n.e.c.; Radio
TRANSEQ	34, 35	Manufacture of motor vehicles; Other transport equipment
INONSPEC	25, 33, 36	Any manufacturing industry not included above

Table 1 Correspondence of IEA flows and ISIC Revision 3 descriptions

possible to apply CP to the raw data but it would be hard to recognize any structure. Therefore we conduct CP on the *clr* transformed data. The number of dimensions is chosen as F=2 using a convex hull procedure. The paired components plots of the first two modes A and B are shown in Figure 1. Three clusters of industries are seen in the mode B plot: the high tech MACHINE and TRANSPEQ, the energy intensive industries CHEMICAL, METALS and NONMETALS and the rest. Also there are clusters of countries in the mode A plot. The all-component plot is useful in our case since the third mode has a natural (time) ordering. The two components from the CP model of the clr transformed energy intensity data, shown in the left panel of Figure 2 have completely different trend. While component 1 runs smoothly throughout the period, component 2 grows steeply up to 2008, jumps abruptly up in 2009 and then continues smoothly. The per-component plot shown in the right panel of Figure 2 presents the tree modes on the first component. The flows mode (B) shows, similarly as the pair component plot of mode B the clustering of the high tech MACHINE and TRANSEQ flows against the energy intensive METALS, CHEMICAL and NONMET with the rest in the middle. The third mode does not show visible trend throughout the years but in the per-component plot on the second component (not shown here) three periods are clearly identified.

4 Summary and conclusions

Only illustrative results of the novel approach to analysis of the structure of the extremely important nowadays energy efficiency issue is presented in this short contribution. It clearly demonstrates that the compositional character of the data must be taken into account in order to obtain meaningful results. The importance of creating a high quality, coherent data set based on internationally comparable data sources is emphasized. Future research should improve the quality of the presented data set.

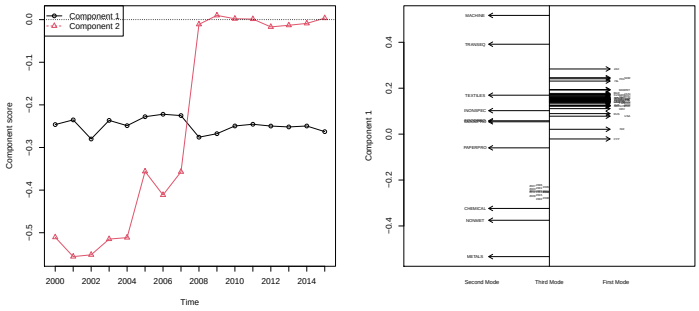

Fig. 2 All components plot and per-component plot of the CP model for *clr* transformed energy intensity (in the left, resp. right, panel)

and link the global energy intensity structure to other variables applying supervised methods. This will go hand in hand with the future development of the software for three-way data analysis implemented in the package **rrcov3way**.

Identification of high-energy $\gamma-$ray sources via nonparametric clustering

Individuazione di sorgenti di raggi γ ad elevata energia mediante clustering non parametrico

Giovanna Menardi, Denise Costantin, and Federico Ferraccioli

Abstract High-energy $\gamma-$ray sources exhibit as energy flares in the sky map, produced by variously concentrated photon emissions. The identification of these sources is a fundamental task to better understand the mechanisms that both create and accelerate particles emitted by celestial objects. We discuss the application of nonparametric clustering for $\gamma-$ray source detection and provide an algorithm specific for this task. The procedure accounts for the intrinsic uncertainty associated to the available data, arising as an effect of the instrument-pitch and multiple scattering.

Abstract Le sorgenti di raggi γ ad elevata energia si manifestano come bagliori nella mappa celeste, prodotti da emissioni di fotoni molto concentrati. L'identificazione di tali sorgenti è fondamentale per una migliore comprensione dei meccanismi che determinano la creazione e l'accelerazione delle particelle emesse dai corpi celesti. In questo lavoro si discute l'applicazione dell'approccio non parametrico al *clustering* per l'identificazione di sorgenti di raggi γ ad elevata energia e si sviluppa una procedura specifica per tale obiettivo. La procedura sfrutta l'incertezza insita nei dati a disposizione, dovuta al livello di precisione dello strumento di rilevazione dei fotoni e al fenomeno dello *scattering* multiplo.

1 Introduction

The Large Area Telescope (LAT) is a wide field-of-view pair-conversion telescope onboard the Fermi spacecraft. It performs an all-sky survey generally aimed to a better understanding of the mechanisms that both create and accelerate particles emitted by celestial objects. Discovering and locating high-energy $\gamma-$ray sources in the whole sky map is one of main purposes of the survey, and a declared target of the Fermi LAT collaboration. High-energy $\gamma-$ray sources exhibit as flares in the sky map, produced by variously concentrated photon emissions.

The standard procedure of the Fermi LAT collaboration for source detection relies on so-called *single-source* models, where the presence of a possible new source is evaluated after splitting the whole sky map on small regions, on the basis of some significance tests on the pixel-by-pixel photon counts. *Variable-source-number* models address the problem via more comprehensive approaches, where the number of sources in the whole map are jointly estimated. See [2] for further details.

According to the latter perspective, the aim of this work is to develop a model for detecting high energy emitting sources. While the signal of the sources is known to be blended by a diffuse $\gamma-$ray background which spreads over the entire area observed by the telescope, we assume that background processes have been pre-filtered out via some pre-processing, so that we can explicitly focus on the detection of the emitting sources.

Our goal is pursued via the suitable adaptation of *nonparametric*, or *modal* clustering ideas to the considered framework. With respect to most clustering methods, relying on heuristic ideas of similarity between objects, the nonparametric formulation is built on a probabilistic framework, which guarantees a sounder theoretical ground, and allows, for instance, a natural application of inferential tools. Additionally, the number of clusters is determined itself within the estimation process. Modal clustering relies on the assumption that a probability density underlies the data, and clusters are defined as the domains of attraction of the density modes. Two main issues arise in the operational implementation of these ideas: the density function needs to be appropriately estimated, usually via nonparametric methods, and its modes detected. We address both points by taking advantage of the context at hand.

The rest of the paper is organized as follows. After providing an overview about non-parametric clustering (Section 2.1), we propose and discuss a novel method specifically conceived for high-energy $\gamma-$ray sources detection (Section 2.2), and illustrate its application on a set of data simulated from one of the catalogues released by the Fermi LAT Collaboration (Section 3).

2 Nonparametric clustering for high-energy $\gamma-$ray sources detection

2.1 Overview on nonparametric clustering

Nonparametric, or *modal* clustering hinges on the assumption that the data $(x_1,\dots,x_n)'$ are sampled from a probability density function f. The modes of f represent the archetypes of the clusters, which are in turn described by the surrounding regions. The identification of the modal regions may be performed by associating each cluster to the set of points along the steepest ascent path towards a mode, in turn located by some optimization method. Alternatively, clusters can be identified as the disconnected density level sets of the sample space, without attempting the explicit task of mode detection. This is also the route followed in this work. Specifically, any section of f, at a level λ, singles out the (upper) level set

$$L(\lambda) = \{x \in \mathbb{R}^d : f(x) \geq \lambda\}, \quad 0 \leq \lambda \leq \max f$$

which may be connected or disconnected. In the latter case, it consists of a number of connected components, each of them associated with a cluster at the level λ.

While there may not exist a single λ which catches all the modal regions, any connected component of $L(\lambda)$ includes at least one mode of the density and, on the other hand, for each mode there exists some λ for which one of the connected components of the associated $L(\lambda)$ includes this mode at most. Hence, all the modal regions may be detected as the connected components of $L(\lambda)$ by varying λ.

A side consequence of varying λ along its range, is the opportunity of building a hierarchical structure of the high-density sets, known as the *cluster tree*. For each λ, it provides the number of connected components of $L(\lambda)$, and each of its leaves corresponds to a cluster, i.e. the largest connected component of $L(\lambda)$ including one mode only. Figure 1 illustrates a simple example of this idea: clusters associated with the highest modes 2 and 3 are identified by the smallest λ larger than λ_3, while the smallest λ larger than λ_1 identifies the cluster associated to mode 1.

Operationally, a few choices are required to implement the ideas underlying modal clustering. Since f is unknown, a nonparametric estimator $\hat{f}$ is employed which, disregarding the specific choice adopted, is in general governed by some parameter defining the amount of smoothing. It stands to reason the need of selecting this parameter appropriately, as it affects the resulting modal structure of $\hat{f}$. A second choice derives from the lack, in multidimensional sample spaces, of an obvious method to identify the connected components of a level set. The issue is usually addressed by building a suitable graph on the observed data and, conditional to their belonging to a level set, the connected components of the graph are identified. A key matter becomes to suitably define the graph. See [3] and reference therein for a detailed review on modal clustering.

In the following, we take advantage of information available on the photon emissions to address the choices of the smoothing amount and the level set graph.

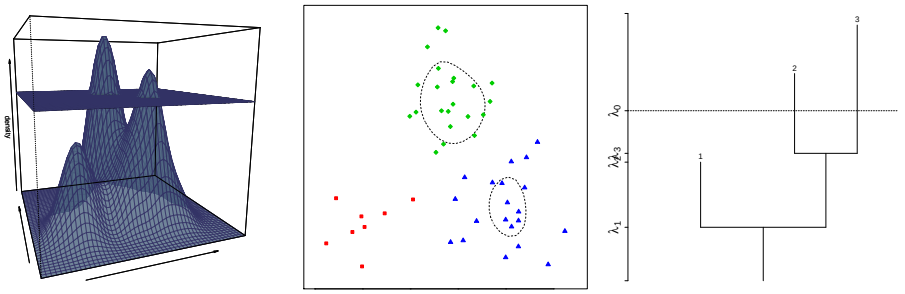

Fig. 1 A section of a density function at a level λ_0 (left), the identified level set (middle panel), formed by two disconnected regions and the associated cluster tree, with leaves corresponding to the modes. The horizontal line is at the level λ_0 (right).

2.2 A novel method for high-energy γ−ray sources detection

Each photon emission i ($i = 1, \dots, n$) is identified by the LAT detector, and the event reconstructed through its trackers and calorimeters. A reconstructed event is finally described by a pair of Galactic coordinates (θ_i, Φ_i), which represent the direction of the emission, along with, among others, the energy of the recorded photon, its incidence angle, and the time of detection. In fact, event reconstruction is subject to several sources of uncertainty due, for instance, to the instrument-pitch and multiple scattering, added in quadrature. Such uncertainty is worth to be accounted for in the analysis as it affects the perceived concentration of the photon emission.

One measure of uncertainty is the 95% *containment angle* (CA95), which broadly speaking depends on the angle of incidence on the LAT surface, the energy, and the event type classification of each individual photon. Information provided by the CA95 is here exploited to perform nonparametric clustering in a twofold way.

The containment angle of each photon $CA95_i$ is roughly defined as the 0.95-quantile of a generalized bivariate Student distribution $t_2(0, \sigma_i^2 \mathbb{I}_2)$, which approximates, at least for high energies, the *point spread function* of the emitting source, measuring the response of the LAT to a point source [1, 4]. An approximated value of σ_i can be then derived as $\sigma_i \simeq CA95_i / t_{2,0.95}$, being $t_{2,0.95}$ the theoretical 0.95-quantile of a $t_2(0, \mathbb{I}_2)$. Then σ_i is used as the bandwidth for an adaptive product kernel density estimator

$$\hat{f}(\theta, \Phi) = \sum_{i=1}^{n} \frac{1}{n\sigma_i^2} K\left(\frac{\theta - \theta_i}{\sigma_i}\right) K\left(\frac{\Phi - \Phi_i}{\sigma_i}\right). \tag{1}$$

Once that the density underlying the data has been estimated via (1), its level sets are determined for varying λ, and its connected components are to be identified. In fact, given $\hat{L}(\lambda)$, finding the connected components of a set is both conceptually and computationally easy in the unidimensional case only, where connected sets are intervals. Conversely, in multidimensional spaces it is immediate to state whether

any given point belongs to $\hat{L}(\lambda)$, while saying how many connected sets comprise $\hat{L}(\lambda)$, and identifying them, is not obvious. We address this issue by shifting the target from the continuous multidimensional space where data are defined, to the finite and discrete set identified by the observations themselves, via the identification of the connected components of a suitable graph built on the data. Specifically, we consider connected two observations i and j when

$$d_a((\theta_i, \Phi_i), (\theta_j, \Phi_j)) < \max(CA95_i, CA95_j),$$

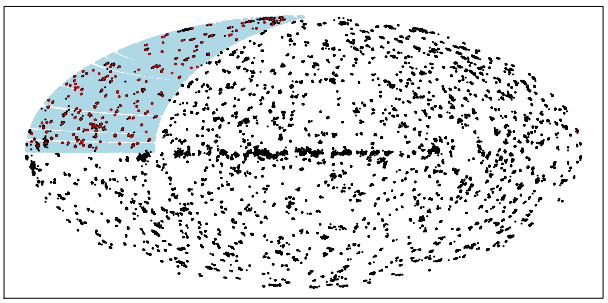
where $d_a(\cdot, \cdot)$ denotes the orthodromic distance function. The underlying rationale is that two photons are likely to be generated by the same source whenever one of them lies within the essential support of the other one. After running nonparametric clustering, detected clusters are associated to emitting sources, whose location is identified by the pertaining density mode.

3 Empirical analysis

This section presents the results of the application of the proposed procedure to a set of data simulated from the 3FHL catalog of the Fermi LAT collaboration and spread on the whole sky map. The sky distribution of the data, illustrated in Figure 2, is quite heteregeneous, with separated sources in the extragalactic sky, overlapping sources in the galactic region and various source sizes. To limit the computational effort, we restrict the analysis to a sub-region of the whole map, as illustrated in Figure 2. Additionally, we remove all the sources with less than four photons emitted. The resulting data set include 6309 photons, emitted by 169 sources, whose size range from 4 to 1015 photons.

As a benchmark, we also apply a single linkage clustering, based on the orthodromic distance between photons. Due to the high concentration of the sources, this methods appears as the most promising, among the standard clustering methods. In this case, there is no obvious method to select the number of detected sources, hence for the sake of comparison, we set this number to the actual number of sources.

Since the data are simulated, we may evaluate the performance of the procedure with respect to the knowledge of the pertaining source of each photon emission and of its location. According to the former aspect, we compute the Adjusted Rand Index (ARI), which takes maximum value equal to one in the case of a perfect classification. As for the second aspect, the estimated source locations, defined by the galactical coordinates of the local maximum of the density within each detected group, are associated to the true source which presents minimum distance. The association is confirmed if the detected source belongs to the range of the positional error available for the true source. As a summarizing measure of the quality of the association, we compute the True Positive Rate (TPR) and the False Positive Rate (FPR). The former index is defined as the proportion of true sources correctly detected, while the latter one corresponds to the proportion of estimated components which are not associated with any source.



Nonparametric method	
ARI	0.985
$\overline{d}(s,\hat{s})$	0.030
TPR	0.675
FPR	0.240
Single linkage	
ARI	0.953
$\overline{d}(s,\hat{s})$	0.409
TPR	0.337
FPR	0.746

Fig. 2 Aitoff projection of the sky map data. The analysis has been restricted to the highlighted area, where location of the true sources is identified by the overimposed red crosses (left). Clustering results; $\overline{d}(s,\hat{s})$ is the average distance between true and detected sources (right).

The procedure identifies 150 out of 169 sources. Results, summarized in Figure 2, show and excellent performance with respect to the allocation of the photons to the pertaining sources with an ARI very close to 1, meaning that the unidentified sources include a very small fraction of photons. The TPR, albeit pretty good, indicates that the precision of source location can be improved, despite the average distance between the true and the detected sources amount to 0.03 degrees only. The procedure outperforms the competitor with respect to all the criteria, despite the competitor has been given an head start by suggesting the true number of sources.

While results have proven more than satisfactory, there is room for improvement. A first aspect which is worth to investigate on derives from the possible use of cartesian coordinates and a kernel function specifically designed for spherical data, as their directional nature cannot be completely caught by the use of galactic coordinates. Additionally, our procedure requires that the background components have been previously filtered out. Future research will focus on how to account for this aspect within the estimation procedure.

Statistical Analysis of Macroseismic Data for a better Evaluation of Earthquakes Attenuation Laws

Analisi statistica dei dati macrosismici per una migliore valutazione delle leggi di attenuazione dei terremoti

Marcello Chiodi, Antonino D'Alessandro, Giada Adelfio, Nicoletta D'Angelo

Abstract In this work we propose a statistical approach, based on the joint analysis of macroseismic data of Italian seismic events of the last two centuries, with which we obtain simultaneously maximum likelihood estimates of attenuation laws and coordinates of hypocenters. Our first results encourage us to use in the future more complex models, with a larger number of historical earthquakes.

Abstract *In questo lavoro proponiamo un'approccio statistico, fondato sull'analisi congiunta di dati macrosismici di eventi sismici italiani degli ultimi due secoli, col quale otteniamo simultaneamente stime di massima verosimiglianza delle leggi di attenuazione e delle coordinate ipocentrali. I primi risultati ci incoraggiano ad usare in futuro modelli più complessi per un numero maggiore di terremoti storici.*

people, the shaking effects due to a moderate to strong earthquake. The macroseismic intensity is an ordinal variable that describes the seismic damage effects of an earthquake.

Macroseismic intensity is still often the only observed parameter to quantify the level of ground motion severity in many towns where seismometric instruments are not available [1, 2]. Moreover, macroseismic intensities are the only intensity measures available for pre-instrumental historical earthquakes and so are an important source to learn from historical earthquakes. Since 1960s reliable measurements of earthquakes shaking are available thanks to seismic networks. Seismograms analysis allow estimation of the severity of an earthquake by means of magnitude determination, which indirectly measures the amount of energy released by the shock.

The ground shaking observed at a site, when and an earthquake occurs, depends not only on the magnitude of the event, but also on its hypocentral depth and observation distance or epicentral distance. In fact, the wave field generated by an earthquake along propagation is subject to a lot of attenuation phenomena due to geometrical spreading, physical attenuation, reflection, refraction, diffraction, scattering of waves, etc. The phenomenon of seismic attenuation is therefore very complicated to model deterministically. Attenuation laws, generally deduced empirically on the basis of instrumental observations like PGA (Peak Ground Acceleration), show a logarithmic dependence from distance.

In general, it is widely accepted that macroseismic intensity depends significantly on ground shaking even if there is no physical model capable of giving quantitative account of these relationships. Due to their different nature, the two quantities PGA and Intensity show moderate levels of correlation, as widely observed in the current literature [3, 5, 6, 7, 8, 9, 12, 13].

In this paper, after a brief description of a dataset of historical eartquakes, we will propose the estimation of attenuation laws by means of a global estimation of a set of parameters including hypocentral coordinates. After some comments on the results, final remarks and ideas for further studies are outlined.

2 Historical earthquakes and data description

In this article we consider the spatial distribution of the effects caused by an earthquake as expressed by the values of the macroseismic intensity recorded at various locations surrounding the epicentre. The dataset here analysed are macroseismic data extracted from the Parametric Catalog of Italian Earthquakes ($CPTI15_{v2.0}$) and the Italian macroseismic database ($DBMI15_{v2.0}$). The $CPTI15_{v2.0}$ provides homogeneous parametric data, both macroseismic and instrumental, relating to earthquakes with maximum intensity ≥ 5 or magnitude ≥ 4.0 of interest for Italy in the time window 1000-2017. The $DBMI15_{v2.0}$ provides a homogeneous set of macroseismic intensities from different sources related to earthquakes with maximum intensity ≥ 5 and of interest for Italy in the time window 1000-2017. More details about these database can be found in [11].

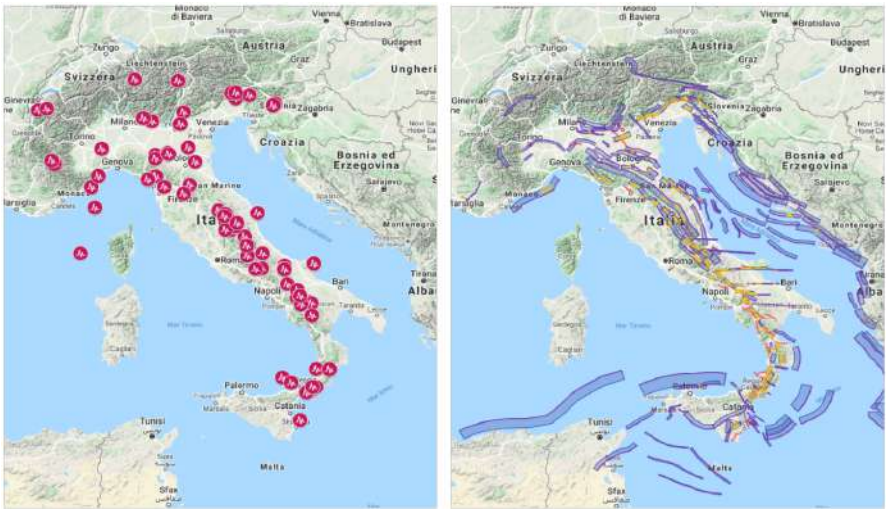

Fig. 1 Epicenters coordinates of 74 historical earthquakes observed from 1783 to 2016 (left); Main seismogenic sources [4]

For this first analysis data consist of 33,588 observations, that is the macroseismic intensities of 74 historical earthquakes (Fig. 1 left) observed from 1783 to 2016. Events have been selected mainly according to the quality of the dataset of historical reports avaliable for each earthquake, so that only events that on $DBMI15_{v2.0}$ have more than 300 macroseismic intensities observed have been used. For each earthquake E_j we have n_j observations ($j = 1,2,...,74$) of macroseismic intensities y_{ij},($i = 1,2,...,n_j$) on a scale ranging from 1 to 11. Observations with missing intensities have been dropped out so that n_j finally ranges from 123 to 1431. Each record contains of course the longitude x_{ij} and the latitude y_{ij} of the place where the macroseismic intensity has been recorded, all around Italy, and approximately centered on the epicenter of the event; estimates $\tilde{x}_{0j}, \tilde{y}_{0j}, \tilde{z}_{0j}$ ($j = 1,2,...,74$) of the hypocentral coordinates are also present in the historical records.

In the following, we illustrate the procedure followed to identify the attenuation law of macroseismic fields relative to the 74 selected earthquakes.

3 Statistical Analysis

To estimate simultaneously parameters of attenuation laws and reasonable location of events, we considered the basic model:

$$I_{ij} = \beta_{0j} + \beta_{1j} \log \sqrt{d^2(P_{ij}, P_{0j}) + z_{0j})^2} + \varepsilon_{ij}, \tag{1}$$

$$j = 1,2,...,k;\ i = 1,2,...,n_j$$

where I_{ij} is the $i-th$ macroseismic intensity, observed in the point P_{ij} of longitude and latitude $P_{ij} : \{x_{ij}, y_{ij}\}$, P_{0j}, is the epicenter, with longitude and latitude $P_{0j} : \{x_{0j}, y_{0j}\}$ and $d^2(P_{ij}, P_{0j})$ is their geodetic distance; z_{0j} is the depth of the $j-$th event and ε_{ij} is a random component (in this first version basic assumptions have been made about their conjoint distribution [1]).

$\beta_{0j}, \beta_{1j}, x_{0j}, y_{0j}, z_{0j}$ $(j = 1, 2, ..., 74)$ must be estimated from observed data.

We used standard optimization methods to obtain simultaneously all Maximum Likelihood estimators. After a preliminary analysis inside each event, We discarded from successive analysis the event number 66, because the estimated values where not reliable: with this elimination the optimization algorythm globally converges and we obtained for each event E_j new hypocentral locations $\hat{x}_{0j}, \hat{y}_{0j}, \hat{z}_{0j}$, together with the parameters which describe the attenuation laws.

4 Comments on first results

We summarized main results in few figures: a very interesting result is the relocation of events according to the Maximum Likelihood estimation of hypocentral parameters Fig. 2.

Particularly the depth $\hat{z}_{0j}$ seems more reliable with respect to original estimates, since many values of $\tilde{z}_{0j}$ were missing or substitued with a value of 10 kilometers. The median distance between estimated and original hypocentral coordinates is of 13.2 km.

Few diagnostic statistical summaries are reported in Fig. 3 residuals have been computed on the final fitted model (model1), where all unknown quantities have been estimated simultaneously for all earthquakes (that is attenuation law parameters β_{0j}, β_{1j} and hypocenter coordinates x_{0j}, y_{0j}, z_{0j}, $j = 1, 2, ..., 74$)

The left plot shows a satisfactory behaviour of residuals distribution with respect to fitted values, given however the elementary assumptions made in this first approach; further on the right we observe that the empirical distribution of residuals shows a marked leptokurtosis [2].

In Fig. 2, on the right, we report the main directions for each event computed on the basis of observed macroseismic intensities and centered on relocated epicenters: we can see that these directions are compatible with th main seismogenetic sources reported in the right panel of Fig. 1.

[1] In a foregoing version more specific assumptions will be made about a possible spatial autocorrelation of the ε_{ij}; some considerations about effects of departure from normality will be made in the final section

[2] Indeed we also estimated a value of the parameter p of a p-normal distribution (also known as Exponential Power Distribution) between 1 and 2, but we will not deal with this problem in the present paper: however a relocation made with maximum likelihood with estimated p led to values very close to normal ones, that is for $p = 2$

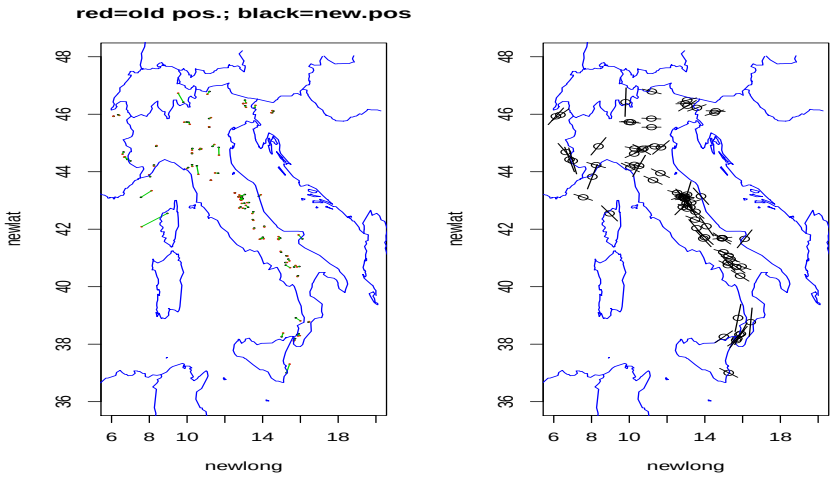

Fig. 2 Relocation of the epicenters on the basis of the model 1. Original location in blank squares, new estimates in black circles. On the right estimation of the main directions for each event on the basis of observed macroseismic intensities

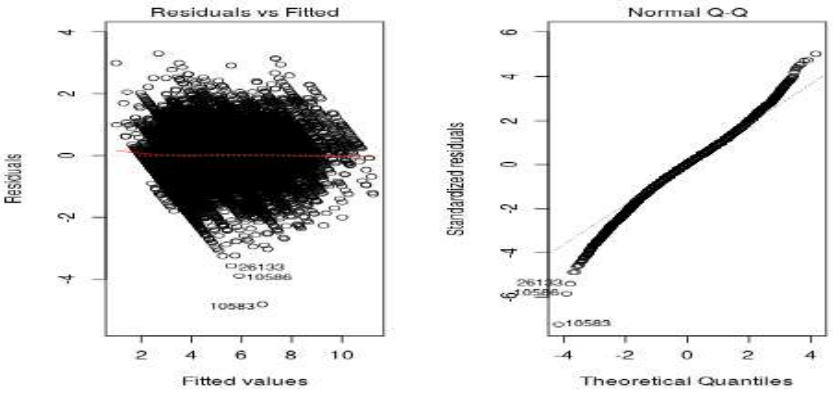

Fig. 3 Final residuals from the model 1. Residuals vs. fitted (left); Q-Q plot of residuals vs a normal distribution

5 Final remarks and future perspectives

The problem of determining quantitative parameters of pre-instrumental earthquakes is an interesting challenge in seismology, because the location of the epicenter must be based on amplitudes since arrival times are not meaningful for macroseismic data, intensity is an ordinal quantity that is only weakly correlated with

the amplitude of the ground motion and the real paths traveled within the Earth's lithosphere by the seismic wave are unknown.

The availability of extensive collections of macroseismic observations, and of modern computing powers, has led to the development of methods that use the spatial distribution of intensities to determine hypocentral parameters and attenuation laws.

In a forecoming study we will analyze information about a larger number of historical earthquakes and we will study the problem of optimal scaling of macroseismic intensity together with a deeper analysis of the spatial components.

Network Modelling in Biostatistics

Natural direct and indirect relative risk for mediation analysis

Rischio relativo naturale diretto e indiretto per l'analisi di mediazione

Monia Lupparelli and Alessandra Mattei

Abstract We consider a mediation setting involving a mediator which may channeling a part of the treatment effect along the causal pathway between the treatment and the primary outcome. Under a sequential ignorability assumption, we propose a recursive regression framework for binary outcomes so that the total causal relative risk can be decomposed into the natural direct and indirect relative risk by combining model parameters. Inference is performed by maximum likelihood methods.
Abstract *Nel contesto dell'analisi di mediazione si prevede la presenza di un mediatore che potrebbe interferire sull'effetto del trattamento sulla variabile finale di interesse. Sotto l'assunzione di ignorabilitá sequenziale, si propone un modello di regressione ricorsivo per variabile risposta binaria in cui il rischio relativo totale del trattamento rispetto alla variabile di interesse si puó scomporre nel rischio relativo naturale diretto ed indiretto combinando i parametri del modello. Metodi di massima verosimiglianza sono usati per l'inferenza.*

Key words: binary or continuous mediator, potential outcome, causal model

1 Introduction

Casual mediation analysis focuses on understanding the causal pathways by which a treatment affects an outcome, by investigating the mediating role of an intermediate variable, named mediator, in the treatment-outcome relationship. When the effect of the treatment on the response might be channeled by a mediator, the interest is on

disentangling *indirect effects*, that are through the mediator of interest, and *direct effects*, that are through other pathways other than the mediator [4, 3, 2, 8].

We focus on causal relative risks, defining natural direct and indirect effects for binary outcomes on the risk ratio scale [7]. Under a sequential ignorability assumption, which is usually invoked in mediation analysis, we propose to draw inference on the natural direct and indirect relative risks using a recursive regression framework, where a regression model for the binary outcome, based on the log-link function, is coupled with another regression model for binary responses if the mediator is binary and a linear regression model for continuous responses if the mediator is continuous. We show that under the assumption that models are correctly specified, the natural direct and indirect relative risks can be derived by analytically combining model parameters. Inference can be performed by maximum likelihood methods.

The method is applied to the observational Swedish National March Cohort (NMC) study to investigate the causal mechanism between physical activity, body mass index, and cardiovascular disease.

2 Notation and causal estimands

Let Y be a binary outcome, W a binary treatment and M a mediator, a post-treatment intermediate variable lining in the causal pathway between the treatment and the outcome. The outcome and the treatment take value $y, w \in (0,1)$, respectively, and the mediator $m \in \mathscr{M}$, e.g., $\mathscr{M} = \{0,1\}$ whether the mediator is binary and $\mathscr{M} = R$ whether it is continuous. Also, let X be a vector of covariates with generic element $x \in R^k$, where k denotes the size of X.

Let $M(w)$ and $Y(w)$ denote the potential outcomes for the mediator and the primary endpoint, respectively: they are the values of M and Y under assignment to treatment w, $w = 0,1$. Let W, M^{obs} and Y^{obs} denote the observed values of the treatment, the mediator and the outcome: $M^{\text{obs}} = M(W) = WM(1) + (1-W)M(0)$ and $Y^{\text{obs}} = Y(W) = WY(1) + (1-W)Y(0)$. We are interested in disentangling *direct* and *indirect effects* of the treatment, W, on the outcome, Y, in the presence of the mediator, M.

Following the literature on mediation analysis (e.g., [4, 3]), to formalize the concepts of direct and indirect effects, we introduce potential outcomes of the form $Y(w,m)$ and $Y(w,M(w'))$, $w, w' \in \{0,1\}$: $Y(w,m)$ would be the value of the outcome Y if the treatment were set to the level w and the mediator M were set to the value m; and $Y(w,M(w'))$ would be the value of the outcome Y if the treatment were set to the level w and the mediator M were set to the value it would have taken if the treatment had been set to an alternative level, w'.

The causal relative risk conditional on covariates level $X = x$,

$$RR_{Y|x} = \frac{P(Y(1)=1|X=x)}{P(Y(0)=1|X=x)} = \frac{P(Y(1,M(1))=1|X=x)}{P(Y(0,M(0))=1|X=x)} \tag{1}$$

can be decomposed into the product of a 'natural' direct relative risk,

$$RR_{Y|x}^{dir} = \frac{P(Y(1,M(0)) = 1|X = x)}{P(Y(0,M(0)) = 1|X = x)} \tag{2}$$

and a 'natural' indirect relative risk,

$$RR_{Y|x}^{ind} = \frac{P(Y(1,M(1)) = 1|X = x)}{P(Y(1,M(0)) = 1|X = x)} \tag{3}$$

as $RR_{Y|x} = RR_{Y|x}^{dir} \times RR_{Y|x}^{ind}$. Direct and indirect relative risks can be identified under these assumptions [1, 2]:

Assumption 1 *(Ignorability of the treatment).*

$$\{Y(w,m), M(w')\} \perp\!\!\!\perp W \mid X \qquad \textit{for all } w,w' \in \{0,1\}, m \in \mathscr{M}$$

Assumption 2 *(Ignorability of the mediator).*

$$Y(w,m) \perp\!\!\!\perp M(w') \mid W = w', X \qquad \textit{for all } w,w' \in \{0,1\}, m \in \mathscr{M}$$

which [2] jointly refer to as *sequential ignorability*. Ignorability of the treatment states that the treatment assignment mechnism is ignorable conditional on the observed covariates and holds by design in randomized experiments. Ignorability of the mediator states that the mediator is ignorable given the observed treatment and covariates. Under Assumptions 1 and 2, the mediation formula holds [3]:

$$P[Y(w,M(w')) = 1 \mid X = x] = \int_{m \in \mathscr{M}} P(Y^{\text{obs}} = 1 \mid M^{\text{obs}} = m, W = w, X = x) f_{M^{\text{obs}}|w',x}(m \mid w', x) \nu(dm)$$

where $f_{M^{\text{obs}}|w',x}(m \mid w', x)$ is the probability density/mass function for the random variable $M^{\text{obs}} \mid \{W = w', X = x\}$, with $w' \in \{0,1\}$ and $x \in R^k$, and ν is the Lebesgue measure if M is continuous and the counting measure if M is discrete. Therefore, under Sequential Ignorability we can use regression models for estimate natural direct and indirect causal relative risks.

3 The model

3.1 Binary mediator

We consider a recursive regression framework based on the log-link function for the binary random vector $(W^{\text{obs}}, M^{\text{obs}}, Y^{\text{obs}})$:

$$\log P(M^{\text{obs}} = 1 \mid W, X) = \beta_\emptyset + \beta_W W + \beta_X^T X \tag{4}$$

$$\log P(Y^{\text{obs}} = 1 \mid M^{\text{obs}}, W, X) = \alpha_\emptyset + \alpha_W W + \alpha_M M^{\text{obs}} + \alpha_X^T X. \tag{5}$$

For the sake of simplicity, we consider additive models with no interaction terms; the generalization including multiplicative effects is straightforward. Regression coefficients in Equation (4) and (5) correspond to the logarithm of conditional relative risks, for any $x \in R^k$:

$$\beta_W = \log RR^{\text{obs}}_{M|W.x} = \log \frac{P(M^{\text{obs}}=1|W=1,X=x)}{P(M^{\text{obs}}=1|W=0,X=x)},$$

$$\alpha_W = \log RR^{\text{obs}}_{Y|W.m,x} = \log \frac{P(Y^{\text{obs}}=1|W=1,M^{\text{obs}}=m,X=x)}{P(Y^{\text{obs}}=1|W=0,M^{\text{obs}}=m,X=x)}; \qquad m \in \mathscr{M} = \{0,1\}$$

$$\alpha_M = \log RR^{\text{obs}}_{Y|M.w,x} = \log \frac{P(Y^{\text{obs}}=1|W=w,M^{\text{obs}}=1,X=x)}{P(Y^{\text{obs}}=1|W=w,M^{\text{obs}}=0,X=x)}; \qquad w \in \{0,1\}.$$

The $k-$dimensional parameter vector α_X and β_X represent the effect of the individual covariate X on the distribution of Y and of M, respectively.

Then, under Assumptions 1 and 2, and under correct specification of the regression models, the natural direct and indirect relative risks are given by

$$RR^{dir}_{Y|x} = \frac{[1 - e^{(\beta_\emptyset + \beta_X x)}]e^{\alpha_W} + e^{(\beta_\emptyset + \beta_X x)}e^{(\alpha_W + \alpha_M)}}{1 - e^{(\beta_\emptyset + \beta_X x)} + e^{(\beta_\emptyset + \beta_X x)}e^{\alpha_M}} = e^{\alpha_W}$$

and

$$\begin{aligned} RR^{ind}_{Y|x} &= \frac{[1 - e^{(\beta_\emptyset + \beta_W + \beta_X^T x)}]e^{(\alpha_\emptyset + \alpha_W + \alpha_X^T x)} + e^{(\beta_\emptyset + \beta_W + \beta_X^T x)}e^{(\alpha_\emptyset + \alpha_W + \alpha_M + \alpha_X^T x)}}{[1 - e^{(\beta_\emptyset + \beta_X^T x)}]e^{(\alpha_\emptyset + \alpha_W + \alpha_X^T x)} + e^{(\beta_\emptyset + \beta_X^T x)}e^{(\alpha_\emptyset + \alpha_W + \alpha_M + \alpha_X^T x)}} \\ &= \frac{[1 - e^{(\beta_\emptyset + \beta_W + \beta_X^T x)}] + e^{(\beta_\emptyset + \beta_W + \beta_X^T x)}e^{\alpha_M}}{[1 - e^{(\beta_\emptyset + \beta_X^T x)}] + e^{(\beta_\emptyset + \beta_X^T x)}e^{\alpha_M}}. \end{aligned}$$

It is worth noticing that, assuming the convention that $RR^{reg}_{Y|M.w,x} = 1$ for $M^{\text{obs}} = 0$, the natural indirect relative risk can be written as ratio of weighted averages of conditional relative risks of the mediator M^{obs} on the outcome, Y^{obs} with weights given by the conditional probabilities $P(M^{\text{obs}} = m \mid W = w)$, $w = 0, 1$:

$$RR^{ind}_{Y|x} = \frac{\sum_{m=0}^{1} RR^{\text{obs}}_{Y|M.w,x} P(M^{\text{obs}} = m \mid W = 1, X = x)}{\sum_{m=0}^{1} RR^{\text{obs}}_{Y|M.w,x} P(M^{\text{obs}} = m \mid W = 0, X = x)}.$$

3.2 Gaussian mediator

In studies where the mediator is continuous, we assume that $M^{\text{obs}} \mid \{W, X\} \sim N\left(E[M^{\text{obs}} \mid W, X], \sigma^2\right)$ and use the following recursive regression framework:

$$E[M^{\text{obs}} \mid W, X] = \gamma_0 + \gamma_W W + \gamma_X^T X \tag{6}$$

$$\log P(Y^{\text{obs}} = 1 \mid W, M^{\text{obs}}, X) = \alpha_0 + \alpha_W W + \alpha_M M^{\text{obs}} + \alpha_X^T X. \tag{7}$$

Under Assumptions 1 and 2, and under correct specification of the regression models, we can show that the natural direct and indirect relative risks are given by

$$RR_{Y|x}^{dir} = \frac{e^{(\alpha_0+\alpha_W+\alpha_X^T x)} e^{\left[(\gamma_0+\gamma_X^T x)\alpha_M+\sigma^2\frac{\alpha_M^2}{2}\right]}}{e^{(\alpha_0+\alpha_X^T x)} e^{\left[(\gamma_0+\gamma_X^T x)\alpha_M+\sigma^2\frac{\alpha_M^2}{2}\right]}} = e^{\alpha_W}$$

and

$$RR_{Y|x}^{ind} = \frac{e^{(\alpha_0+\alpha_W+\alpha_X^T x)} e^{\left[(\gamma_0+\gamma_W+\gamma_X^T x)\alpha_M+\sigma^2\frac{\alpha_M^2}{2}\right]}}{e^{(\alpha_0+\alpha_W+\alpha_X^T x)} e^{\left[(\gamma_0+\gamma_X^T x)\alpha_M+\sigma^2\frac{\alpha_M^2}{2}\right]}} = e^{\gamma_W \alpha_M}.$$

In case of continuous mediators, both the natural direct and indirect effect are independent of the covariate set. We remark that the indirect effect specified on the odds ratio scale through logistic regression models, is not invariant with respect to the covariates, even for the case of continuous mediators; see [7].

4 Case study

The method is applied to a real data set taken from the observational Swedish National March Cohort (NMC) study, previously analyzed by [6, 5]. The NMC data set includes information on self-reported physical activity (PA) level, body mass index (BMI), and baseline covariates (X), measured for each subject at enrollment. Subjects are followed from year 1997 to 2004 and each cardiovascular disease (CVD) event is recorded. Following [6], we classify each subject as either a "low-level exerciser" ($W = 1$) or a "high-level exerciser" ($W = 0$). Let $Y^{\text{obs}} = 1$ for subjects who report at least one CVD event before end of follow-up, and $Y^{\text{obs}} = 0$ otherwise.

Our focus is on the extent of a causal effect of PA on CVD risk mediated or not mediated through BMI. We answer this research question applying the framework for mediation analysis we propose with BMI both as a continuous mediator on its original scale and as a binary mediator, which classifies subjects as either "Obese" ($M^{\text{obs}} = 1$) if their BMI ≥ 30 or "Not Obese" ($M^{\text{obs}} = 0$) if their BMI < 30. Under Assumptions 1 and 2 the analysis is conducted specifying models in Equations (4) and (5) for binary BMI and in Equations (6) and (7) for continuous BMI conditional on the following covariates: Gender (1 = Male, 0 = Female), age (in years), a binary indicator for smoking (1 = Current/Former smoker, 0 = No smoker), and a binary indicator for alcohol use (1 = Medium/High drinker, 0 = Low/No drinker).

Results are collected in Table 1 both for the case of binary and continuous mediator. If we consider continuous BMI, the estimates of the causal effects are all positive and highly significant. If we consider the model for binary BMI, the value of the estimates of the causal effects are comparable with the previous case, never-

Table 1 NMC study: Estimate and standard error (SE) of the total relative risk of PA on CVD and of the natural direct and indirect relative risks of PA on CVD with mediator BMI

Binary BMI[a]			Continuous BMI		
Estimand	Estimate	SE	Estimand	Estimate	SE
RR^{dir}_{CVD}	1.160	0.116	RR^{dir}_{CVD}	1.125	0.110
$RR^{ind}_{CVD\|x}$	1.024	0.165	RR^{ind}_{CVD}	1.052	0.008
$RR_{CVD\|x}$	1.187	0.225	RR_{CVD}	1.184	0.116

[a] In the case of binary BMI we show the estimate and the standard error of $RR^{ind}_{CVD|x}$ and of $RR_{CVD|x}$ for a woman aged 48 (sample mean of age), who is a no smoker and a low/no drinker.

theless the standard error of the estimate of the indirect causal effect is higher (0.165 instead of 0.008). The greater uncertainty may depend by the dichotomization of the BMI, since the sub-sample with $BMI \geq 30$ shows a greater sparsity.

We consider the model for the continuous mediator easier to interpret since both the natural direct and indirect effect are independent of the covariate set. Nevertheless, the marginal indirect causal effects could be derived even for the model with the binary BMI by summing over the sampling distribution of the covariate set.

New issues on multivariate and univariate quantile regression

Mixtures of linear quantile regression models for longitudinal data: an R package

Misture di modelli di regressione quantile per dati longitudinali: un pacchetto R

M.F. Marino, M.G. Ranalli, and M. Alfò

Abstract In this paper, we introduce **`lqmix`**, an R package that has been specifically tailored to the estimation of mixtures of linear quantile regression models, based on time-constant and/or time-varying, discrete, random coefficients. An Expectation-Maximization (EM) algorithm is used to obtain maximum-likelihood estimates of model parameters and likelihood-based information criteria are adopted to select the number of mixture components. For the regression coefficients, bootstrap-based standard errors and confidence intervals are also provided.

Abstract *In questo paper, si introduce il pacchetto R* ***`lqmix`****, specificamente pensato per la stima di misture di modelli di regressione quantilica basate sull'utilizzo di coefficienti casuali discreti tempo-costanti e/o tempo-variabili. Un algoritimo EM è utilizzato per la stima dei parametri tramite un approccio di massima verosimiglianza, mentre si considerano criteri standard basati sulla penalizzazione della funzione di verosimiglianza per la scelta del numero ottimale di componenti della mistura finita. In output, si ottengono infine le stime degli errori standard e degli intervalli di confidenza per i parametri del modello impiegando ricampionamento via bootstrap.*

1 Introduction

In the statistical literature, quantile regression [5] has become a quite popular and established technique for the analysis of data when the interest is not focused on and goes beyond the (conditional) mean. With longitudinal data, dependence between observations recorded on the same individual need to be taken into account to avoid bias and inefficiency issues in parameter estimates. This can be achieved by including in the quantile regression model individual-specific, time-constant and/or time-varying, random coefficients that, being shared by all measures associated to a given individual, make repeated observations dependent of each other. In this framework, a standard way of proceeding is that of specifying a parametric distribution for the random coefficients [see, e.g. 3, 4]. A further alternative is that of leaving such a distribution unspecified and estimate it directly from the observed data, by exploiting a finite mixture specification of the model. This can be either time-constant or time-varying, as we will detail in the following. Such an approach offers a number of specific advantages: (*i*) it allows us to avoid unverifiable assumptions on the random coefficient distribution; (*ii*) it allows us to account for extreme and/or asymmetric departures from the homogeneous model, as random coefficients are completely free to vary over the corresponding support; (*iii*) the discrete nature of the mixing distribution allows us to avoid integral approximations and considerably reduces the computational effort to derive parameter estimates.

2 Modeling alternatives

Random coefficient models represent a standard approach to model the effect of observed covariates on an outcome repeatedly observed over time. This also holds in the quantile regression framework, where the interest is in modeling the (conditional) quantiles of the outcome distribution as a function of fixed and random coefficients. To ensure flexibility and avoid unverifiable parametric assumptions on the random coefficient distribution, a specification based on the use of (dynamic) finite mixtures represent a viable strategy to adopt. According to the chosen specification, time-constant (time-varying), discrete, random coefficients are added to the model to capture time-constant (time-varying) sources of individual-specific unobserved heterogeneity.

2.1 Linear quantile regression with time-constant random coefficients

To account for sources of individual-specific unobserved heterogeneity, [1] proposed to include in a quantile regression model time-constant random coefficients without a pre-specified parametric distribution. Such a distribution is directly estimated from the data via a NonParametric Maximum Likelihood approach [NPML - 7, 8, 9]. In this framework, the NPML approach leads to the estimation of

a (quantile-specific) discrete mixing distribution defined over a finite number of (quantile-specific) locations. For a given quantile level $\tau \in (0,1)$, the model likelihood resembles that of a finite mixture of linear quantile regressions:

$$L(\cdot \mid \tau) = \prod_{i=1}^{n} \left\{ \sum_{g=1}^{G[\tau]} \left[\prod_{t=1}^{T_i} f(y_{it} \mid c_{ig} = 1; \tau) \right] \pi_g[\tau] \right\}, \tag{1}$$

where $i = 1, \ldots, n$, and $t = 1, \ldots, T_i$, index individuals and time occasions, respectively. The component label c_{ig} is the generic element of the random vector $\mathbf{c}_i = (c_{i1}, \ldots, c_{iG[\tau]})'$, with $G[\tau]$ being the number of mixture components for the the τ-th quantile level; in particular, c_{ig} is equal to one if unit i belongs to the g-th component of the finite mixture and is zero otherwise. Component probabilities are denoted by $\pi_g[\tau] = \Pr(c_{ig} = 1; \tau)$, $g = 1, \ldots, G[\tau]$, while $f(y_{it} \mid c_{ig} = 1; \tau)$ is the conditional density of the Asymmetric Laplace (AL) distribution, with skewness and scale parameters equal to τ and σ respectively, and location parameter modeled as

$$\mu_{it}[c_{ig}; \tau] = \mathbf{x}'_{it}\beta[\tau] + \mathbf{z}'_{it}\zeta_{c_{ig}}[\tau].$$

Here, $\mathbf{x}_{it}$ and $\mathbf{z}_{it}$ denote the vectors of observed covariates associated to fixed ($\beta[\tau]$) and random ($\zeta_{c_{ig}}[\tau]$) coefficients, respectively.

2.2 Linear quantile regression with time-varying random coefficients

To account for the presence of time-varying sources of individual-specific unobserved heterogeneity influencing the outcome of interest, [2] considered in the model specification time-varying random intercepts. These are assumed to evolve over time according to a homogeneous, first order, hidden Markov chain $\{S_{it}[\tau]\}$ defined over the state space $\mathscr{S}[\tau] = \{1, \ldots, m[\tau]\}$, with initial and transition probabilities given by $\delta(s_{i1}; \tau)$ and $q(s_{it} | s_{it-1}; \tau)$, respectively. Clearly, a broader specification based on general, time-varying, random coefficients can also be considered.

As for the model described above, the convenient assumption of AL-distributed responses is introduced and, for a given quantile level $\tau \in (0,1)$, model parameters are estimated by maximizing the following likelihood function:

$$L(\cdot \mid \tau) = \prod_{i=1}^{n} \left\{ \sum_{\mathbf{s}_i} \left[\delta(s_{i1}; \tau) f(y_{i1} \mid s_{i1}; \tau) \right] \left[\prod_{t=2}^{T_i} q(s_{it} | s_{it-1}; \tau) f(y_{it} \mid s_{it}; \tau) \right] \right\}. \tag{2}$$

In the above expression, $\sum_{\mathbf{s}_i}$ is a shorthand for $\sum_{s_{i1}} \cdots \sum_{s_{iT_i}}$, while $f(y_{it} \mid s_{it}; \tau)$ denotes the AL density with scale and skewness equal to τ and σ respectively, while the location parameter is modeled as

$$\mu_{it}[s_{it}; \tau] = \mathbf{x}'_{it}\beta[\tau] + \mathbf{w}'_{it}\alpha_{s_{it}}[\tau].$$

Here, $\mathbf{x}_{it}$ and $\mathbf{w}_{it}$ denote the vectors of covariates associated to fixed ($\beta[\tau]$) and random ($\alpha_{s_{it}}[\tau]$) coefficients, respectively. When looking at equation (2), we may easily recognize an dynamic extension of the likelihood reported in equation (1); that is, it represents the likelihood of a dynamic finite mixture model, where random coefficients associated to a generic individual i vary according to the hidden state he/she visits at each time occasion.

2.3 Linear quantile regression with time-constant and time-varying random coefficients

In some real data applications, both time-constant and time-varying sources of individual-specific unobserved heterogeneity may affect the outcome distribution. This makes the quantile regression models described above no longer appropriate as they account for one source at a time only. To face such situations, [10] proposed to include both types of random coefficients in the model specification. In this framework, the likelihood function is given by

$$L(\cdot \mid \tau) = \prod_{i=1}^{n} \left\{ \sum_{g=1}^{G[\tau]} \sum_{\mathbf{s}_i} \left[\delta(s_{i1};\tau) f(y_{i1} \mid s_{i1};\tau) \right] \times \right. \\ \left. \times \left[\prod_{t=2}^{T_i} q(s_{it}|s_{it-1};\tau) f(y_{it} \mid c_{ig}=1, s_{it};\tau) \right] \right\} \pi_g[\tau], \tag{3}$$

where $f(y_{it} \mid \mathbf{c}_{ig}=1, s_{it};\tau)$ denotes the AL density with location parameter modeled as

$$\mu_{it}[c_{ig}=1, s_{it};\tau] = \mathbf{x}'_{it}\beta[\tau] + \mathbf{z}'_{it}\zeta_{c_{ig}}[\tau] + \mathbf{w}'_{it}\alpha_{s_{it}}[\tau],$$

while all other quantities are defined as above.

In this framework, unobserved individual-specific features that remain constant over time may be captured thanks to the random coefficients $\zeta_{c_{ig}}[\tau]$. Similarly, sudden temporal shocks in the individual profiles, due to time-varying sources of unobserved heterogeneity may be easily captured by the random coefficients $\alpha_{s_{it}}[\tau]$ in the model. These features render therefore the proposed model more flexible and general than the alternatives described so far, at the cost of a higher computational complexity.

3 The `lqmix` R package

In this paper, we introduce the R [11] package **`lqmix`**, specifically tailored to the estimation of (dynamic) finite mixtures of linear quantile regression models. Separate functions allow to estimate the three model specifications described above, based on time-constant (1), time-varying (2), and time-constant and time-varying (3) random coefficients, respectively. Both random intercepts and random slopes are supported.

An EM algorithm is used to derive estimates in a maximum likelihood framework, even though the parametric specification for the (conditional) distribution for the responses is only introduced as a computational convenient trick to recast estimation in such a framework. Standard penalized likelihood criteria are computed to identify the optimal number of mixture components. Standard errors and confidence intervals for model parameters are obtained according to a non-parametric block-bootstrap. That is, they are obtained by re-sampling individuals and retaining the corresponding sequence of measurements to preserve within individual dependence [6]. Missingness in the responses is also taken into account, according to the implicit assumption of a Missing At Random (MAR) mechanism.

4 Concluding remarks

In this paper, the class of (dynamic) finite mixtures of quantile regression models for the analysis of longitudinal data has been explored. Besides having recently become rather popular in statistics, there is still a lack of support within the most popular statistical software. Here, we have introduced a novel and efficient R package specifically conceived for fitting and making inference on the parameters defining this class of models.

Multivariate Mixed Hidden Markov Model for joint estimation of multiple quantiles

Modello Hidden Markov Multivariato ad effetti misti per la stima congiunta di quantili condizionati

Merlo Luca, Petrella Lea and Tzavidis Nikos

Abstract This paper develops a Mixed Hidden Markov Model for joint estimation of multiple quantiles in a multivariate linear regression for longitudinal data. This method accounts for association among multiple responses and study how the relationship between dependent and explanatory variables may vary across different quantile levels of the conditional distribution of the multivariate response variable. Unobserved heterogeneity sources and serial dependence are jointly modeled through the introduction of individual-specific, time-constant random coefficients and time-varying parameters that evolve over time with a Markovian structure, respectively. Estimation is carried out via a suitable EM algorithm without parametric assumptions on the random effects distribution. We assess the empirical behaviour of the proposed methodology through the analysis of the Millennium Cohort Study data.

Abstract Questo lavoro sviluppa un modello di Markov nascosto multivariato ad effetti misti per la stima congiunta di quantili marginali condizionati associati a variabili risposta multivariate, nell'ambito di una regressione lineare per dati longitudinali. La metodologia proposta consente di tenere conto dell'associazione esistente tra le variabili risposta e intende studiare come tale struttura di associazione varia quando si considerano diversi quantili della distribuzione condizionata della variabile risposta. Le fonti di eterogeneità non osservate, costanti e variabili nel tempo, vengono modellate congiuntamente introducendo effetti casuali costanti e coefficienti che variano nel tempo secondo una catena di Markov latente. Key words: Longitudinal data, Mixed Hidden Markov Model, Multivariate Asymmetric Laplace Distribution, Quantile Regression, Random Effects Model

1 Introduction

Ever since quantile regression was first introduced in the seminal work of [6], it has attracted researches' and practitioners' attention. It provides a way to model the conditional quantiles of a response variable with respect to a set of covariates in order to have a more complete picture of the entire conditional distribution compared to the classical mean regression. In a univariate quantile regression analysis, the likelihood based inferential approach to estimate the parameters relies on the introduction of the Asymmetric Laplace (AL) distribution: the maximization of the likelihood associated with the AL density is equivalent (in terms of parameter estimates) to the minimization of the quantile loss function of [6]. When multivariate response variables are concerned, the existing literature on quantile regression is less extensive due to the fact that there is not a unique definition of quantile for a multivariate random variable because there is no "natural" ordering in a p-dimensional space, for $p > 1$. Hence, the concept of multivariate quantile is still a debatable issue (see [7] and the references therein for relevant studies). Recently, [12] generalized the AL distribution inferential approach of the univariate case to a multivariate framework by using the Multivariate Asymmetric Laplace (MAL) distribution defined in [8]. By using the MAL distribution as likelihood based inferential tool, the authors sidestep the problem of defining a multivariate quantile, and meanwhile they implement a joint estimation of the marginal conditional quantiles of a multivariate response variable, taking into account for possible correlation among marginals.

When dealing with longitudinal data, because measurements recorded on the same individuals are likely correlated, the potential association between dependent observations should be taken into account in order to provide correct inferences. In such cases, random effect models have been proposed to accommodate for time-constant, within-subject correlation and between subject heterogeneity (see [10, 5]). However, when the assumption of time-constant random coefficients does not hold, adopting such model specification may lead to biased parameter estimates (see [3]). To account for serial heterogeneity, [4] suggested the use of Hidden Markov Models (HMM). The key assumption is the conditional independence of the response variables given a latent process that follows a Markov chain on a finite number of states. In this context, the application of HMMs is well justified by their versatility and mathematical tractability (see [11]).

The purpose of this article is to extend the work of [12] by introducing a Mixed Hidden Markov Model (MHMM) to the longitudinal data setting to account for the correlation between responses. The MHMM (see [2]) encompasses Generalized Linear Mixed Models and HMMs as it accommodates time-constant and time-varying sources of random variation. Time-constant unobserved heterogeneity is described via individual-specific random coefficients while temporal effects are captured through state-specific effects that evolve over time depending on a hidden Markov chain. In order to prevent inconsistent parameter estimates due to misspecification of the random effects distribution, we adopt the Non-Parametric Maximum Likelihood (NPML) approach of [9] in which it is left unspecified and approximated by a discrete finite mixture distribution. Model parameters are estimated through maximum likelihood by using the Expectation-Maximization (EM) algorithm while standard error estimates rely on bootstrap resampling. From a computational perspective, we provide an efficient version of the EM algorithm with M-step updates in closed form for all model parameters.

2 Methodology

Let $\mathbf{Y}_{it} = (Y_{it}^{(1)}, \ldots, Y_{it}^{(p)})$ be a continuous p-variate response variable vector and $\mathbf{X}_{it} = (X_{it}^{(1)}, \ldots, X_{it}^{(k)})$ be a k-dimensional vector of explanatory variables for every subject $i = 1, \ldots, N$ and time occasion $t = 1, \ldots, T_i$. Given p quantile indexes $\tau = (\tau_1, \ldots, \tau_p)$, with $\tau_j \in (0,1)$, $j = 1, \ldots, p$, let $S_{it}(\tau)$, $i = 1, \ldots, N$, $t = 1, \ldots, T_i$ be a homogeneous, first-order, hidden Markov chain defined over a discrete states space $\mathscr{S} = \{1, \ldots, M\}$ with initial and transition probabilities denoted by $\mathbf{q} = (q_1, \ldots, q_M)$ and $\mathbf{Q} = \{q_{jk}\}$ over $\mathscr{S} \times \mathscr{S}$, respectively. Finally, let $\mathbf{b}_i(\tau)$ be a time-constant, subject-specific, random effects matrix having distribution $f_{\mathbf{b}}(\cdot \mid \tau)$ which, as they are meant to capture different unobserved characteristics, is independent of the hidden Markov chain, $S_{it}(\tau)$, and where $\mathbb{E}(\mathbf{b}_i(\tau)) = 0$ is used for parameter identifiability. We assume that the τ_j-th quantile of each of the j-th components of $\mathbf{Y}_{it}$ can be modeled as a function of some explanatory variables. Let $\beta(\tau) = (\beta_1(\tau), \ldots, \beta_p(\tau))$ be the $k \times p$ matrix of unknown regression coefficients. Then, the multivariate Mixed Hidden Markov Model (MHMM) is defined as follows:

$$\mathbf{Y}_{it} = \mathbf{X}_{it}\beta(\tau) + \mathbf{Z}_{it}\mathbf{b}_i(\tau) + \mathbf{W}_{it}\alpha_{s_{it}}(\tau) + \varepsilon_{s_{it}}(\tau), \tag{1}$$

where $\mathbf{Z}_{it}$ is a subset of $\mathbf{X}_{it}$, $\mathbf{W}_{it}$ is a further subset of $\mathbf{X}_{it}$ whose effects are assumed to vary over time, $\varepsilon_{s_{it}}(\tau)$ denotes a p-dimensional vector of error terms with univariate component-wise quantiles (at fixed levels $\tau_1, .., \tau_p$, respectively) equal to zero and where the coefficients matrix $\alpha_{s_{it}}(\tau)$ evolves over time according to the hidden Markov chain, $S_{it}(\tau)$, and takes one of the values in the set $\{\alpha_1(\tau), \ldots, \alpha_M(\tau)\}$.

Our objective is to provide joint estimation of the p marginal conditional quantiles of $\mathbf{Y}_{it}$ taking into account for potential correlation among the dependent variables. Conditional on the hidden state occupied at time t, $S_{it}(\tau)$, and on the

individual-specific random coefficients, $\mathbf{b}_i(\tau)$, observations from the same individual are independent and the following equality holds:

$$f_{\mathbf{Y}|S,\mathbf{b}}(\mathbf{y}_{it} \mid \mathbf{y}_{i1:t-1}, s_{i1:t}, \mathbf{b}_i, \tau) = f_{\mathbf{Y}|S,\mathbf{b}}(\mathbf{y}_{it} \mid s_{it}, \mathbf{b}_i, \tau), \tag{2}$$

where $\mathbf{y}_{i1:t-1}$ represents the history of the responses for the i-th subject up to time $t-1$ and $s_{i1:t}$ is the individual sequence of states up to time t.

In order to derive maximum likelihood estimates for the regression model in (1), we consider the Multivariate Asymmetric Laplace (MAL) distribution, $\mathscr{MAL} \sim (\mu_{it}, \mathbf{D}\tilde{\xi}, \mathbf{D}\Sigma\mathbf{D})$ (see [8]), whose conditional density function is given by:

$$f_{\mathbf{Y}|S,\mathbf{b}}(\mathbf{y}_{it} \mid s_{it}, \mathbf{b}_i, \tau) = \frac{2\exp\left\{(\mathbf{y}_{it}-\mu_{it})'\mathbf{D}^{-1}\Sigma^{-1}\tilde{\xi}\right\}}{(2\pi)^{p/2}|\mathbf{D}\Sigma\mathbf{D}|^{1/2}} \left(\frac{\tilde{m}_{it}}{2+\tilde{d}}\right)^{\nu/2} K_{\nu}\left(\sqrt{(2+\tilde{d})\tilde{m}_{it}}\right), \tag{3}$$

where the location parameter μ_{it} is defined by the linear model $\mu_{it} = \mu(s_{it}, \mathbf{b}_i, \tau) = \mathbf{X}_{it}\beta(\tau) + \mathbf{Z}_{it}\mathbf{b}_i(\tau) + \mathbf{W}_{it}\alpha_{s_{it}}(\tau)$, $\mathbf{D}\tilde{\xi} \in \mathbb{R}^p$ is the scale (or skew) parameter with $\mathbf{D} = \text{diag}[d_1, ..., d_p]$, $d_j > 0$ and $\tilde{\xi} = [\tilde{\xi}_1, \tilde{\xi}_2, ..., \tilde{\xi}_p]'$ having generic element $\tilde{\xi}_j = \frac{1-2\tau_j}{\tau_j(1-\tau_j)}$, $j = 1, ..., p$. $\tilde{\Sigma}$ is a $p \times p$ positive definite matrix such that $\Sigma = \Lambda\Psi\Lambda$, with Ψ being a correlation matrix and $\Lambda = \text{diag}[\sigma_1, ..., \sigma_p]$, with $\sigma_j^2 = \frac{2}{\tau_j(1-\tau_j)}$, $j = 1, ..., p$. Moreover, $\tilde{m}_{it} = (\mathbf{y}_{it} - \mu_{it})'(\mathbf{D}\Sigma\mathbf{D})^{-1}(\mathbf{y}_{it} - \mu_{it})$, $\tilde{d} = \tilde{\xi}'\Sigma\tilde{\xi}$, and $K_{\nu}(\cdot)$ denotes the modified Bessel function of the third kind with index parameter $\nu = (2-p)/2$. The constraints imposed on $\tilde{\xi}$ and Λ represent necessary conditions for model identifiability for any fixed quantile level $\tau_1, ..., \tau_p$ and guarantee that $\mu_{it}^{(j)}$ is the τ_j-th conditional quantile function of $Y_{it}^{(j)}$ given $S_{it}(\tau)$ and $\mathbf{b}_i$, for $j = 1, \ldots, p$.

It is worth noting that our methodology reduces to the (multivariate) linear quantile Hidden Markov Model of [4] when $\mathbf{W}_{it} = \mathbf{1}$ and $\mathbf{b}_i(\tau) = \mathbf{0}$ for all $i = 1, \ldots, N$ and $t = 1, \ldots, T_i$; whereas it reduces to the (multivariate) linear quantile Mixed Model of [10] when there is only one state of the hidden Markov chain, i.e. $M = 1$.

In the case of a continuous parametric distribution for the random effects, the likelihood for the model in (1)-(3) involves the integration over the distribution of the random effects, $f_{\mathbf{b}}(\cdot \mid \tau)$. Such integral cannot be solved analytically and maximum likelihood parameter estimates can be obtained through numerical integration techniques. In addition parametric assumptions on the distribution of the random coefficients can be too restrictive and misspecification of the mixing distribution can lead to biased parameter estimates. For these reasons, we may rely on the Nonparametric Maximum Likelihood (NPML) estimation theory of [9]: $f_{\mathbf{b}}(\cdot \mid \tau)$ is left unspecified and we approximate it by using a discrete distribution on $G < N$ locations, $\mathbf{b}_g(\tau)$, with associated probabilities defined by $\pi_g(\tau) = \Pr(\mathbf{b}_i(\tau) = \mathbf{b}_g(\tau))$, $i = 1, ..., N$ and $g = 1, ..., G$. That is, $\mathbf{b}_i(\tau) \sim \sum_{g=1}^{G} \pi_g(\tau)\delta_{\mathbf{b}_g}(\tau)$ where δ_{θ} is a one-point distribution putting a unit mass at θ. In this case, if we suppress the index τ to simplify the notation, the observed data likelihood of the model has the form:

$$L(\Phi_\tau) = \prod_{i=1}^{N} \prod_{g=1}^{G} \sum_{\mathscr{S}^{T_i}} \left\{ \left[\prod_{t=1}^{T_i} f_{\mathbf{Y}|S,\mathbf{b}}(\mathbf{y}_{it} \mid s_{it}, \mathbf{b}_g) \right] q_{s_{i1}} \prod_{t=2}^{T_i} q_{s_{it-1}s_{it}} \right\} \pi_g, \tag{4}$$

where $\Phi_\tau = (\beta, \mathbf{D}, \Psi, \mathbf{b}_1, \ldots, \mathbf{b}_G, \pi_1, \ldots, \pi_G, \alpha_1, \ldots, \alpha_M, \mathbf{q}, \mathbf{Q})$ denotes the vector of model parameters and $f_{\mathbf{Y}|S,\mathbf{b}}(\mathbf{y}_{it} \mid s_{it}, \mathbf{b}_g)$ represents the response distribution of unit i of being in the hidden state s_{it} at time t and of belonging to the g-th component of the finite mixture, which is assumed to have a MAL density in (3) with location parameter given by $\mu_{it} = \mu(s_{it}, \mathbf{b}_g, \tau) = \mathbf{X}_{it}\beta(\tau) + \mathbf{Z}_{it}\mathbf{b}_g(\tau) + \mathbf{W}_{it}\alpha_{s_{it}}(\tau)$.

2.1 Estimation

Given the representation in (4), let us denote by w_{ig} the indicator variable that is equal to 1 if the i-th unit belongs to the g-th component of the finite mixture, and 0 otherwise. Similarly let $u_{it\,j}$ be equal to 1 if unit i is in state j at time t and 0 otherwise; let $v_{it\,jk}$ be equal to 1 if unit i is in state j at time $t-1$ and in state k at time t, and 0 otherwise. Finally, we denote by $z_{it\,jg}$ the indicator of the i-th individual being in state j at time t and coming from the g-th component of the mixture. The log-likelihood for the complete data has the following form:

$$\ell_c(\Phi_\tau) = \sum_{i=1}^{N} \left\{ \sum_{g=1}^{G} w_{ig} \log \pi_g + \sum_{j=1}^{M} u_{i1\,j} \log q_j + \sum_{t=2}^{T_i} \sum_{j=1}^{M} \sum_{k=1}^{M} v_{it\,jk} \log q_{jk} + \sum_{t=1}^{T_i} \sum_{j=1}^{M} \sum_{g=1}^{G} z_{it\,jg} \log f_{\mathbf{Y}|S,\mathbf{b}}(\mathbf{y}_{it} \mid S_{it} = j, \mathbf{b}_g) \right\}. \tag{5}$$

In the E-step of the algorithm, the presence of the unobserved indicator variables $w_{ig}, u_{it\,j}, v_{it\,jk}$ and $z_{it\,jg}$ is handled by taking their conditional expectation given the observed data and the current parameter estimates. Calculation of such quantities may be addressed via an adaptation of the forward and backward variables; see [14]. Subsequently, the M-step solutions are updated by maximizing the conditional expectation of (5) given the observed data and the current parameter estimates with respect to Φ_τ and solving the M-step equations. We derive closed form update expressions of the model parameters, based on the mixture representation of the MAL distribution. Finally, the E- and M-steps are alternated until convergence. To avoid convergence to local maxima, for each value of the pair (G, M), we initialize model parameters using a multi-start strategy.

3 Application

To investigate the behaviour of the proposed methodology, we analyse the data from the Millennium Cohort Study (MCS) which has been studied by [1] and [13] in the context of M-quantile regression with time-constant random-effects. The MCS is a longitudinal survey which aims at better addressing the effects of social disadvan-

tage on children's outcomes in the UK. The two outcomes of interest, emotional problems and behavioural problems, measured by the SDQ internalizing score and by the SDQ externalizing score, respectively, were collected at ages 3, 5 and 7 years. A description of the included demographic and socio-economic covariates can be found in [13]. We used the proposed model with constant random intercepts and time-varying random slopes specified for age. A summary of the results when $\tau = (0.25, 0.25), \tau = (0.50, 0.50)$ and $\tau = (0.75, 0.75)$ is reported in Table 1. The estimated regression coefficients are consistent with those obtained by [13]. In particular, we selected a number of mixture components equal to $G = (3,5,5)$ at quantile levels $0.25, 0.50$ and 0.75 respectively, and we identified a decreasing number of hidden states $M = (5,4,3)$ as the analyzed quantile level increases.

Recent methodological advances in finite mixture modeling with applications (CLADAG-SIS)

Aggregating Gaussian mixture components
Come aggregare le componenti gaussiane di un miscuglio

Roberto Rocci[1]

Abstract The finite mixture of Gaussians is a well-known model frequently used to classify a sample of observations. It considers the sample as drawn from a heterogeneous population where each subpopulation, cluster, is Gaussian and corresponds to one component of the mixture. Whenever such assumption is false, the model may use two or more Gaussians to describe a single cluster. In this case, the researcher has the problem of how to identify the clusters starting from the estimated components. This work proposes to solve this problem by aggregating the components in clusters by optimizing an appropriate criterion based on their posterior probabilities.

Abstract *I modelli miscuglio di gaussiane sono spesso utilizzati nell'analisi dei gruppi. L'idea è quella di considerare la popolazione che ha generato il campione come formata da sottopopolazioni, gruppi, ognuna ben descritta da una componente del miscuglio. Quando questa assunzione risulta falsa, il modello tende ad utilizzare due o più componenti per rappresentare un unico gruppo, creando così il problema di come identificare i gruppi a partire dalle componenti stimate. In questo lavoro proponiamo di risolvere il problema aggregando le componenti in modo da ottimizzare un criterio basato sulle loro probabilità a posteriori.*

Key words: Unsupervised Classification, Finite mixtures of Gaussians, Within and Between deviances.

1 Introduction

In cluster analysis, or unsupervised classification, quite frequently observations are classified by using a finite mixture of Gaussians (see for example Hennig et al., 2015). The idea is to consider the population as heterogeneous, i.e. formed by sub-populations, clusters, which are well represented by the mixture components.

[1]Department of Statistical Science, Sapienza University of Rome; email: roberto.rocci@uniroma1.it

Such approach works well in practice unless one or more subpopulations have a distribution different from, or not well approximated by, a single component of the mixture. In this case, the model may use more than one component, i.e. a sub-mixture of two or more Gaussians, to describe a single cluster destroying the one to one correspondence between clusters and components. This problem is well recognized in practice and several solutions have been proposed.

The first idea is to assume for each component a functional form that is more flexible than the Gaussian (see McNicholas, 2016, for an excellent review about this approach). This solves the problem in many cases in practice. However, it cannot be considered as the definitive solution because even in this case we cannot exclude that more than one component could be necessary to represent a cluster. This derives from the identifiability of the finite mixture model. For example, a cluster that is a finite mixture of two components cannot be represented by only one and vice versa.

A different idea comes up by observing that, if the mixture fits well the data, then the information about the clustering structure is contained in the estimated model and it can be recovered by aggregating, in an opportune way, the components. This allow us to represent a very wide variety of possible distributions for the clusters and to relax the, usually made and sometimes restrictive, assumption of same functional form for the distribution of each cluster. Technically, the model would become a finite mixture of finite mixtures of Gaussians, i.e. a finite mixture where each component is a finite mixture of Gaussians. Unfortunately, such a model is not identified because different aggregations of the components give the same population distribution. The estimation is then possible only by using some constraints on model parameters making the model identified (see for example Di Zio et al. 2007), or by introducing a criterion determining the aggregation. On the latter approach, there are several proposals in the literature where the Gaussian components are hierarchically aggregated into clusters on the basis of a measure of proximity (see Hennig 2010, Comas-Cufi et al. 2017 and references there in for some examples). However, such methods are optimal only locally. They establish what is the best way to merge two components not what is the best way to aggregate, say G, components into, say K, clusters. It is not specified how the "internal cohesion" and "external isolation" (Cormack, 1971) are measured, related and optimized (e.g. total deviance = within deviance + between deviance in K-means). To achieve this goal a partitioning method should be adopted but, as far as we know, only Li (2005) considered a partitioning approach based on the application of the K-means on the mean components. This proposal makes clear the aforementioned aspects but it is based on a measure of dissimilarity between components depending only on their locations. Our purpose is to go beyond the limits of this proposal.

In our paper we are going to propose a new method to aggregate the Gaussian components of a finite mixture model making clear how the identified partition optimize the "internal cohesion" and "external isolation" of the clustering. The plan of the paper is the following. Our proposal, based on the use of the Kullback Leibler divergence to measure the dissimilarity among components, will be presented in section 2. In section 3, some insights on how to extend the technique are presented with particular reference to other dissimilarity measures and its hierarchical version.

2 Partitioning Gaussian components by the Kullback-Liebler divergence: the KL-components method

The finite mixture of Gaussians (McLachlan & Peel, 2000) is based on the assumption that the probability density of a multivariate observation is of the form

$$f(\mathbf{x}_i;\Theta) = \sum_{g=1}^{G} \pi_g f_g(\mathbf{x}_i;\vartheta_g)\,. \tag{1}$$

where $\mathbf{x}_i = [x_{i1}, x_{i2},\ldots,x_{iJ}]'$ is a random vector of J variables sampled from a population parametrized by $\Theta = \{\vartheta_1,\vartheta_2,\ldots,\vartheta_G, p_1,p_2,\ldots,p_G\}$, which consists of G groups, or subpopulations, in proportions $\pi_1, \pi_2,\ldots, \pi_G$, where π_g is the prior probability to sample one observation from group g. The density $f_g(\mathbf{x}_i;\vartheta_g)$ of $\mathbf{x}_i$ in the g^{th} group is multivariate normal (Gaussian). Let $\mathbf{x}_1$, $\mathbf{x}_2$, …, $\mathbf{x}_n$ be a sample of n independent and identically distributed observations, we can use the above model to classify the observations into G classes. First, we compute the posterior probabilities

$$\mathrm{P}(g \mid \mathbf{x}_i) = \pi_{g|i} = \pi_g f_g(\mathbf{x}_i;\vartheta_g) \Big/ \sum_{h=1}^{G} \pi_h f_h(\mathbf{x}_i;\vartheta_h)\,, \tag{2}$$

then, we use the MAP rule (Maximum A Posterior probability) to assign the observations to the Gaussian components. Usually, the parameter Θ and the number of components G are unknown and estimated from the data.

Our method, named the KL-components technique, originates from the observation that two components, say g and h, are equal, with respect to the data, if and only if their posterior probabilities are proportional. In formulas

$$g = h \Leftrightarrow \boldsymbol{\pi}_g = \mathrm{P}(g \mid \mathbf{x}_i) / \pi_g = \mathrm{P}(h \mid \mathbf{x}_i) / \pi_h = \boldsymbol{\pi}_h\,,\ g,h = 1,\ldots,G \text{ and } i = 1,\ldots,n. \tag{3}$$

It seems quite natural to measure the dissimilarity between components as a function of the diversity between the normalized posteriors, say profiles. In particular, we investigate the use of the Kullback-Leibler (KL) divergence

$$\mathrm{KL}(\boldsymbol{\pi}_g, \boldsymbol{\pi}_h) = \frac{1}{n}\sum_{i=1}^{n} \frac{\pi_{g|i}}{\pi_g} \log\left(\frac{\pi_{g|i}}{\pi_g}\frac{\pi_h}{\pi_{h|i}}\right) = \frac{1}{n}\sum_{i=1}^{n} \frac{f_g(\mathbf{x}_i)}{f(\mathbf{x}_i)} \log\left(\frac{f_g(\mathbf{x}_i)}{f_h(\mathbf{x}_i)}\right), \tag{4}$$

which can be considered an estimate of

$$\mathrm{E}\left(\frac{f_g(\mathbf{x})}{f(\mathbf{x})} \log\left(\frac{f_g(\mathbf{x})}{f_h(\mathbf{x})}\right)\right) = \int f_g(\mathbf{x}) \log\left(\frac{f_g(\mathbf{x})}{f_h(\mathbf{x})}\right) d\mathbf{x}\,, \tag{5}$$

i.e. the KL divergence between the two components. It is well known, and evident from formula (5), that the KL divergence is not symmetric. However, this is not a problem for us because we use it to define a sort of deviance rather than to measure the dissimilarity between two components. In particular, we define the Total deviance as the weighted sum of the KL divergences among the profiles of the mixture components and their barycenter. By noting that the latter quantity is

$$\sum_{g=1}^{G} \pi_g \frac{\pi_{g|i}}{\pi_g} = 1, \quad i = 1, 2, ..., n, \tag{6}$$

the Total deviance results to be

$$\mathrm{D}_T = \sum_{g=1}^{G} \pi_g \mathrm{KL}(\boldsymbol{\pi}_g, \mathbf{1}) = \frac{1}{n} \sum_{g=1}^{G} \sum_{i=1}^{n} \pi_{g|i} \log\left(\frac{\pi_{g|i}}{\pi_g}\right). \tag{7}$$

Given a partition of the G components into K clusters according to the binary row stochastic membership matrix $\mathbf{U} = [u_{gk}]$, where u_{gk} is equal to 1 if component g belong to cluster k and 0 otherwise, we note that the posteriors probabilities of cluster k are

$$p_{k|i} = \sum_{g=1}^{G} u_{gk} \pi_{g|i}, \tag{8}$$

the priors are

$$p_k = \sum_{g=1}^{G} u_{gk} \pi_g = \sum_{g=1}^{G} u_{gk} \frac{1}{n} \sum_{i=1}^{n} \pi_{g|i} = \frac{1}{n} \sum_{i=1}^{n} \sum_{g=1}^{G} u_{gk} \pi_{g|i} = \frac{1}{n} \sum_{i=1}^{n} p_{k|i}, \tag{9}$$

and the barycenter is

$$\frac{1}{\sum_{g=1}^{G} u_{gk} \pi_g} \sum_{g=1}^{G} u_{gk} \pi_g \frac{\pi_{g|i}}{\pi_g} = \frac{1}{p_k} \sum_{g=1}^{G} u_{gk} \pi_{g|i} = \frac{p_{k|i}}{p_k}, \quad i = 1, 2, ..., n. \tag{10}$$

According to (7), the Within deviance is defined as

$$\mathrm{D}_W(\mathbf{U}) = \sum_{k,g} u_{gk} \pi_g \mathrm{KL}(\boldsymbol{\pi}_g, \mathbf{p}_k) = \sum_{k,g} u_{gk} \pi_g \frac{1}{n} \sum_{i=1}^{n} \frac{\pi_{g|i}}{\pi_g} \left[\log\left(\frac{\pi_{g|i}}{\pi_g}\right) - \log\left(\frac{p_{k|i}}{p_k}\right) \right]. \tag{11}$$

Formula (11) suggests in a very natural way a partitioning method based on its minimization with respect to **U**. The minimization of (11) guarantees the maximum internal cohesion of the clusters. However, we should ask: what about the external

isolation? To give an answer to this question, we should find a way to measure the external isolation, i.e. the cluster separation. In coherence with (7), we can define the Between deviance as the weighted sum of the KL divergences among the cluster profiles and their barycenter, that is the vector of ones even in this case. In formulas

$$\mathrm{D}_B(\mathbf{U}) = \sum_{k=1}^{K} p_k \mathrm{KL}(\mathbf{p}_k, \mathbf{1}) = \frac{1}{n} \sum_{k=1}^{K} \sum_{i=1}^{n} p_{k|i} \log\left(\frac{p_{k|i}}{p_k}\right). \tag{12}$$

Once again, we have a formula suggesting, in a very natural way, a partitioning method corresponding to the maximization of (12) with respect to **U**. However, it is possible to show that, as in the case of *K*-means, the minimization of D_W is equivalent to the maximization of D_B because the sum of the two is constant and equal to D_T. The Within deviance (11) can be minimized by using a coordinate descent algorithm that minimize (11) with respect to **U** and the centroids $\mathbf{p}_1$, $\mathbf{p}_2$, …, $\mathbf{p}_K$.

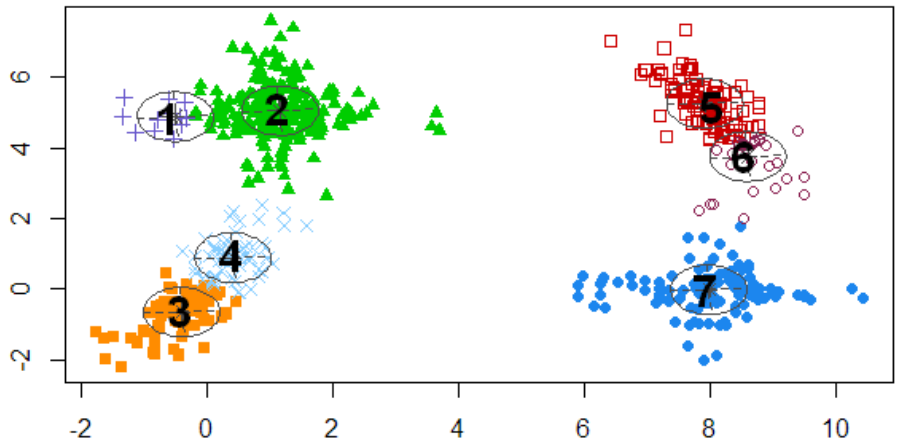

Figure 1: Simulated sample from a 6-component mixture along with the estimated classification in 7 components given by a homoscedastic mixture of Gaussians.

In order to check if the proposed method works properly, we considered the simulated dataset analysed in section 4.1 of Baudry et al. (2010). It is a sample from a finite mixture of 6 bivariate Gaussians. In Figure 1, the data is shown along with the classification in 7 components given by a homoscedastic mixture of Gaussians where the number of components have been selected by using BIC and the parameters estimated by maximum likelihood. Looking at the figure, it is not clear if the number of true clusters is 2 or 4 and then we considered both. The algorithm has been run for $K = 2$ and 4, from several different starting points. The technique aggregated the 7 components as {1,2,3,4} and {5,6,7} for $K = 2$ and as {1,2}, {3,4}, {5,6} and {7} for $K = 4$. From Figure 1, it is clear that in both cases, KL-components has been able to find the correct aggregation of the components.

3 Final comments and extensions

The method here presented has been extended to the use of divergences different from the KL. In particular, we have proven that all the properties of the KL-components technique shown in the previous section do hold if a Bregman divergence (Bregman, 1967) is used. The proofs are not reported here for the sake of space.

In practical applications, especially when the clusters of components are not well separated, the coordinate descent algorithm quite often remains trapped into a local optimum. Frequently, this problem can be simply solved by starting several times the algorithm from different random partitions. However, there is still the need to have a method able to produce good rational, non random, starting points. To this end, a hierarchical clustering procedure has been proposed, not shown here for the sake of space, where at each step two clusters are merged by minimizing the increment of Within deviance. The hierarchical solution is then used to start the partitioning algorithm.

The aim of our method is not to find the true number of clusters, even if it can help us in this task exploring the possible components aggregations. In this respect, further insights can be obtained by looking at the plot of D_W vs K, computing the Calinski-Harabasz index (1974) or any other index based on D_W and/or D_B.

We conclude by noting that the results presented here do not use the assumption that the components of the mixture are normally distributed. It follows that the proposed techniques can be used to cluster components that are not Gaussians.

Local and overall coefficients of determination for mixtures of generalized linear models

Coefficienti di determinazione locali e globali per misture di regressioni lineari

Roberto Di Mari, Salvatore Ingrassia, and Antonio Punzo

Abstract In this paper we define deviance-based local and overall coefficients of determination for mixtures of generalized linear models whose parameters are estimated via the maximum likelihood approach. The aim is to summarize how well the model fits the data both in each group and taken as a whole.

Abstract *In questo lavoro definiamo coefficienti di determinazione locali e globali, basati sulla devianza, per le misture di modelli lineari generalizzati i cui parametri sono stimati attraverso l'approccio della massima verosimiglianza. L'obiettivo è quello di valutare l'adattamento del modello ai dati sia a livello di singolo gruppo che a livello globale.*

Key words: Cluster validation, Mixtures of regressions, Model-based clustering, Maximum likelihood.

1 Introduction

Local and overall coefficients of determination have been first proposed in [3] for mixtures of linear (Gaussian) regressions to take into account different variability within groups. In this paper, we generalize these results to mixtures of generalized linear models. The proposal is based on one of the definitions of coefficient of determination given in [1].

In generalized linear models [5] a monotone and differentiable link function $h(\cdot)$ is introduced to relate the expected value μ of a random response variable Y with respect to a vector $\mathbf{X}$ of J covariates through the relation $h(\mu) = \beta_0 + \beta_1'\mathbf{x}$. Assume now that the regression of Y on $\mathbf{X}$ varies across the k levels (groups or clusters) of

Roberto Di Mari · Salvatore Ingrassia · Antonio Punzo
Department of Economics and Business, University of Catania
Corso Italia 55, 95129 Catania, Italy, e-mail: roberto.dimari@unict.it, s.ingrassia@unict.it, antonio.punzo@unict.it

a categorical latent variable G taking values in $\{1,2,\ldots,k\}$. These data can be conveniently modeled by finite mixtures mixtures of regressions with fixed covariates characterized by the following conditional density function

$$p(y|\mathbf{x};\psi) = \sum_{g=1}^{k} \pi_g q(y|\mathbf{x};\theta_g), \tag{1}$$

where $q(y|\mathbf{x};\theta_g)$ is a component specific density from the exponential family depending on some parameter vector θ_g, with π_g being the mixing weight, where $\pi_g > 0$ and $\sum_{g=1}^{k} \pi_g = 1$, see e.g. [7]. Given a random sample $(\mathbf{x}_1', y_1)', \ldots, (\mathbf{x}_n', y_n)'$ of $(\mathbf{X}', Y)'$, for a fixed number k of groups, the ML estimates of the parameters are typically obtained via the expectation-maximization (EM) algorithm.

2 A deviance-based coefficient of determination R^2

In [1] some R-squared measures, say R^2, are defined for count data regression models based on the scaled deviance $D(\mathbf{y};\widehat{\mu}) = 2\{\mathscr{L}(\mathbf{y};\mathbf{y}) - \mathscr{L}(\widehat{\mu};\mathbf{y})\}$, where $\mathscr{L}(\mathbf{y};\mathbf{y})$ and $\mathscr{L}(\widehat{\mu};\mathbf{y})$ are the log-likelihoods computed on the data $\mathbf{y}$ and on the fitted data $\widehat{\mu}$, respectively. Then, considering the decomposition $\mathscr{L}(\mathbf{y};\mathbf{y}) - \mathscr{L}(\bar{\mathbf{y}};\mathbf{y}) = \{\mathscr{L}(\mathbf{y};\mathbf{y}) - \mathscr{L}(\widehat{\mu};\mathbf{y})\} + \{\mathscr{L}(\mathbf{y};\mathbf{y}) - \mathscr{L}(\bar{\mathbf{y}};\mathbf{y})\}$, the coefficient of determination has been defined as

$$R^2 = 1 - \frac{2\{\mathscr{L}(\mathbf{y};\mathbf{y}) - \mathscr{L}(\widehat{\mu};\mathbf{y})\}}{2\{\mathscr{L}(\mathbf{y};\mathbf{y}) - \mathscr{L}(\bar{\mathbf{y}};\mathbf{y})\}} = \frac{\mathscr{L}(\widehat{\mu};\mathbf{y}) - \mathscr{L}(\bar{\mathbf{y}};\mathbf{y})}{\mathscr{L}(\mathbf{y};\mathbf{y}) - \mathscr{L}(\bar{\mathbf{y}};\mathbf{y})}. \tag{2}$$

In this paper, we extend this measure (2) to mixture of generalized regression models. For simplicity, only the Gaussian and the Poisson cases are here presented.

The Gaussian case. Consider first mixture models with Gaussian components. Thus, conditional on $G = g$ (for $g = 1,\ldots,k$) assume now that $Y|\mathbf{x}$ is Gaussian with parameters $\mu(\mathbf{x};\beta_g)$ and σ_g^2:

$$q(y|\mathbf{x};\beta_g,\sigma_g^2) = \phi(y;\mu(\mathbf{x};\beta_g),\sigma_g^2)$$

where $\beta_g = (\beta_{0g}, \beta_{1g}')'$ is a vector of $J+1$ component specific regression coefficients including the intercept, and $\mu(\mathbf{x};\beta_g) = \beta_{0g} + \beta_{1g}'\mathbf{x}$. Then the maximum likelihood equation is given by

$$\begin{aligned}\mathscr{L}(\psi) &= \sum_{g=1}^{k}\sum_{i=1}^{n} z_{ig} \ln \pi_g + \sum_{g=1}^{k}\sum_{i=1}^{n} z_{ig} \ln\left\{\phi\left[y_i;\mu(\mathbf{x}_i;\beta_g),\sigma_g^2\right]\right\} \\ &= \sum_{g=1}^{k}\sum_{i=1}^{n} z_{ig} \ln \pi_g + \ell(\beta,\sigma^2)\end{aligned} \tag{3}$$

respectively, where $z_{ig} = 1$ if $(\mathbf{x}_i', y_i)'$ comes from component g and $z_{ig} = 0$ otherwise, $\ell(\beta, \sigma^2) = \sum_{g=1}^{k} \sum_{i=1}^{n} z_{ig} \ln \left\{ \phi \left[y_i; \mu(\mathbf{x}_i; \beta_g), \sigma_g^2 \right] \right\}$, $\beta = (\beta_1', \ldots, \beta_k')'$ and $\sigma^2 = (\sigma_1^2, \ldots, \sigma_k^2)'$. In [3] the classical total sum of squares decomposition for regression models is generalized when data come from a heterogeneous population and they are modeled through a mixture of regressions with Gaussian components. This relation can be generalized as follows. Let us focus on the model term in the loglikelihood function and set

$$\ell(\mu, \sigma^2; \mathbf{y}) = \sum_{g=1}^{k} \sum_{i=1}^{n} z_{ig} \left[-\frac{1}{2} \ln \sigma_g^2 - \frac{(y_i - \mu_{i,g})^2}{2\sigma_g^2} \right], \tag{4}$$

where $\mu_{i,g} = \mu(\mathbf{x}_i; \beta_g) = \beta_{0g} + \beta_{1g}' \mathbf{x}_i$ and the constant term has been omitted in (4). Once the model has been fitted to the given data and parameters have been estimated, let us introduce the following quantities:

$$\begin{aligned}
\ell(\widehat{\mu}, \sigma^2; \mathbf{y}) &= \sum_{g=1}^{k} \sum_{i=1}^{n} z_{ig} \left[-\frac{1}{2} \ln \widehat{\sigma}_g^2 - \frac{(y_i - \widehat{\mu}_{i,g})^2}{2\widehat{\sigma}_g^2} \right] \\
\ell(\mathbf{y}, \widehat{\sigma}^2; \mathbf{y}) &= \sum_{g=1}^{k} \sum_{i=1}^{n} z_{ig} \left[-\frac{1}{2} \ln \widehat{\sigma}_g^2 - \frac{(y_i - y_i)^2}{2\widehat{\sigma}_g^2} \right] = \sum_{g=1}^{k} \sum_{i=1}^{n} z_{ig} \left[-\frac{1}{2} \ln \widehat{\sigma}_g^2 \right] \\
\ell(\bar{\mathbf{y}}, \widehat{\sigma}^2; \mathbf{y}) &= \sum_{g=1}^{k} \sum_{i=1}^{n} z_{ig} \left[-\frac{1}{2} \ln \widehat{\sigma}_g^2 - \frac{(y_i - \bar{y})^2}{2\widehat{\sigma}_g^2} \right]
\end{aligned}$$

and consider the decomposition

$$\ell(\mathbf{y}, \widehat{\sigma}^2; \mathbf{y}) - \ell(\bar{\mathbf{y}}, \widehat{\sigma}^2; \mathbf{y}) = \left\{ \ell(\mathbf{y}, \widehat{\sigma}^2; \mathbf{y}) - \ell(\widehat{\mu}, \sigma^2; \mathbf{y}) \right\} + \left\{ \ell(\widehat{\mu}, \widehat{\sigma}^2; \mathbf{y}) - \ell(\bar{\mathbf{y}}, \widehat{\sigma}^2; \mathbf{y}) \right\}. \tag{5}$$

After some algebras we get

$$\begin{aligned}
\ell(\mathbf{y}, \widehat{\sigma}^2; \mathbf{y}) - \ell(\bar{\mathbf{y}}, \widehat{\sigma}^2; \mathbf{y}) = &\sum_{g=1}^{k} \sum_{i=1}^{n} \widehat{z}_{ig} \frac{(y_i - \widehat{\mu}_{i,g})^2}{2\widehat{\sigma}_g^2} + \sum_{g=1}^{k} \sum_{i=1}^{n} \widehat{z}_{ig} \frac{(\widehat{\mu}_{i,g} - \bar{y}_g)^2}{2\widehat{\sigma}_g^2} + \\
&+ \sum_{g=1}^{k} \hat{n}_g \frac{(\bar{y}_g - \bar{y})^2}{2\widehat{\sigma}_g^2}.
\end{aligned}$$

Let us set

$$\begin{aligned}
\Delta\ell_t(\mathbf{y}, \bar{\mathbf{y}}) &= \sum_{g=1}^{k} \sum_{i=1}^{n} \widehat{z}_{ig} \frac{(y_i - \bar{y})^2}{2\widehat{\sigma}_g^2}, & \Delta\ell_r(\mathbf{y}, \widehat{\mu}) &= \sum_{g=1}^{k} \sum_{i=1}^{n} \widehat{z}_{ig} \frac{(y_i - \widehat{\mu}_{i,g})^2}{2\widehat{\sigma}_g^2}, \\
\Delta\ell_f(\widehat{\mu}, \bar{\mathbf{y}}_G) &= \sum_{g=1}^{k} \sum_{i=1}^{n} \widehat{z}_{ig} \frac{(\widehat{\mu}_{i,g} - \bar{y}_g)^2}{2\widehat{\sigma}_g^2}, & \Delta\ell_b(\bar{\mathbf{y}}_G, \bar{\mathbf{y}}) &= \sum_{g=1}^{k} \hat{n}_g \frac{(\bar{y}_g - \bar{y})^2}{2\widehat{\sigma}_g^2}
\end{aligned}$$

where $\bar{\mathbf{y}}_G = (\bar{y}_1, \ldots, \bar{y}_k)'$. Thus, the decomposition (5) can be written as

$$\Delta\ell_t(\mathbf{y}, \bar{\mathbf{y}}) = \Delta\ell_r(\mathbf{y}, \widehat{\mu}) + \Delta\ell_f(\widehat{\mu}, \bar{\mathbf{y}}_G) + \Delta\ell_b(\bar{\mathbf{y}}_G, \bar{\mathbf{y}}) \tag{6}$$

which generalizes the relation (32) in [3] because here the component variances are now included. According to [1] and [3], we define the local coefficient of determination for the gth group ($g = 1, \ldots, k$) as

$$R^2_g = \frac{\Delta\ell_{f,g}(\widehat{\mu}, \bar{\mathbf{y}}_g)}{\Delta\ell_{r,g}(\mathbf{y}, \widehat{\mu}) + \Delta\ell_{f,g}(\widehat{\mu}, \bar{\mathbf{y}}_g)} \tag{7}$$

and afterwards we define the overall coefficient of determination as

$$R^2 = \frac{\Delta\ell_f(\widehat{\mu}, \bar{\mathbf{y}}_g)}{\Delta\ell_r(\mathbf{y}, \widehat{\mu}) + \Delta\ell_f(\widehat{\mu}, \bar{\mathbf{y}}_g)}. \tag{8}$$

The Poisson case. Conditional on $G = g$ (for $g = 1, \ldots, k$) assume now that $Y|\mathbf{x}$ is Poisson with parameter $\mu_g(\mathbf{x}; \beta_g)$, for some $\beta_g \in \mathbb{R}^{p+1}$; that is, $Y|\mathbf{x}(G = g) \sim \text{Poi}\left[\mu_g(\mathbf{x}; \beta_g)\right]$, and set

$$q(y|\mathbf{x}; \beta_g) = \exp\left[-\mu_g(\mathbf{x}; \beta_g)\right] \frac{\left[\mu(\mathbf{x}; \beta_g)\right]^y}{y!},$$

where $\mu(\mathbf{x}; \beta_g) = \exp(\beta_{0g} + \beta'_{1g}\mathbf{x})$. Using similar arguments like in the previous case, we set

$$\begin{aligned}
\Delta\ell_t(\mathbf{y}, \bar{\mathbf{y}}) &= \sum_{g=1}^{k}\sum_{i=1}^{n} \widehat{z}_{ig}\left\{y_i \ln y_i - y_i - y_i \ln \bar{y} + \bar{y}\right\} \\
\Delta\ell_r(\mathbf{y}, \widehat{\mu}) &= \sum_{g=1}^{k}\sum_{i=1}^{n} \widehat{z}_{ig}\left\{y_i \ln y_i/\widehat{\mu}_{i,g} - (y_i - \widehat{\mu}_{i,g})\right\} \\
\Delta\ell_f(\widehat{\mu}, \bar{\mathbf{y}}_G) &= \sum_{g=1}^{k}\sum_{i=1}^{n} \widehat{z}_{ig}\left\{y_i \ln \widehat{\mu}_{i,g}/\bar{y}_g - (\widehat{\mu}_{i,g} - \bar{y}_g)\right\} \\
\Delta\ell_b(\bar{\mathbf{y}}_G, \bar{\mathbf{y}}) &= \sum_{g=1}^{k}\sum_{i=1}^{n} \widehat{z}_{ig}\left\{y_i \ln \bar{y}_g/\bar{y} - (\bar{y}_g - \bar{y})\right\}
\end{aligned}$$

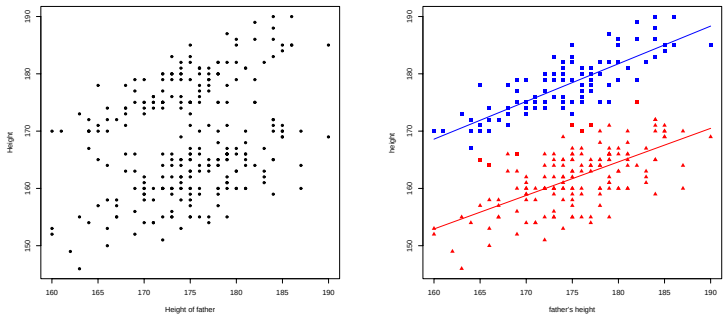
where again $\bar{\mathbf{y}}_G = (\bar{y}_1, \ldots, \bar{y}_k)'$. Therefore, the decomposition (5) can be written as

$$\Delta\ell_t(\mathbf{y}, \bar{\mathbf{y}}) = \Delta\ell_r(\mathbf{y}, \widehat{\mu}) + \Delta\ell_f(\widehat{\mu}, \bar{\mathbf{y}}_G) + \Delta\ell_b(\bar{\mathbf{y}}_G, \bar{\mathbf{y}}).$$

Finally the indices (7) and (8) can be derived accordingly.

3 A real data application

In order to illustrate the proposed fit measures, we analyze a data set from a survey of $n = 270$ students of basic Statistics at the Department of Economics and Business of the University of Catania in the academic year 2011/2012. The data set was first used by [2] and is available from the R package **flexCWM**; see [4]. The aim is to model the height of a student based on the information about the height of his/her father.



(a) Scatter plot **(b)** Scatter plot with fitted components

Fig. 1: Panel 1a is the scatter plot of the variables *Height* and *Height of father* of the *students* data; panel 1b is the scatter plot with fitted mixture component labels and regression lines. Red triangles indicate first group membership, blue squares indicate second group membership.

Figure 1 presents the scatters of the unlabeled data (Panel 1a), and of the labeled data as estimated by the two-component mixture of linear regression models (Panel 1b), including the regression lines. Overall we observe a positive association between *Height of father* and *Height* in both clusters. The cluster labels that are found are close enough to the classification of the gender variable (not reported), with an Adjusted Rand Index of about 0.899.

Cluster	1	2
π_j	0.583	0.417
R^2_j	0.389	0.646

R^2	0.531
$\Delta\ell_t(\mathbf{y},\bar{\mathbf{y}})$	1035.294
$\Delta\ell_r(\mathbf{y},\widehat{\boldsymbol{\mu}})$	133.997
$\Delta\ell_f(\widehat{\boldsymbol{\mu}},\bar{\mathbf{y}}_G)$	151.856
$\Delta\ell_b(\bar{\mathbf{y}}_G,\bar{\mathbf{y}})$	749.441

Table 1: Local and overall fit measures for the finite mixture of two linear regressions fitted to the *students* data.

Table 1 reports the local and overall fit measures for the output model. Interestingly, the regression fit for group 2 (male) has a higher local R^2 than that of group

1 (female) - respectively 0.646 and 0.389. We report an overall R^2 of about 0.5. In addition, from the other overall deviance measures we observe that more than 70% of the total deviance is due to the separation on the y-axis between the groups (as measured by $\Delta\ell_b(\bar{\mathbf{y}}_G, \bar{\mathbf{y}})$).

4 Concluding remarks

The decomposition here proposed concerns an intuitive tool aiming at facilitating the interpretation of the results of statistical modeling based on mixtures of regressions. In this framework, we remark that this approach should not to be used for model selection.

The decomposition involves essentially the response variable. While for simplicity, we have illustrated the approach for mixtures of regressions, the proposal holds in general for other kinds of mixture of regressions. In particular, the results here presented can be easily extended to mixtures of regressions with concomitant values and to Cluster-Weighed Models, see e.g. [6] and [2].

Statistical Analysis of Satellite Data (SDS-SIS)

Functional Data Analysis for Interferometric Synthetic Aperture Radar Data Post-Processing: The case of Santa Barbara mud volcano

Analisi di dati funzionali per il post-processamento di dati interferometrici: Il caso dei vulcanelli di Santa Barbara

Matteo Fontana, Alessandra Menafoglio, Francesca Cigna, Deodato Tapete

Abstract The systematic and widespread availability of cheap computing power and storage space, alongside the drastic improvement in data transmission and active sensor technologies, has triggered an increasing interest by scientific and government institutions in the use of satellite data. One of the most promising applications is to provide emergency management agencies with early warning systems for catastrophic natural events, in order to support decision making. The data used in this work are ground displacement records gathered via interferometric processing of satellite RADAR data. We provide a novel post-processing approach based on a Functional Data Analysis paradigm, and apply it to Santa Barbara mud volcano.

Abstract *La sistematica disponibilità di memoria e potenza di calcolo, insieme al drastico miglioramento nelle tecnologie di tramissione dati e dei sensori attivi, ha stimolato un interesse crescente da parte di istituzioni scientifiche e governative verso l'utilizzo di dati satellitari. Una delle applicazioni più promettenti è fornire sistemi di allerta precoce alle agenzie di gestione delle emergenze, per supportare i processi decisionali. I dati usati in questo studio sono stime di spostamento del terreno ottenute dall'elaborazione interferometrica di immagini RADAR satellitari. Viene proposto un innovativo metodo di post-processamento basato sul paradigma dell'analisi di dati funzionali, e la sua applicazione ai vulcanelli di Santa Barbara.*

1 Motivation

In the last years, a significant advance in data transmission technologies and availability of computing power, storage space and sensors, have triggered a boost in terms of possible applications of satellite imaging data. Among the wealth of data that can be acquired by passive or active sensor arrays on-board satellites, Synthetic Aperture Radar (SAR) images and their processing with Interferometric SAR (InSAR) methods are one of the most useful sources of information for natural hazard monitoring [10].

The statistical analysis of the output products of advanced InSAR processing is still at an early stage. We are witnessing several attempts at using standard statistical frameworks such as time-series analysis and geostatistics, as shown in the review by [2]. To the best of our knowledge, no attempts have been made yet to combine the dynamics in time and in space, or to employ more advanced statistical techniques to gather novel insights from these specific data.

Our aim is to provide a proof of concept for the application of advanced statistical techniques in this realm, tackling the issue of geological hazard monitoring and early-warning. We provide deeper explanations about the novelty of our approach with respect to the current state of the art in [6]. We exploit, as a test case, the event of a mud volcano eruption occurred in the village of Santa Barbara, in the eastern sector of the city of Caltanissetta, in Sicily (Italy). On the 11^{th} of August 2008 the area was affected by paroxysmal eruption that caused damage to urban infrastructure as far as 2 km from the main eruptive vent. A more detailed description of the event and its geological features can be found in [5] and [8].

2 The Application: InSAR data of Caltanissetta

We used 32 ENVISAT Advanced SAR scenes acquired along ascending track T172 between 12/10/2002 and 07/06/2008 (i.e. before the mud volcano erupted). These data are in C-band (5.6 cm wavelength, 5.3 GHz frequency) and characterized by a Line-Of-Sight (LOS) with ~23° look angle, VV co-polarization, ~20 m ground resolution and nominal site revisit of 35 days.

InSAR processing was carried out with the Small Baseline Subset (SBAS) technique developed by [1] and parallelized by [3]. The output dataset consists of $n = 1735$ coherent targets, distributed across an area of 150 km^2. For each target, the annual LOS velocity over the monitoring period, LOS displacement time series, temporal coherence, and elevation above the reference ellipsoid were estimated. The position of the targets can be seen in Fig. 1, while a plot of the corresponding temporal dynamics is shown in Fig. 2a. The 2002-2005 ground deformation scenario in Caltanissetta was described by [13]. Previous semi-automated analysis of a different InSAR dataset was carried out in [5], where the computation of Deviation Indices was proposed to identify trend changes in InSAR time series (see also [12]). We present the main findings about the mud volcano area in [6].

3 A Functional Approach for InSAR data post-processing

Each displacement series estimated via InSAR consists of a set of discrete, time-indexed evaluations of a continuous trajectory in time, with some degree of smoothness given by the physics of the deformation phenomenon. We can also assume some measurement error to be present, due to the particular nature of the measuring and processing technique. Moreover, in this specific experimental setting, derivatives of such continuous trajectories carry a lot of information: the first derivative represents the velocity of the measured displacement, while the second derivative is the acceleration profile and, via a multiplicative constant, force values. These specific and nonstandard data features call for the use of statistical methods able to correctly include and model them into the analysis process.

A very good candidate to do so is Functional Data Analysis (FDA) [9], the field of statistics which uses, as the unit of the analysis, one or more continuous functions over a domain, either univariate or multivariate. The first step in every FDA pipeline is the extraction of continuous functions from the discrete, longitudinal data points. In our case this was performed via a smooth B-spline basis. Further details about the procedure, and the choice of the smoothing parameter can be found in [6], while a plot of the smoothed data is shown in Fig. 2b. After the data smoothing, we performed a functional Principal Component Analysis (PCA) to assess and quantify the variability of the displacement curves. A functional clustering based on the K-Mean Alignment (KMA) procedure [11] was also performed, to identify a group structure

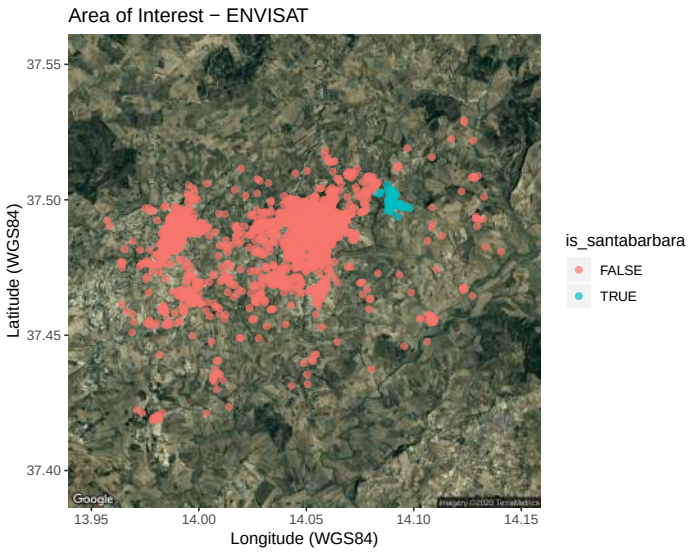

Fig. 1: Map of the geographical position of the target points on a satellite image of the area of Caltanissetta (Italy), with indication of Santa Barbara village.

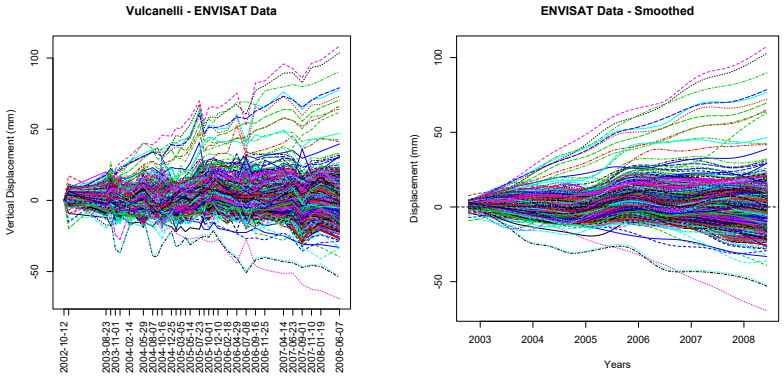
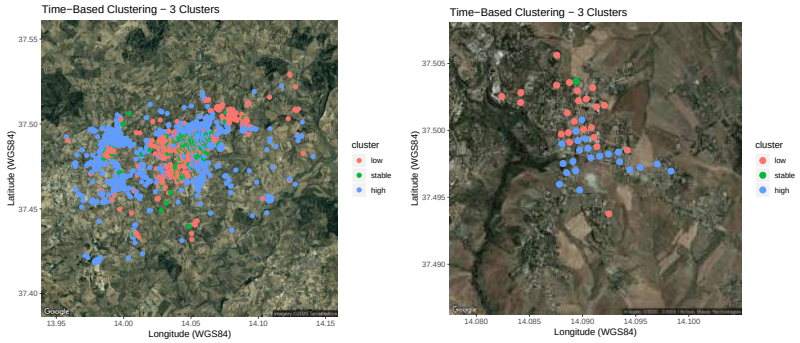


(a) Unsmoothed Case (b) Smoothed Case

Fig. 2: Plot of the time dynamics of displacement for the target points in the smoothed and unsmoothed case.

in the data. In Fig. 3 we present a spatialization of the clusters obtained via the KMA procedure, with a zoom on the Santa Barbara area. Further details about the results of the exploratory analysis can be found in [6].



(a) Map of the whole area (b) Zoom over Santa Barbara

Fig. 3: A map of the target points over the city of Caltanissetta, where the color depends on the cluster that was assigned to the corresponding displacement curve by the KMA procedure, with a zoom on the Santa Barbara area

After the exploratory analysis, we focused our attention on the issue of set forecasting for these complex data objects, that is defining a prediction region for an infinite-variate data object such as a function. Providing meaningful forecasts with

associated uncertainty for a given data object is, in general, a key problem from a theoretical and applied perspective. If we frame the early warning problem as identifying a time instant at which the time series departs significantly from its expected value, it appears immediately evident how an appropriate set forecast method represents a key stepping stone to realize any kind of outlier identification system.

The simplest and possibly the most natural way to forecast a time series of data objects is to use an autoregressive model. Let δ_t be the displacement surface measured at time t, which is here assumed to be a square-integrable function defined over bidimensional Euclidean space S, $\delta_t \in L^2(S)$. Modeling the surface at $t+1$ with a concurrent functional autoregressive (FAR) model of order 1 $FAR(1)$, we can write

$$\delta_{t+1}(s) = \Phi(s)\delta_t(s) + \varepsilon(s) \tag{1}$$

where $s \in S$ and $\Phi \in L^{\infty}(S)$. The main issue in this setting is the substantial lack of usable and interpretable methods for interval forecasting. A very powerful approach to tackle this kind of problems is represented by Conformal Prediction (CP) [14]. CP was developed in the late 1990s in the Machine Learning community as a method to provide interval forecast for support vector machines. Since then, it has been extended in several ways, and used as a framework to provide distribution-free prediction sets in the scalar case, and very recently also in the functional one [7].

To provide meaningful forecasts for the concurrent FAR(1) model in Equation 1, we extend the framework in [7] in two directions. The first one is moving from the functional univariate case to the bivariate one, required in this application. The second, and most challenging one, is to move from the case of iid observations (described in [7]) to setting of data with (temporal) dependence. This is performed by adapting the ideas described in [4] for the scalar case to the case of functions whose domain is bidimensional. The complete mathematical description of the method, alongside a detailed analysis of the Santa Barbara test case can be found in [6].

4 Conclusions

Motivated by the need to test advanced statistical methodologies to analyse displacement series obtained from satellite InSAR techniques, we illustrate a Functional Data Analysis framework for the analysis of displacement data related with a mud volcano eruption occurred in 2008 close to the city of Caltanissetta, Italy. Aiming to develop an early warning system, we describe an extension (fully shown in [6]) of a newly developed forecasting technique based on Conformal Prediction to the case of dependent functional observations defined over a multivariate domain.

Recent Contributions to the Understanding of the Uncertainty in Upper-Air Reference Measurements

Recenti Contributi alla Comprensione dell'Incertezza delle Misure Climatiche dell'Alta Atmosfera

Alessandro Fassò

Abstract Measurement uncertainty of climatic variables in the Upper Troposphere/-Lower Stratosphere (UTLS) is a key for the understanding of climate warming. Beyond traditional measurement uncertainty, the focus of the atmospheric science community is moving to an uncertainty which is related to the spatial and temporal scales, and to the comparison of different instruments. This paper reviews some recent contributions to the analysis of data related to radiosonde and satellite observation. In particular, techniques based on functional data analysis approach, spatio temporal models, regularisation, and cross-validation are applied to radiosonde profile data and satellite data.

Abstract *L'incertezza della misura di variabili climatiche nell'alta troposfera/bassa stratosfera (UTLS) è fondamentale nella comprensione del riscaldamento globale. Tale incertezza non riguarda solo la tradizionale incertezza strumentale ma coinvolge anche aspetti legati alla dimensione spaziale e temporale ed al confronto fra strumenti diversi. I metodi statistici considerati riguardano la functional data analysis, i modelli spazio-temporali, anche 4D, e le tecniche di cross-validazione.*

Key words: radiosonde, functional data, Gaussian process, cross-validation

1 Introduction

Climate variables in the Upper Troposphere/Lower Stratosphere (UTLS) may be measured in-situ, for example through a flying radiosonde balloon, or remotely, for example through an optical instrument on-board a satellite. Data products related to the latter are fast increasing in quality and quantity, by providing massive regularly spaced observations. Nevertheless, radiosonde observations are considered crucial, not only because they provide long time series, but also because they are used for

Alessandro Fassò
University of Bergamo, Dalmine (BG), Italy, e-mail: alessandro.fasso@unibg.it

calibration and validation of both satellite observations and climate models such as the ERA-interim re-analysis, [2].

In this frame, an important role is played by GRUAN, the GCOS[1] Reference Upper-Air Network (www.gruan.org). Despite having a limited spatial coverage, GRUAN aims at providing fully traceable reference measurements. To do this, not only has more then 20 stations around the world but also implements data processing covering measurement uncertainty estimation, [1].

For this reason climatological studies are largely based on baseline measurement networks, which have an intermediate metrological quality but a larger spatio-temporal coverage.

In metrology, measurement uncertainty is a characteristics of the statistical dispersion of the values attributed to a measured quantity. In this paper, using a statistical approach, we use the Root Mean Square Error (RMSE) to quantify measurement uncertainty. An empirical assessment of it is often given by means of a statistical model able to describe the natural variability attributable to environmental forcing factors. Hence, the model RMSE is used to assess measurement uncertainty.

The rest of the paper is organised as follows. Section 2 deals with the uncertainty arising in the comparison of partially misaligned profiles using a functional data analysis approach. The first case is related to the comparison of pair of radiosonde profiles from sites in the same climatic area. The second case study considers the comparison of radiosonde and satellite data, which have quite different vertical smoothing properties. Section 3, considers the harmonisation of 40-years global time-series, using a combination of 4D local Gaussian process modelling and fused LASSO. Section 4 considers the uncertainty propagation in interpolation of missing data using a Gaussian process approach coupled with block-bootstrap correction.

2 Co-location uncertainty

In the comparison of two profiles obtained by two different instruments, various mismatch sources should be taken into account: the spatio-temporal mismatch between profiles; the different vertical smoothing and resolution of the two instruments/data sets; the different horizontal smoothing and resolution of the two instruments; and the comparator uncertainty. In particular, considering radiosonde, comparator uncertainty is related to instrument issues, including solar radiation, dry-bias when measuring humidity, ventilation effects, ground calibration effects, and all the other problems detailed in [3].

In Section 2.1, pairs of temperature radiosonde profiles from nearby GRUAN stations are compared, hence the main source of discrepancy is related only to the spatio-temporal mismatch. In Section 2.2, the temperature profiles of baseline quality radiosondes and satellite observations are compared.

[1] GCOS is the Global Climate Observing System of the World Meteorological Organisation (WMO)

2.1 Heteroskedastic Regression for Functional Data

Let us consider the comparison of pairs of temperature profiles, $(y(h), y'(h))$ from nearby stations, where h denotes the altitude, as discussed by [6, 9]. Each profile is modelled as a functional data object. Hence, considering the co-location error $z(h) = y(h) - y'(h)$, the following functional regression is established:

$$z(h) = \beta(h)'x(h) + \varepsilon(h)$$
$$\sigma_\varepsilon^2(h|x) = \gamma(h)'x(h).$$

In this model $\sigma_\varepsilon^2(h|x) = Var(\varepsilon(h)|x(h))$ defines the irreducible co-location uncertainty, which depends on altitude and other variables characterising the local condition of the atmosphere.

After suitable estimation of the unknown parameters, this approach gives the following total profile uncertainty budget:

$$\sigma_z^2(h) = \beta_0^2 + \sigma_{x\sim\beta_0}^2(h) + \sigma_\omega^2(h) + \sigma_{\hat{\beta}}^2(h) + \sigma_{\Delta_\varepsilon}^2$$

whose elements are discussed in the sequel.

1. β_0^2 accounts for co-location bias. This error component may be easily covered with this approach.
2. $\sigma_{x\sim\beta_0}^2(h) = \beta'(h)\Sigma_x(h)\beta(h) - \beta_0^2$ is the (marginal) reducible collocation uncertainty. It is called "reducible" because it depends on environmental forcing factors x. Hence, knowing x allows to correct for this error component.
3. $\sigma_\omega^2(h) = E_x\left(\hat{\sigma}_\omega^2(h|x)\right)$ is the irreducible collocation uncertainty. It is called "irreducible" because, using this model and information in x this term can not be reduced.
4. $\sigma_{\hat{\beta}}^2(h) = E(x(h)'\Sigma_{\hat{\beta}}(h)x(h))$ is the estimation uncertainty or sampling error;
5. $\sigma_{\Delta_\varepsilon}^2 = 2\sigma_\varepsilon^2$ is the measurement error.

2.2 Comparing Radiosonde and IASI profiles

The validation of satellite products is important to ensure their quality for climate and weather applications. To do this, a fundamental step is the comparison with other instruments. In [7], the temperature profiles obtained by the Infrared Atmospheric Sounding Interferometer (IASI) instrument, on board EUMETSAT satellite MetOP-A and –B, are compared to the radiosonde observations within the network of the Universal Rawinsonde Observation Program (RAOB).

In this type of comparison, the mismatch uncertainty is dominated by the difference in vertical smoothing. In fact IASI data products give profiles which are known to have a limited number of degrees of freedom. In some cases the so-called averaging kernels are available, defining the vertical smoothing by a set of weights.

In other cases, for example when handling dated time series, the averaging kernels are not available and [7] estimated such weights using the Maximum Likelihood principle.

To see this, we adopt a simplified version of [7], hence we ignore the so-called comparator uncertainty. The idea is to let each RAOB profile to mimicking the corresponding IASI profile. In other words the true signal of the $k-th$ profile is considered as a smooth function denoted by $s_k(h)$. It is related to the observation $y_{J,k}(h)$ with $J = R, I$ for RAOB and IASI respectively, by the following equations

$$y_{J,k}(h) = s_{J,k}(h) + \varepsilon_{J,k}(h), J = R, I$$

where $\varepsilon_{J,k}(h)$ is Gaussian distributed, $N(0, \sigma^2_{J,k}(h))$ and the two are related by

$$s_{I,k}(h) = \int_{VR} s_{R,k}(h) w(q;h) dq.$$

where VR is the vertical range of the profiles. The best weighting function w resulted to be the generalised extreme value probability density function, selected by cross-validation among a number of candidates.

3 Harmonisation of radiosonde time series

Copernicus is the European union's Earth observation programme (www.coopernicus.eu) and is involved in collecting data from multiple sources. In particular, the Copernicus Climate Change Service (C3S), will provide comprehensive climate information covering a wide range of components of the Earth-system and timescales spanning decades to centuries, [4].

In reconstructing radiosonde global timeseries, harmonisation is essentially made by change detection and adjustment of data for any kind of known and quantifiable inhomogeneities, including bias, change of sensors, calibration drift, local environment changes [8, 11, 10].

In this frame, [5] discusses the harmonisation of 40-year time-series of temperature profiles from the Integrated Global Radiosonde Archive (IGRA), covering about $n = 800$ sites around the world. To do this, a two step procedure is used.

In the first step a 4D local Gaussian Process modelling is developed

$$y(s,t,h) = z(s,t,h) + \varepsilon(s,t,h)$$

where $s = (lat, lon) \in Spherical\ shell,\ h \in [925hPa, 50hPa],\ t \in R^+$. Moreover, for each site $j = 1, ..., n$, the following residuals are computed

$$e(s_j,t,h) = E[y(s_j,t,h)|Y_{\sim j}] - y(s,t,h)$$

where $Y_{\sim j}$ contains all the IGRA information excluding $j-th$ site.

At the second step a fused LASSO change detection on each residual time-series is applied [12]. In particular, ignoring site subscript j, we assume

$$e_t = \beta_t + \zeta_t,\ t = 1,...,T$$

where $\zeta_t \equiv NID(0,\sigma^2)$ and $(\beta_1,...,\beta_T)$ is given by the the (regularised) optimisation of

$$\sum_{t=1}^{T}(e_t-\beta_t)^2 + \lambda_1\sum_{t=1}^{T}|\beta_t| + \lambda_2\sum_{t=2}^{T}|\beta_t-\beta_{t-1}|$$

where the first penalty term controls the number of $\beta_t \neq 0$ and the second one controls smoothness of β_t, hence identifying temporary and permanent changes.

4 Interpolation uncertainty of high-vertical-resolution profiles

Modern radiosondes, such as Vaisala RS41, send data to ground site second by second. For various reasons, missing data are sometimes spread along the atmospheric profile. A common strategy is to compute (linear) interpolation to fill the gaps in order to have a regularly spaced data product. In the perspective of uncertainty full traceability of climate data products, the issue of the resulting interpolation uncertainty is of interest.

To see this, considering a single radiosonde profile, we assume that $y(t)$ is the observation of the true temperature profile, say $s(t)$, at flying time $t = 1,...,T$ and

$$y(t) = s(t) + \varepsilon(t)$$

where $\varepsilon(t) \sim N(0,\sigma_t^2)$ is the measurement error with possibly non constant measurement uncertainty σ_t.

If there is an observation gap in the interval (t^-,t^+), the linear interpolation at time t, for $t^- \leq t \leq t^+$, is given by the straightforward formula

$$\hat{y}(t) = \alpha(t)y^+ + (1-\alpha(t))y^-$$

where, $y^\pm = y(t^\pm)$, and $\alpha(t) = \frac{t-t^-}{t^+-t^-}$. If we assume that $s(t) = \omega(t)$ is a Gaussian process with autocorrelation function $\gamma(t,t')$, the linear interpolation mean squared error is given by

$$MSE_y(t) = E[(\hat{y}(t)-s(t))^2] = \vec{a}'\Sigma\vec{a} + \sigma_t^2$$

where Σ is the 3×3 variance covariance matrix of $(y^+,y^-,y(t))$ and $\vec{a}' = (\alpha(t),1-\alpha(t),-1)$.

Under the above Gaussian process assumption and if σ_t is known, this formula propagates the uncertainty from $y^\pm$ to $y(t)$, hence making the interpolated value fully traceable. Nonetheless, if the Gaussian process is only an approximation, so

that $s(t) = \omega(t) + \delta(t)$ than the above MSE underestimate the true interpolation uncertainty, say $u(t)^2$, by the quantity $E(\delta(t)^2)$. For this reason, using a sample of profiles, an extensive Block-Bootstrap cross-validation exercise may be used to estimate $E(\delta(h)^2)$ as a function of altitude and provide a Bootstrap-based semi-parametric estimate of $u(t)^2$. The same cross-validation design may be used to assess the gain in precision in using a kriging interpolation instead of the simpler linear interpolation.

Statistical models and methods for Business and Industry

Modelling and monitoring of complex 3D shapes: a novel approach for lattice structures

Modellazione e monitoraggio di forme complesse 3D: un nuovo approccio per strutture lattice

Bianca Maria Colosimo, Marco, Grasso, Federica Garghetti

Abstract The industrial breakthrough of novel manufacturing paradigms, like additive manufacturing, enables the production of innovative shapes, characterized by complex 3D structures going beyond more 2.5D free-form surfaces and other geometries produced with traditional methods. This opens novel challenges for product qualification and statistical process monitoring. This study focuses on a category of complex shapes known as lattice structures (or metamaterials), where a unit cell regularly repeats in space to achieve advanced mechanical and functional performances. We present a novel solution for statistical process monitoring of these structures, aimed at identifying local out-of-control cells within- and between-parts.

Abstract *Lo sviluppo industriale di nuovi paradigmi di produzione, come le tecnologie additive, permette di produrre forme innovative, caratterizzate da strutture complesse 3D che vanno ben oltre le superfici 2.5D e altre forme prodotte con tecnologie tradizionali. Questo apre nuove sfide in termini di qualificazione di prodotto e monitoraggio di processo. Lo studio si concentra su forme complesse note come strutture lattice (o metamateriali), dove una cella si ripete regolarmente nello spazio per ottenere prestazioni avanzate. Presentiamo una nuova soluzione per il monitoraggio statistico di processo con l'obiettivo di identificare celle fuori controllo all'interno di una singola parte o in produzioni in serie.*

1 Introduction

Thanks to the industrial breakthrough of new manufacturing and inspection technologies, innovative kinds of complex shapes can be made available for several different applications. The level of shape complexity that can be achieved nowadays (e.g., by means of additive manufacturing methods) goes beyond the one of simpler 2.5D free-form surfaces and more traditional products. This yields brand new challenges in the design and use of data modelling and process monitoring methodologies. It also motivates an increasing interest for statistical analysis of complex geometries and spatially dense metrology data.

The problem of statistical process monitoring of free-form surfaces based on 2.5D or 3D point cloud data was investigated by various authors (Del Castillo et al., 2015; Shi et al., 2019). Some authors focused on identifying the nature of part-to-part variation (Shi et al., 2019; Shan and Apley, 2008; Lee and Apley, 2004), whereas other authors focused on the design of statistical quality monitoring methods (Colosimo et al., 2015; Colosimo et al., 2014; Colosimo, 2018; Zang and Qiu, 2018a, 2018b). Some authors focused on the analysis of stochastic textures in the absence of a golden standard shape (Bui and Apley, 2018) and random cellular structures (Menafoglio et al., 2018).

Some novel kinds of complex shapes exhibit much more complicated geometrical features than the ones investigated in previous studies. This motivates the study of novel methods to determine the quality of such complex product (even in the presence of small lots and one-of-a-kind productions) and to monitor the stability of the production process. Lattice structures belong to this category (Wu et al., 2019, Cansizoglu et al., 2008). Lattice structures are complex geometries where a unit cell, usually characterized by a trabecular shape, regularly repeats in space within the part. They gain their functional properties from their structure rather than inheriting them directly from the material they are composed of, and hence they are also called metamaterials (Wu et al., 2019).

This study presents a statistical modelling and monitoring approach for the identification of local geometrical distortions in one (or more) cells within one single part and between parts. The proposed method grounds on the estimation of the "real geometry" of the lattice structure via X-ray computed tomography (CT), and on the comparison with such real geometry with the "nominal geometry", i.e., the originating CAD file. A profile monitoring approach is proposed the model and monitor the evolution of the deviation between the real and nominal geometries of each cell along the building direction (Ramsay, 2004; Woodall, 2007). The method is demonstrated by means of a real case study involving the production of metal lattice structures via Laser Powder bed Fusion (LPBF), an additive manufacturing process where a laser beam is used to locally melt a metal powder bed and produce complex shapes on a layer-by-layer basis.

Section 2 introduces the case study related to the additive production of lattice structures. Section 3 briefly presents an overview of the proposed approach. Section 4 presents the results and Section 5 concludes the paper.

2 The lattice structure case study

Lattice structures combine a lightweight design with high specific stiffness and strength, with appealing performances in industrial sectors like aerospace and racing. Moreover, their isotropic structure and cell geometry-dependent properties make them suitable for several applications, from heat exchange to energy absorption and acoustic insulation. Finally, in the biomedical sector, the trabecular structure is particularly suitable to enhance the osteo-integration and the compatibility with the human tissue. Additive manufacturing methods enable the production of this kind of structures in a wide range of materials and for a wide range of applications. (Colosimo, 2018; Colosimo et al., 2018).

The case study consists of an Al-Si-Mg alloy lattice structure with a designed porosity of 90%, composed by $N = 64$ dodecahedron unit cells of size $l = 10\ mm$ within a specimen of dimension $40 \times 40 \times 40$ mm. Each unit cell consists of 32 prismatic elements with struct diameter of 0.67 mm (Figure 1). The lattice structure was produced via Laser Powder Bed Fusion (LPBF). The as-built structure was inspected by means of an X-ray CT scan system with a resolution or 33 μm.

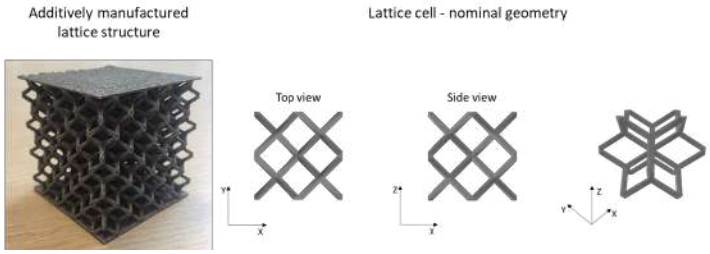

Figure 1: Left panel: picture of the as-built lattice structure; right panel: nominal geometry of the cell

3 Overview of the proposed approach

The underlying idea of the proposed methodology consists of modelling the deviation between the real and nominal geometry for each unit cell of a lattice structure. By modelling such deviation, a statistical monitoring scheme allows one to determine whether one or more unit cells exhibit an out-of-control geometrical distortion with respect to the natural variability of the deviations. Figure 2 shows a schematic overview of the overall method. The real geometry, reconstructed via X-ray CT scan, is sliced along the build direction, Z, into a stack of images: each image represents the real geometry of each cell at a given height along the Z axis. The corresponding image representing the nominal geometry at the same height along Z is obtained by slicing the originating CAD model. By comparing, slice by slice, the real and nominal geometry of each cell, it is possible to estimate a deviation index, which can be represented in terms of a 1D profile along Z. Each unit cell in the structures can therefore be associated to a 1D deviation profile.

The proposed approach consists of using the 1D profile data to synthetize the 3D deviation between the real and nominal geometry of the cell. A profile monitoring approach can then be applied to model these profiles – a B-spline basis was proposed (Ramsay, 2004) – and detect any out-of-control deviation by means of a control charting scheme applied to the B-spline coefficients and the model residuals.

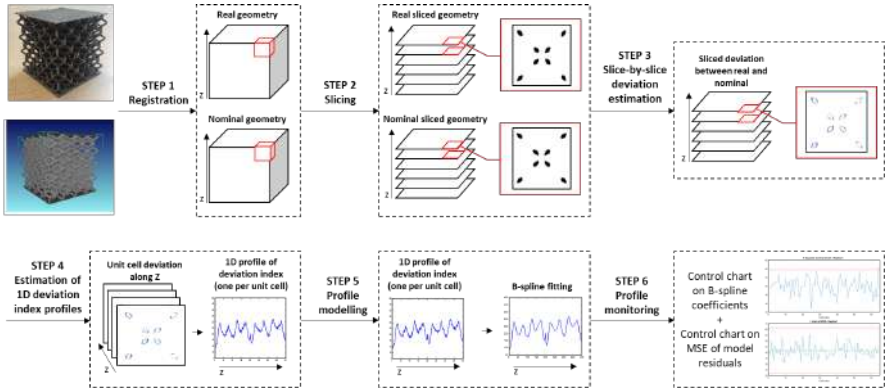

Figure 2: Scheme of the proposed approach

4 Results

Figure 3 shows the deviation profiles for all the unit cells of the lattice structure and the corresponding B-spline model fits. The general pattern of the deviation index profiles can be regarded as a signature of the process, where the main discontinuities correspond to the salient geometrical features of the unit cell (i.e. junctions of the cell struts). The cell-to-cell variability is caused by the small local variations as a result of the additive manufacturing process itself. The general oversizing of the real geometry with respect to the nominal one, can be regarded as a signature of the process too.

The control charts for within-part variability analysis of the printed structure are shown in Figure 4, designed with familywise Type I error α=0.0027.

The T^2 control chart on the B-spline model coefficients signals an out-of-control in correspondence of the 52-th unit cell. In that cell, an actual geometrical distortion was present, possibly caused by an error in the powder recoating while that cell was produced.

The method can be applied to model and analyse the within-part variability, i.e., the cell-to-cell variability in one single part, like in the example here presented, but also to monitor the stability over time of the part-to-part variability in a series production. The capability to identify a geometrical distortion in one (or more) unit cells enables a novel solution for product qualification even in the presence of a one-of-a-kind product, regardless of the complexity and actual geometry of the structure.

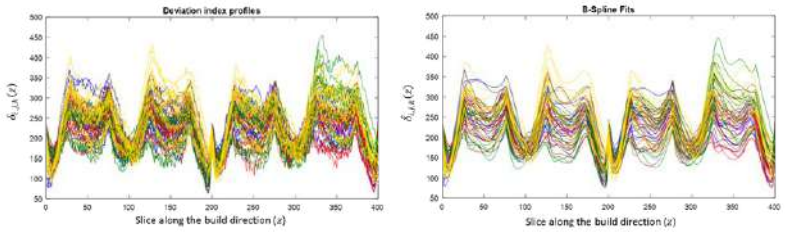

Figure 3: Left panel: original deviation profiles for all the cells; right panel: B-pline fits of the deviation profiles

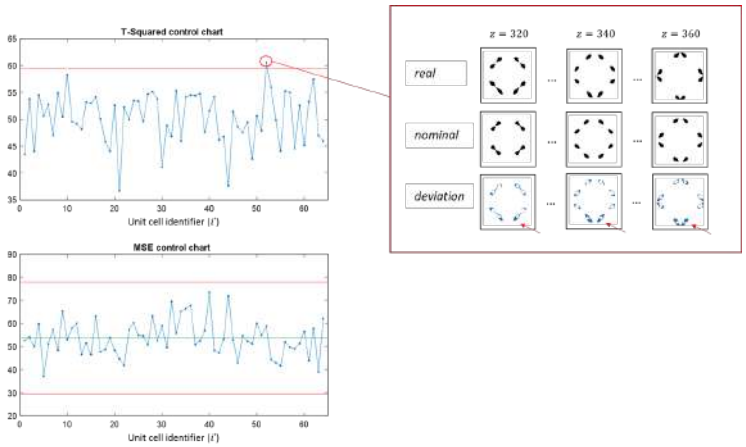

Figure 4: Control charts applied to monitor the within variability of the lattice structure, with an example of the unit cell signalled as out-of-control (real and nominal geometry and deviation).

5 Extendibility to other geometries

One major issue in novel manufacturing paradigm regards the lack of statistical methods to model and monitor the quality of innovative products characterized by complex 3D shapes. This study presented a first approach aimed at tackling this challenge. The underlying idea of studying the deviation between the real and nominal shapes can be extended to different kinds of complex geometries, and it opens up to a wide range of possible applications. This study is inserted into a research framework focused on the quality characterization, modelling and monitoring of complex geometries, not limited to lattice structures. As an example, in another study in collaboration with the Department of Mathematics, Politecnico di Milano (Scimone et al., 2020), the study of methods to synthetize and monitor the deviations between a real and nominal geometry was extended to structures without regularly repeating cells. Generally speaking, the proposed methods can be extended not only to different families of shapes, but also to geometrical reconstructions gathered while the part was produced, rather than at the end of process (Grasso and Colosimo, 2017; Everton et al., 2016; Colosimo and Grasso, 2018). This possibility

is enabled by the layerwise paradigm of additive manufacturing processes and it paves the way to novel in-line and in-situ part qualification capabilities.

Open data powered territorial planning - Case study: The Turin historical center

L'Open data per potenziare la pianificazione territoriale – un caso di studio sul Centro storico di Torino

Silvia Casagrande[1], Gianmaria Origgi[1], Alberto Pasanisi[1], Martina Tamburini[1], Pascal Terrien[2], Tania Cerquitelli[3], Alfonso Capozzoli[3]

Abstract This study focuses on the harvesting of energy-related open data to support territorial planning, thus discovering interesting insights useful to support the decision-making process. To this aim, we selected the Energy Performance Certificates because of the heterogeneity of the attributes characterizing buildings, released by the Piedmont region as open data. We derived a data-driven methodology to identify a high-quality set of data to build a baseline energy scenario in a major Italian city. Different urban requalification scenarios were simulated by analyzing financial, environmental, energy and social Key Performance Indicators.

Abstract. Il presente lavoro riguarda il trattamento e l'utilizzo di open data energetici a supporto della pianificazione territoriale, derivandone utili spunti propedeutici al processo decisionale. Sono stati utilizzati gli attestati di certificazione energetica, forniti dalla Regione Piemonte, per via dell'eterogeneità degli attributi degli edifici. Su questa base, è stata sviluppata una metodologia per identificare un set di dati di alta qualità e costruire una scenaristica di riqualificazione energetica per una grande città italiana, analizzando indicatori finanziari, ambientali, energetici e sociali.

Keywords: Open data, energy performance certificates, urban planning.

1 Introduction

A key research challenge in the context of open data (i.e., data freely available to everyone to use and republish as they wish) is to use them in real-life applications

(including business cases) with no restrictions from copyright, patents or other control mechanisms. However, the effective exploration of such data in real-life settings is very challenging and requires a lot of expertise in the field of open data and a lot of effort for extracting useful knowledge from poor quality data as frequently open data are.
This study focuses on the harvesting of open data for the characterization of the energy performance of buildings with the final goal of creating value for different stakeholders. In particular, the research is aimed at exploring how open data on energy consumption of buildings can be exploited to design and appraise urban requalification policies. After a detailed census of data related to buildings issued as open, a database of Energy Performance Certificates (EPCs) was selected. It provides a variety of heterogeneous information related to each certified building including the standard-based calculation of energy performance, thermo-physical and geometrical features and geospatial information. The exploration of such energy-related database to support business cases and providing interesting insights to various stakeholders is challenging because of the heterogeneity of the attributes, the need of both energy and data science expertise. The available data set was used to build a baseline energy scenario. Then, several urban requalification scenarios were simulated by analyzing financial, environmental, energy and social KPIs.
The paper is organized as follows. Section 2 describes the work done to transform the raw available open data in valuable input information for building requalification scenarios. Then, in Section 3, the scenarios built and their evaluation (by means of a specific urban planning digital tool) are presented. Finally, Section 4 stresses the main conclusions and perspectives of this study.

2 Treatment of Open Data

In this work a dataset consisting of a number of EPCs was analysed; it was collected in the Piedmont Italian Region during the period from 2009 to 2018. The dataset has been gathered and openly released by CSI Piemonte (the regional Information System Consortium) and regulated by the Piedmont Region authority (Sustainable Energy Development Sector). The dataset includes nearly 270,000 EPCs. In this study, the portion of EPCs related to buildings located in Turin was mainly analysed, because of the high number of data available in this area (47,623).

Data Cleaning. Since EPCs are available as open data, different kind of inconsistencies could be present. In this context, the data pre-processing is a fundamental step to handle good quality data in the next analytics steps. As in [1, 2] two main data cleaning steps were performed: (i) geospatial data cleaning and (ii) outlier detection and removal.

Geospatial data cleaning. Since the final goal of the analytics process consists in displaying the energy performance of the buildings on a map, a good quality of geospatial data is an essential prerequisite. Considering that addresses, house numbers, ZIP codes and coordinates included in EPCs belong to open text fields, the potential number of errors is not negligible. As in [1, 2], the addresses reported in

each EPC were compared with the city's street database and then matched if the Levenshtein similarity is higher than a given threshold (i.e. 0.95 in our case study).

The Levenshtein similarity is based on the computation of the Levenshtein distance, which is the minimum number of single-character edits (insertions, deletions or substitutions) required to change one word into the other. In case of lower similarity (i.e. the minimum threshold is not satisfied during the comparison), geocoding requests have been sent via the Google GeocodingAPIs[1] to reconstruct EPCs' addresses and coordinates. Thanks to the proposed solution, 99% of the addresses have been resolved correctly.

Outlier detection and removal. Open data are often affected by the presence of outliers, which are observations that deviate markedly from the data. Therefore, a semi-supervised outlier detection was computed based on both univariate and multivariate analysis. Specifically, for the univariate outlier analysis three stages were performed:

1) *Definition of acceptability ranges for each energy-related attribute* defined with a detailed expert analysis. The final acceptability ranges for a relevant set of features are shown in Table 1

Table 1: Example of EPCs' variables with the defined validity range

Feature (Acronim)	***Unit***	***Validity Range***
Normalised Primary heating energy consumption	[KWh/m^2]	[0 - 682]
Aspect ratio (S/V)	[m^{-1}]	[0.1 – 2]
Surface area (SA)	[m^2]	[24.9 - 880]
Floor area (FA)	[m^2]	[21.5 - 296]
Average U-value of the vertical opaque envelope (UO)	[W/m^{2}K]	[0.15 - 3]
Average U-value of the windows (UW)	[W/m^{2}K]	[0.9 - 7]
Heating system global efficiency (ETAH)	--	[0.3 - 1.06]
Construction year (Year)	--	[1700 - 2018]

2) *Univariate outlier detection with generalised Extreme Studentised Deviate (gESD)* [3]. It requires the number of outliers defined by the energy expert. Given the upper bound value for the number of outliers, the gESD test essentially performs r separate tests: a test for one outlier, a test for two outliers, and so on up to *r* outliers. In our use case, *r* was set to 0.5% of EPCs and the critical value to 0.01

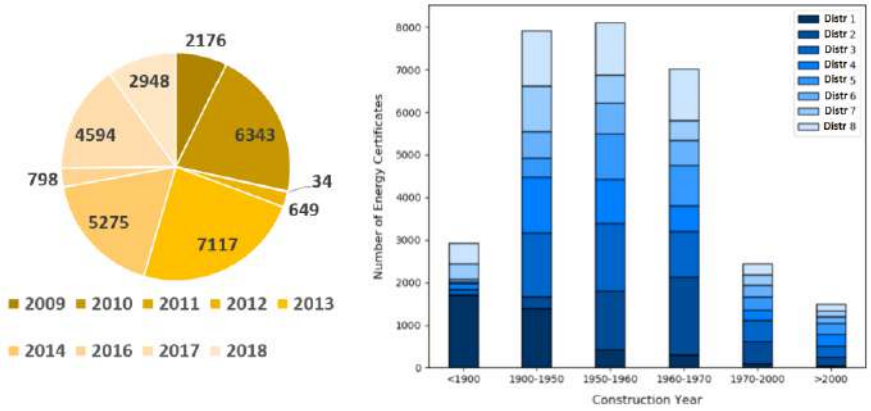
3) *Analysis of the frequency data distribution to identify outliers in the first percentile.* The records belonging to the first percentile were removed, to eliminate inconsistent values with a low deviation from the rest of the observations.

Lastly, the presence of outliers with a multivariate analysis were discovered by applying the Density-Based Spatial Clustering of Application with Noise algorithm (DBSCAN) [4]. In particular, DBSCAN identifies clusters of data by searching higher-density regions separated by lower-density regions. In order to automatically set the DBSCAN input parameters (*MinPoints* and *Epsilon*), the methodology presented in [5] was employed, thus *MinPoints*=5 and *Eps*=0.28 were set. The final

[1] https://developers.google.com/maps/documentation/geocoding/intro

dataset includes roughly 30,000 EPCs, issued in the period 2009-2018 (distributed as shown in Figure 1 (left)), and related to buildings built on different ranges of construction year (see Figure 1 (right)) and distributed across all districts in Turin.

Figure 1: (left): Pie-chart distribution of the number of EPCs for each year under analysis; (right) stacked bar graph of the number of EPCs for each district of the Turin city separately for different ranges of construction year of the dwellings.

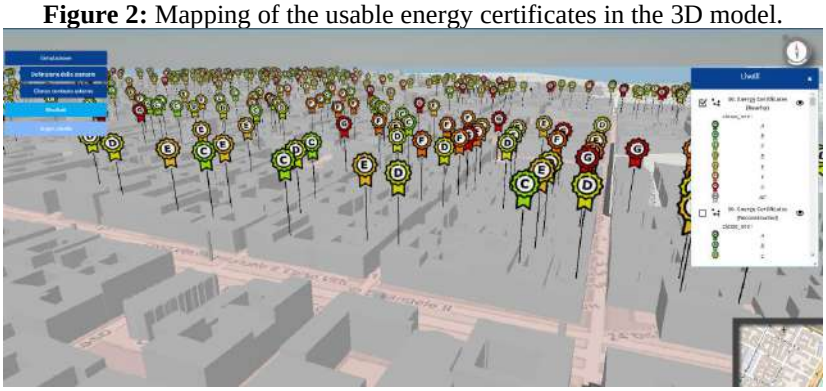


3 Building and evaluating urban renovation scenarios

Starting from the data treatment described in Section 2, the software *City Platform* was customized on a part of the City to build and evaluate renovation scenarios.
City Platform is a digital decision support system tool (DDS) with the main purpose to support urban decision makers in designing, evaluating and comparing different strategies, in order to find the one that best fits a given set of objectives, represented by a number of KPIs (financial, energy-related, environmental, social, quality of life etc.). It was used worldwide [6, 7] with significant applications in Singapore, Berlin, Shanghai, Moscow. The customized version on Turin was concerned with the improvement of the urban buildings stock: reducing the energy consumption, costs and CO_2 emissions, decreasing management costs and creating positive impacts on local economy.
The implementation started with a careful analysis of the city urban fabric, which led to the identification of the historical city centre of Turin as the working area. This area was selected for the presence of several public buildings of interest, the high density of historical buildings with different technological and architectural features and the large potential of renovation.
The following KPIs were considered for this study: (i) private investments (€), (ii) public subsidies (€), (iii) CO_2 emissions (%), (iv) PM_{10} emissions (%) (v) energy consumptions (%), (vi) local jobs created by the investments (n. of employees).
Attributes of interest from EPCs dataset include envelope thermal transmittance, system efficiency, energy class, specific primary energy consumption, architectural

features, the period of construction and the building typology (function, public or private, historical or not, etc.). Additional information necessary to build the model and related to spatial data for describing the urban fabric, was gathered from the topographic database of Piedmont Region.
The study consisted first in creating a 3D model of the selected city district using the regional topographic database. The energy performance and the construction period of each building along with the results of the simulated scenarios were then displayed on this 3D model (see Figure 2).

Figure 2: Mapping of the usable energy certificates in the 3D model.



Different scenarios were designed gathering interventions on energy systems and envelope. For each building, interventions are compliant with architectural restrictions, the existing situation and the eligibility to public subsidy (Ecobonus). A preliminary evaluation of the IRR and ROI also assure that proposed interventions are realistic by an economic viewpoint.
The energy performance of each building after renovation was evaluated by a steady state calculation method according to ISO 13790 standard. For the purpose of the study, 3 scenarios were defined (each one is scheduled on 10 years):
A) Moderate improvement: replacement of all diesel and oil boilers with gas ones the envelope refurbishment and BEMS. It involves 22 buildings.
B) Significant improvement: deep improvement (envelope, boiler, BEMS) of 50% of all the eligible residential stock (approx. 300 buildings). In addition to the buildings refurbished in Scenario A, it includes also non-gas boiler buildings.
C) High improvement: This was the most ambitious scenario. It is like scenario B, but interventions concern 100% of the eligible stock (approx. 600 buildings).
The effectiveness of each combination of measures (scenario) was evaluated by assessing the value of several KPIs (Table 2). The scenario C led to particularly good results considering the number of buildings renovated, the total amount of the investments, the improvement of environmental quality of the city and local job created by the interventions.

Table 2: Main KPI from the analysis of the 3 scenarios of urban renovation

KPI	*Unit*	*Scenario A*	*Scen. B*	*Scen. C*
Private investment after public subsidy	M€	14	54	96

Total investment	M€	32	116	205
Reduction of CO2 emissions	%	18	35	53
Reduction of PM10 emissions	%	23	38	55
Decrease of energy consumptions (heating)	MWh	69,455	137,236	212,307
Jobs created (full time equivalent)	n.	169	611	1081

4 Conclusions and perspectives

This work highlights the huge potential of open data, associated to powerful data cleaning, pre-processing tools and urban simulation capacities. As a main outcome of the study, we mention the impact consequent to the energy renovation policy at urban scale: more than 50% cut on CO_2 emission and 1000 full time equivalent jobs created (based on the simulated scenario). As a major perspective, the analysis reported in this paper can be easily extended to other cities and territories in Italy (in both urban and suburban areas) and in other countries, in particularly in European Union, where ECPs are established since 2002 (Directive 2002/91/EC) as a standard tool to foster energy efficiency. However, the study has also shown that often the quality of available EPCs is not satisfactory. Having a large quantity of good-quality data, coupled with powerful decision support tools (like City Platform) could be a game-changer for local powers, and more generally for urban decision maker. Finally, this study proved the usefulness of tailor-made digital decision support tools in urban planning, to build and evaluate scenarios, but also to define realistic goals to be achieved by urban policies.

Process optimization in Industry 4.0: Are all data analytics models useful?

Ottimizzazione dei processi nell'industria 4.0: tutti i modelli di analisi dei dati sono appropriati?

Alberto Ferrer

Abstract: Not all data analytics models are equally useful in industry 4.0. Machine learning models are currently often used in many Big Data projects in Industry 4.0. These models are proven to be very powerful for passive applications (predictive modelling and maintenance, pattern recognition and classification, and process monitoring, fault detection and diagnosis). However, its indiscriminate use, no matter the type of application, can be counterproductive. They should not be used for process optimization unless data come from a design of experiments (what is a severe limitation in industrial practice). On the other hand, predictive methods based on latent variables (such as partial least squares regression) can be used for process optimization regardless of whether the data come from a design of experiments or daily production process (historical/happenstance data).

Abstract: *Non tutti i modelli di analisi dei dati sono ugualmente appropriati nell'industria 4.0. Attualmente, i modelli di Machine Learning sono spesso utilizzati in molti progetti di Big Data nell'Industria 4.0. Questi modelli hanno già dimostrato di poter garantire performance molto soddisfacenti per applicazioni passive come la modellazione e la manutenzione predittiva, il riconoscimento di pattern, la classificazione, il monitoraggio di processo ed il rilevamento e la diagnosi di guasti operazionali. Tuttavia, il loro utilizzo indiscriminato può essere controproducente: non è possibile, ad esempio, ricorrere ad essi al fine di ottimizzare un processo industriale (applicazione attiva) a meno che i dati analizzati non siano stati raccolti a partire da un disegno sperimentale (il che costituisce una grave limitazione dal punto di vista pratico). D'altro canto, i metodi predittivi basati su variabili latenti (come la regressione ai minimi quadrati parziali) possono essere utilizzati per*

l'ottimizzazione del processo indipendentemente dal fatto che i dati provengano da un progetto di esperimenti o da un processo di produzione giornaliero (dati storici).

Key words: process optimization, industry 4.0, latent variable methods, PLS model inversion, quality by design (QbD).

1 Introduction

Industry 4.0 paradigm is being adopted by industry and technology fostered by the Industrial Internet of Things (IIoT). Processes not only produce goods or provide services but also data, and there is a strongly belief that data contain useful information that has to be mined for helping the decision-making process (Ferrer, 2020). This is leading to the so-called Big Data environment, characterized by the four V′s: volume, variety, velocity and veracity. This has not caused only a change in the number of the variables but also a change in the nature of the registered data, coming from customers, quality properties and processes, and even from equipment. There are a wide variety of sensors providing different type of signals: spectra (chemical signals), pressures, temperatures, flows, etc. (physical signals), pH, conductivity, dissolved oxygen, etc. (biochemical signals), electronic eyes (digital images), electronic noses and tongues (potentiometric signals), electronic ears (acoustic signals), and so on. These data mostly collected from routine daily production often exhibit high auto and cross correlation, rank deficiency, low signal-to-noise ratio, multi-stage and multi-way structure, and missing values. In most of the cases they are happenstance data (i.e., data from daily routine production and not generated from any experimental design) and, therefore, correlation does not necessarily mean causation.

Process data in industry, although shares many of the characteristics represented by the four V′s may not really be Big Data in comparison to other sectors such as social networks, sales, marketing and finance. However, the complexity of the questions we are trying to answer with industrial process data is really high, and the information that we wish to extract from them is often subtle. This info needs to be analyzed and presented in a way that is easily interpreted and that is useful to process engineers. Not only do we want to find and interpret patterns in the data and use them for predictive purposes, but we also want to extract meaningful relationships that can be used to improve and optimize a process (García-Muñoz and MacGregor 2016).

Latent variables (LV) models, such as principal component analysis–PCA (Jackson 2003) or partial least squares–PLS (Wold et al 2001), are especially suited for successfully addressing the characteristics 4 V′s of Big Data. They are compressing tools that handle the dimensionality and collinearity issues of the high volume of data. They can cope with the variety of data by using multiblock methods (Westerhuis 1998) for integrating data from different sources (data fusion). LV models can be updated in real time to cope with the speed of data acquisition

(velocity) and are especially suited for outlier detection, missing and noisy data, typical issues for checking the data veracity.

LV methodology exploits the correlation structure of the original variables by revealing the few independent underlying events (latent variables) that are driving the process at any time. This is done by projecting the information in the original variables down onto low-dimensional subspaces defined by a few LV (i.e. scores). The multivariate scores are mathematically orthogonal and optimal summaries of the measured variables. The scores are also less noisy than the measured variables, because they are weighted averages (linear combinations) of the measured variables. Classical statistical assumptions (independency, normality and so on) which in general are not appropriate for the original variables recorded, can be reasonable for the scores, and therefore classical statistical tools are appropriate to analyze them. We could conclude that in the latent space, dealing with big data is easier than in the original variables space (Ferrer 2020).

2 Are all data analytics models useful?

MacGregor (2018) states that to analyze historical data, one needs to make use of models, usually empirical – such as linear regression-LR, machine learning-ML (e.g., deep learning, random forest, etc.) or LV models. All models are wrong but some are useful (Box 1976). But all empirical (i.e. data analytics) models are not equally useful. Whether a data analytics model is useful depends on three issues: i) the objectives of the model (passive vs active); ii) the nature of the data used for the modeling (historical operating data vs data from design of experiments–DOEs); and iii) the regression method used to build the model (ML and classical LR vs LV models such as PLS).

Regarding the objective, there are two major classes of models – those to be used for passive use and those to be used for active use. Models for passive use are intended to be used just to passively observe the process in the future (e.g. predictive modelling and maintenance, pattern recognition and classification, and process monitoring, fault detection and diagnosis). For such passive uses one does not need or even want causal models, rather one wants to just model the normal variations common to the operating process. Historical data are ideal for building such models. On the other hand, models for active use are intended to be used to actively alter the process to gain causal information (i.e., process understanding) from the data (e.g., trouble-shooting, optimization and control). For active use one needs causal models. Causality implies that for any active changes in the adjustable variables in the process, the model will reliably predict the changes in the output of interest (MacGregor 2018).

To guarantee causality when using data-driven approaches, however, independent variation in the input variables is required (Box et al 2005). While a Design of Experiments (DOE) on the plant would provide data satisfying this requirement, in practice such approach may be difficult to carry out, if not unfeasible (i.e. the number of potential factors to consider as inputs can be really

high, and due to the complex correlation structure among them there are a lot of restrictions that prevent moving some factors independently from others). On the other hand, nowadays large amounts of historical data are available in most production processes. The problem is that this data is highly collinear and low rank because the variation in the inputs is commonly not independent (i.e., data are not obtained from a DOE that guarantees this independent variation in the inputs). Therefore, input-output correlation does not mean necessarily causation. In this context, classical predictive models (such as LR and ML), proven to be very powerful in passive applications, cannot be used for process optimization (active use). They cannot be used for extracting interpretable or causal models from historical data for active use. With historical data, there are an infinite number of models that can arise from any of these LR or ML methods, all of which might provide good predictions of the outputs, but none of which is unique or causal. Because the process variables are all highly correlated and the number of independent variations in the process is much smaller than the number of measured variables, one can get many of those models all using different variables and having different weights or coefficients on the variables that give nearly identical predictions. This does not allow for meaningful interpretations, even more so if the results come from averaging or voting on many models, such as in random forest (MacGregor 2018). This is the essence of the Box et al (2005)´s warning: predictive models based on correlated inputs must not be used for process optimization if they are built from observational data (i.e. data not coming from a DOE). Note that this is a mistake that is beginning to occur in industry 4.0 with the indiscriminate use of ML tools.

Methods based on LV, such as PLS regression, allow the analysis of large datasets with highly correlated data. Since they assume that the input (X) space and the output (Y) space are not of full statistical rank, they not only model the relationship between X and Y (as classical LR and ML models do), but also provide models for both the X and Y spaces. This fact gives them very nice properties: uniqueness and causality in the reduced latent space (this is the only space within which the process has varied) no matter if the data come either from a DOE or daily production process (historical/happenstance data) (Liu et al 2011, MacGregor et al 2015). These properties make them suitable for process optimization (active use) no matter where the data come from.

3 Process optimization through latent variables (PLS) models

As already commented, model-based process optimization requires building a causal model that relates changes in the process inputs with those in the process outputs. To this purpose, deterministic (i.e. first principles) models are always desirable. However, the lack of knowledge and the generally ample need of resources required to properly construct such models makes their use unfeasible in a large number of cases, and data-driven models are often resorted to, instead.

Optimizing a process using predictive data-driven methods that directly relate the registered input variables with the output variables (such as LR and ML models) requires causality in this input-output relationship, and this is only guaranteed if data are obtained from a DOE, what is highly difficult (or even unfeasible) to get in industrial practice. Nevertheless, LV models, such as PLS, can model causality in the latent space and, therefore, can be used for process optimization even with happenstance data[2].

By moving the LV one can reliably predict the outputs (Y) But to move the latent variables one cannot just adjust individual X variables, but rather combinations of the X variables that respect the correlation structure of the model[3].

This property makes them suitable to be used in process optimization for finding the so-called design space (DS), i.e. the combinations of input variables that are consistent with the historical correlation structure and region where the process has been operated, and also guarantee the desired outputs (Jaeckle and MacGregor 2000, MacGregor et al 2015).

In order to apply the QbD initiative, two distinct strategies have been proposed in the literature (Palací-López et al 2020): i) defining or estimating the DS as a whole, and ii) solving an optimization problem in an attempt to obtain single sets of process conditions within the DS.

The first of these strategies, when resorting to LV models, relies on the so-called null space (NS), i.e. the subspace in the latent space within which the prediction of the outcome responses does not vary (Jaeckle and MacGregor 2000, García-Muñoz et al 2006), for which the uncertainty in its definition can also be accounted for (Facco et al 2015, Bano et al 2018, Palací-López et al 2019). Regarding the second strategy, since the initial number of variables involved is reduced to a smaller number of uncorrelated LV, the computational cost of any optimization problem in the latent space will decrease with respect to the same problem in the original space (Palací-López et al 2019, Tomba et al 2012).

4 Conclusions

Not all data analytics models are equally useful in industry 4.0. The usefulness of a model depends on the objective of the study (passive or active), the nature of the data (historical operating data vs. data from design of experiments – DOEs) and the technique used (ML and classical LR vs LV models such as PLS). ML models are currently being implemented in many Big Data projects in Industry 4.0. Although

[2] This is not the same as optimizing via LR or ML models. In such case, causality cannot be inferred and there is no guarantee that the solution would respect the correlation structure of the data, leading to unfeasible solutions.

[3] The latent variables cannot be explicitly manipulated by the user, but the original variables can be manipulated in a way that changes on the process conditions are done along the directions of the latent variables, which is equivalent to implicitly "manipulating" the latent variables themselves.

these models are proven to be very powerful for passive applications (e.g. predictions) they cannot be used for extracting interpretable or causal models from historical data for active use (e.g. process optimization). On the contrary, predictive methods based on LV (such as PLS) much less known in Big Data environments, have two important properties: uniqueness and causality in the latent space, which allow them to be used for process optimization regardless of whether the data come from a DOE or daily production process (historical / happenstance data). This is illustrated with several real industrial examples.

Technology and demographic behaviours (AISP-SIS)

Internet and the Timing of Births

Internet e le Tempistiche di Fecondità

Maria Sironi, Osea Giuntella, and Francesco C. Billari

Abstract Technological innovations directly related to fertility have been linked to the timing of births, i.e. with postponement in the case of contraceptive technology and with "recuperation" in the case of assisted reproductive technology. We argue that the diffusion of the Internet also plays a role as an "enabling" factor in fertility choices, with a particular effect on the timing of fertility. We hypothesize that Internet access contributes to the postponement of fertility during the earlier ages and stages of the life course, and to a recuperation in later ages and stages of the life course. We use data drawn from different sources to test our hypothesis. Consistent with our prior, results provide evidence that high-speed Internet decreases fertility among young women and increases adult fertility among high-skilled women.

Abstract *Le innovazioni tecnologiche correlate alla fecondità sono state direttamente associate all'età a cui si hanno i figli, come per esempio nel caso dei contraccettivi che permettono di posticipare la nascita dei figli o della riproduzione assistita che permette di avere figli in età più avanzata. Questo lavoro ipotizza che anche la diffusione di internet giochi un ruolo importante nelle tempistiche di fecondità, aiutando a posticipare la nascita dei figli in giovane età e a velocizzare il processo in età più matura. Per verificare la nostra ipotesi abbiamo utilizzato diverse fonti di dati e i risultati confermano che internet riduce la fecondità per le donne giovani e la aumenta per le donne adulte e altamente qualificate.*

Key words: Internet, Fertility, Teenage Pregnancy

1 Introduction

Has the effect of technological change on the timing of fertility reached its peak with the introduction of modern contraceptives (and perhaps household appliances)? We here argue that the incredibly fast diffusion of digital technologies, and the Internet in particular, might play an important role in shaping the transition to parenthood. The diffusion of the Internet has been incredibly fast. In the U.S., Internet usage rates grew from 5 percent to 74 percent between 2000 and 2009 (Dettling, 2017). The fast diffusion of the Internet might have had effects on teen birth rates and to the postponement of fertility. These effects are potentially offsetting, and there could be opposite forces at work. Some forces could contribute to an earlier timing of fertility, and potentially to higher teen birth rates. This is the case of partnership formation an easier access to a wider market for partners who can be prospective co-parent, or of the easier access to sexual stimuli. Other forces could contribute to a postponement of fertility, in particular information and social interaction. A third set

Francesco C. Billari, Bocconi University; email: francesco.billari@unibocconi.it

of forces could contribute to a "recuperation" effect: if the Internet allows to lower the costs of combining work and parenthood, the effects of the Internet would change and potentially reverse over age. Moreover, social stratification, and the presence of "digital divides", might contribute to differential effects across different social strata, as even "digital natives" are socially stratified in terms of Internet skills and uses (Hargittai, 2010).

In this paper, we use data from multiple sources to analyze the effects of Internet on fertility over the life-cycle. First, using individual-level data from the National Longitudinal Study of Youth 1997 (NLSY97) we study the relationship between Internet access and the propensity to give birth among young men and women (under 31). We test a series of hypotheses on the timing of fertility and on differences between genders, educational and occupational groups. Our findings show a significant postponement effect of the Internet on the timing of births. We complement this analysis using data from the Current Population Survey which have less precise information on fertility, but because of the larger size of the sample allows us to use an instrumental variable approach using regional Internet penetration and to further explore the heterogeneity of the effects by age, education, and marital status. Finally, we provide further evidence on the relationship between Internet and fertility using county-level data. In particular, we exploit data from the Natality Detail Vital Statistics covering the universe of births occurring in counties with at least 100,000 inhabitants and merge these data with information on broadband deployment across US counties drawn from the Federal Communication Commission.

2 Empirical Analysis

2.1 Longitudinal analysis using NSLY97

We analyse fertility of younger adults using the National Longitudinal Survey of Youth 1997 for the United States (NLSY97). The NLSY97 is an ongoing, nationally representative longitudinal study of 8,984 youths who were 12 to 16 years old in 1997. It started in 1997 and people in the sample are interviewed every year. The most recent wave that is available has been collected in 2011-2012, when surveyed individuals were between 27 and 31 years old. Since our aim is to study how the diffusion of the Internet is associated with childbearing and the timing of childbearing, our key independent variables are built upon the question: "Do you currently have access to the internet?"

Because we are interested in fertility timing, and how this decision of having a child is connected to Internet access, we look at two different points in time for which we present our descriptive statistics. We focus first on the period 2003-2006, when the respondents are between 19-23 and 22-26, and then on the period from 2007 to 2011, when they are between 23-27 and 27-31 years old. By dividing the analysis into these two time periods we can test the hypothesis that access to Internet is negatively associated with fertility in young ages, and positively associated to fertility at older ages.

In order to test the hypothesis that effects are more marked for women than for men we run all analyses separately for men and women. Moreover, given that we

expect that the association between Internet access and fertility is stronger for individual with high socioeconomic status and higher educational background, and we want to test whether results are explained by partnership formation, we take into account the highest grade completed by each individual, parents' level of education, and partnership status in our multivariate analysis.

After presenting some descriptive statistics, we use discrete-time event history analysis regression models (Allison, 1982) to study the association between Internet access and timing of births. More specifically, we restrict our analysis to individuals who haven't had a child before 2003, so that everyone in the sample starts with a parity of zero. This leaves us with 4,312 individuals. To take into account the fact that some individuals may be more at risk than others for reasons that are not fully captured by the variables included in the model, we run discrete-time multilevel event history logistic models, in which individual birth episodes are nested within individuals (Barber et al., 2000). Multilevel event history models allow us to introduce random effects, which represent individual-specific unobservables. Recurrent events give a two-level hierarchical structure: episodes (i.e. birth of a child) are clustered into individuals (i.e. mother or father). We follow individuals in the sample over time and we look at when they have their first child and subsequent children.

Our regression models include some time-varying covariates other than the key explanatory variable related to Internet access such as age, partnership status, birth parity, region of residence, if living in an urban or rural area, enrolment in school, and educational attainment. They also include time-constant variables, i.e. race, parents' education, and family income in 1997. All the models are run separately for men and women (see Table 1 as an example for men).

2.1.1 Results using NLSY97

Our first two hypotheses seem to be partially confirmed, with a negative association between Internet access and fertility at younger ages, and a less negative relationship and eventually positive relationship at older ages. Our third hypothesis, that the association of Internet and fertility is stronger for women, doesn't seem to be confirmed. Our fourth hypothesis, that the relationship between the Internet and fertility is stronger among those with higher socio-economic status (highly educated parents), is confirmed for both men and women. And finally, our "partnership' hypothesis is confirmed for women but not for men: the association between Internet access and fertility doesn't change based on the presence of a partner among men, but it does among women. The evidence presented so far suggests a significant negative association between access to high-speed Internet and fertility of young men and women. A main caveat is that these results cannot be interpreted causally as there could be unobserved factors not accounted for by the multi-level event-history models that may be correlated with both access to highspeed Internet and fertility.

To partially address this limitation, we complement the analysis exploiting geographical variation in the penetration of broadband internet across areas. In practice, we estimate the relationship between Internet penetration within a county and childbirth. Due to the small sample size we are unable to conduct a two-stage

relationship instrumenting individual access to Internet with the average access in the county, the instrument is too weak. But we document the reduced-form relationship between average access to Internet in the county and fertility patterns. While the coefficients are not precisely estimated given the small sample size available in the NLSY, the pattern is consistent with the hypothesis that Internet may decrease fertility among the very young women, while it may have an opposite and positive effect among older women.

2.2 Individual Analysis Using CPS Data

To further explore the heterogeneity of effects across sociodemographic groups, we complement the analysis using data from the Current Population Survey. The CPS is a monthly U.S. household survey conducted jointly by the U.S. Census Bureau and the Bureau of Labor Statistic. The CPS contains a battery of labor force and demographic questions and since 1997 periodically collects supplemental information on Internet usage and since 2000 on the type of internet connection (Dial-up, faster-connection type such as DSL (Direct Subscriber Line), cable modem, satellite, mobile broadband service, or fiber-optic service. This information is available in the Computer and Internet Use Supplement for the years 2000 and 2001 and in the October Education Supplement in years 2003, 2007 and 2009. Importantly for the purpose of our project, the CPS also contains information on the number of own children in the household, the age of the youngest own child and then number of own children under age 5 which can be used to analyse fertility decisions. We focus on access to high-speed internet distinguishing fast connections (DSL, fiber optic cable, coaxial cable, wireless technology and satellite) from dial-up Internet.

The large size of the CPS sample allows us to adopt an instrumental variable approach. We instrument Internet access with the average access to high-speed internet in the respondents' state. Our instrument is a strong and relevant predictor of internet access and the first-stage F statistic is well above the conventional weak-instrument thresholds. All estimates include controls for a quadratic in age, race dummies, an indicator for reporting Hispanic ethnicity, dummies for citizenship status, state and year fixed effects. As we expected, results show that the relationship between access to highspeed internet and the number of young children in the household is non-significant among younger and unmarried individuals, and positive and significant among older and married individuals. We find similar results when considering as an alternative outcome a dummy for whether individuals had children younger than 5 years old in the household.

2.3 Internet and fertility rate using county-level data

Finally, we provide further evidence on the heterogeneous relationship between Internet and fertility rates by age and education using data drawn from the Natality Detail Data (1999-2004) and broadband data from the Federal Communication Commission. The Natality Data are drawn from the National Vital Statistics System of the National Center for Health Statistics and provide demographic and health data for births occurring during the calendar year. The microdata are based on information abstracted from birth certificates filed in vital statistics offices of each

State and District of Columbia. Using intercensal population estimates by age and gender from the United States Census Bureau we construct birth rates for different socio-demographic groups and linked these rates with county-level broadband data drawn from the Federal Communications Commission (FCC). As we only have data from the FCC since 1999 and as county information is available only until 2004, we restrict the county-level analysis to the years 1999-2004. It is worth noting that information is publicly available only for counties with more than 100,000 inhabitants and thus the results cannot inform about the effects of Internet on fertility in rural and less populated counties.

The county birth rate is positively associated with broadband penetration. A one standard deviation increase in the percentage of the county with at least one provider is associated with a .26 standard deviation (a 14% increase with respect to the mean) increase in fertility rate among 25-44 old women. The coefficient isn smaller and non-significantly different from zero among low-skilled, unmarried, and teenagers. It is instead largest among married women for whom a 1 standard deviation increase in broadband penetration increases fertility by 0.35 standard deviation (a 19% increase with respect to the mean).

3 Conclusions

Internet has revolutionized the way we organize and use our time. This study analyses the effects of access to high-speed internet on fertility in the US. We presented an analysis of the links between one of the main aspects of the digital revolution that took place at the end of the Twentieth Century, the deployment of the Internet, and fertility decisions. In a sample of young adults from the NLSY97, within the age range 18-31, we found that having access to the Internet tends to be associated with lower fertility. We also found that this negative association tends to fade away with age, indicating a role of the Internet in the postponement of fertility. Moreover, the negative association is weaker for men and women from a higher socioeconomic background. We did find evidence for the role of partnership formation as a mediating factor in the relationship between Internet access and fertility among women, but not among men. These results are mainly in line with the findings of Guldi and Herbst (2017) and with an interpretation that emphasizes the role of information availability and social interaction. This interpretation is in line with the idea that the Internet amplifies the information effects that other, older communication technologies, like the TV, have been shown to have on fertility (Jensen and Oster, 2009; La Ferrara et al., 2012).

Using data from other the CPS and Natality Detail Data we also find evidence of the role of the Internet in the “recuperation” of fertility at later ages. Access to high-speed Internet is positively associated with fertility outcomes of high-skilled women in their thirties, while we find non-significant results among low-skilled, young and unmarried women. These results are consistent with the findings of Dettling (2017) and Billari et al. (2017) and the hypothesis that internet may relax time constraints of high-skilled working women reconciling family, motherhood and work.

The Internetization of Marriage: Effects of the Diffusion of High-Speed Internet on Marriage, Divorce, and Assortative Mating

L'Internetizzazione del Matrimonio: Effetti della Diffusione di Internet Veloce sul Matrimonio, Divorzio e sul Processo di Selezione del Partner

Francesco C. Billari, Osea Giuntella and Luca Stella

Abstract The advent of the Internet has radically changed the process of finding a stable partner. We exploit some historical and technological features of the broadband roll-out across Germany to provide instrumental variable (IV) estimates. Our IV results suggest that high-speed Internet increases the hazard of marriage, with the effects being concentrated among the high-educated people. Furthermore, we show that broadband access significantly increases educational homogamy, which we interpret as our potential channel underlying the relationship of interest.

Abstract *L'avvento di Internet ha modificato in modo radicale il processo di selezione di un partner. In questo lavoro sfruttiamo alcune caratteristiche storiche e tecnologiche della rete telefonica in Germania per fornire stime a variabili strumentali. In particolare, troviamo che Internet veloce aumenta la probabilita' di sposarsi, soprattutto tra le persone piu' istruite. Inoltre, troviamo che Internet veloce aumenta l'omogamia per livello di istruzione, il che potrebbe spiegare la nostra relazione di interesse.*

Key words: Internetization, Marriage, Divorce, Assortative Mating

1 Introduction

Since the mid 1990s, the world entered full-speed in what Castells (2001) defined the Internet Galaxy. Daily life has become shaped by the presence of the Internet in all its domains. Partnership dynamics, and marriage, are no exception. What are the consequences of the diffusion of the Internet for partnership formation and dissolution? In this paper, we argue and document with a set of empirical analyses, that the diffusion of the Internet has radically changed the transition to marriage, both in terms of speed and in terms of type of match, with ambiguous effects on marital stability. We have entered the era of the Internetization of Marriage.

In general, the notion of Internetization refers to the pervasive two-way effects of the Internet on social and economic phenomena. This notion, importantly, acknowledges that social and economic phenomena that become internetized become radically different from the pre-internetized era, also in their offline nature. The social theorist Leopoldina Fortunati defines and discusses, for instance, the Internetization of mass media. In the context of mass media, the presence of the Internet on the one side allows, and even forces, traditional media to be active online in order to be visible and seen, and on the other side changes the way classic mass media exist--as they change and their traditional forms (e.g. in print, audio, or video), also become internetized (Fortunati, 2005).

The Internetization of Marriage can therefore be seen as a process with two main channels, and possibly two stages, in analogy to mass media. First, the Internet provides, directly, new ways to find a partner online. Referring to this direct role, Rosenfeld and Thomas (2012) defined the Internet as the rising and new "social intermediary" in the search for mates. For instance, online dating is defined as "the use of websites that provide a database of potential partners - typically in close geographical proximity - that one can browse and contact, generally for a fee" (Sautter et al., 2010, p. 555). Second, the presence of the Internet radically changes partnership dynamics, including partnerships that have been formed offline. If we include this second stage, which has been less studied so far, the effects on marriage of the Internet becomes more ambivalent.

For what concerns the first stage of the Internetization of marriage, the speed at which information can be collected, and the possibility to make targeted search, such as for specific combinations of characteristics of a prospective co-parent, as in the case of online dating (Potarca et al., 2015) might in general imply a quicker transition to a partnership. Online interaction allows to gather more information on prospective partners (within social media or online dating, but also in general including prospective partners met offline), with a decline of the role of distance with respect to the pre-Internet era (Mok and Wellman, 2007). For these reasons, more stable partnership situations can be expected as the outcome of better matches in the era of the Internet (Cacioppo et al., 2013; Rosenfeld, 2017). The width of the partnership market might increase and therefore allow a search from a wider pool, which would take longer and imply a postponement of partnership formation, creating a sort of "information overload" (Rosenfeld, 2017).

For what concerns the second stage of the Internetization of marriage, the empirical literature here is scarce. An exception is a study that uses aggregate-

level data and exploits the timing of broadband diffusion in the US, in which Bellou finds that broadband diffusion is positively correlated to marriage rates (Bellou, 2015). The presence of the Internet is changing relationships in general, in many ways, including communication among partners (Coyne et al., 2011), and brings the possibility of new conflicts emerging within the family (Mesch, 2003), and of larger intergenerational contacts outside the co-residential family (Gubernskaya and Treas, 2016). Using data from the U.S. General Social Survey for the year 2000, Wasserman and Richmond-Abott (2005) showed that married individuals were more likely to access the Internet, while they did not significantly differ in the type of use from individuals who were not married. Using the same data, the quality of a marital relationship, for instance, was found to be a predictor of the use of Internet pornography (Stack et al., 2004).

The Internetization of Marriage has additional implications for social stratification and inequality that might go beyond its effects on assortative mating, which by itself has implications on inequality (Schwartz, 2010). In terms of stratifying factors, there is no particular reason to believe that gender plays a specific role in this case. However, other aspects of social stratification will play a role, in addition to the mere access to the Internet, as prospective parents from upper socioeconomic strata might have a bigger advantage from interactions that start online. A first level of inequality relates to the material "digital divide" in access, and the quality of this access, to the Internet itself (Norris, 2001). A second level of "digital inequality" refers to the knowledge of search strategies, the capability to evaluate the quality of information, and to exploit the potential of the Internet (DiMaggio et al., 2001). Eszter Hargittai has termed this latter inequality in online skills as the "second-level digital divide" (Hargittai, 2002). Potarca (2017), for instance, shows that couple who meet online are less endogamous than couples who meet at school, religious venues, or through family and friends.

Our empirical study is based on the German Socio-Economic Panel (SOEP), a longitudinal panel dataset of the German population containing information on a rich set of individual socio-economic characteristics. Three features of the SOEP are key to our analysis. First, for every respondent, the survey contains a detailed marital history, allowing us to use information on the year of marriage and divorce to construct our main outcomes of interest. Second, the survey not only collects household information on whether Internet access is available, but also data on whether Internet access is based on a broadband (DSL) technology. This information is exploited to build our key explanatory variable. Finally, the SOEP collects not only respondents' education but also educational attainment of their spouses. This enables us to examine assortative mating by education, and thus shed light on the potential mechanism through which high-speed Internet access may influence partnership formation. To address the concern regarding endogeneity of broadband Internet use, we follow the identification strategy adopted by Falck et al. (2014) and later replicated by Billari et al. (2019). Our 2SLS estimates suggest that DSL access increases the hazard of marriage. These results are entirely driven by the high-educated people. We find ambiguous results for divorce. Furthermore, we show that broadband access significantly

increases educational homogamy, which we interpret as our potential channel underlying the relationship of interest.

2 Introduction

As previously stated, the focus of this paper is to investigate how access to broadband Internet affects marriage, divorce and assortative mating. To this end, we estimate the following linear probability model:

$$Y_{ist} = \alpha + \beta DSL_{ist} + \gamma X_{ist} + \mu_t + \eta_s + \varepsilon_{ist} \quad (3)$$

where the index ist denotes an individual i residing in federal state s at the year of interview t. We have a set of outcome variables, Yist, defined as follows: 1) the annual hazard of marriage (i.e., the annual probability of getting married for unmarried individuals); 2) the annual hazard of divorce (i.e., the annual probability of divorce for married individuals); 3) educational homogamy, operationalized by an indicator equal to one if the couple has the same educational level (only for individuals who are married); and 4) the distance (in absolute value) between the educational level of the respondent and his/her partner (only for individuals who are married). Our main explanatory variable of interest is DSList, which represents a dummy variable taking value one if an individual has a high-speed Internet subscription at home, and zero otherwise. Accordingly, the coefficient of interest, β, captures the impact of access to high-speed Internet on the outcome of interest. To address the concern regarding endogeneity of broadband Internet use, we follow the identification strategy adopted by Falck et al. (2014). Their main idea is to exploit historical variation in pre-existing telephone infrastructure which significantly affected the cost of broadband adoption across Germany. In particular, Falck et al. (2014) exploit three unique historical and technological peculiarities of the traditional public telephone network, which influenced the deployment of DSL in German municipalities. Table 1 reports the 2SLS results for marriage (see Panel A) and divorce (see Panel B). The 2SLS coefficient in column 1 of Panel A suggests a positive and significant impact of broadband Internet on the transition into marriage: having a high-speed Internet subscription increases the hazard of marriage by 13.3 percentage points. In columns 2 and 3 of Panel A, we test for the presence of digital inequalities, analyzing whether the effect differs by the educational group of the respondent. The effect of broadband Internet on marriage is driven by the high-educated individuals. Panel B of Table 1 reports the 2SLS parameter estimates of high-speed Internet on the hazard of divorce. Because marriage is a prerequisite of divorce, we conduct this analysis on the sample of married individuals. As shown in columns 1 to 3, we do not find evidence of a significant effect of high-speed Internet on divorce, with the effects

being very small in magnitude. DSL technology reduces the cost of searching and allows for the selection of a similar partner with minimum efforts. Therefore, DSL access provides individuals with more opportunities to match with partners that share the same background. To test this hypothesis, we analyze the effects of DSL access on educational assortative mating. Specifically, we measure assortative mating along two dimensions: homogamy, and the distance (in absolute value) between the educational level of the respondent and her partner. Overall, the results suggest that DSL access is associated with higher homogamy, and thus it reduces the educational distance between the partners (results of this analysis are available from the authors upon request).

Assessing the impact of the intermediate event in a non-markovian illness-death model

Valutazione dell'impatto dell'evento intermedio in un modello multistato "illness-death" non-markoviano

Davide Paolo Bernasconi, Elena Tassistro, Maria Grazia Valsecchi, Laura Antolini

Abstract In the illness-death model the transition from the initial state to the final state (death) involves an intermediate state (illness). When it is of interest to compare the hazards of mortality before and after illness, one could resort to the Mantel-Byar test, an extension of the logrank test that accounts for the time-dependent nature of illness by ascribing all patients to the illness-free group until they (possibly) become ill; at that time, they are moved to the illness group using left truncation. However, in this approach, time is always measured by the clock forward scale and this is not valid under non markovian processes. We propose an alternative approach, suitable for semi-Markov and extended semi- Markov scenarios, based on the adoption of the clock reset scale to measure time after illness. The method is a modification of the logrank test that involves the coefficient of the time to illness from a Cox model fitted only on ill patients to determine the number of patient at risk in time after illness. We compare the two approaches in a simulation protocol.

Abstract *Nel modello "illness-death" la transizione dallo stato iniziale a quello finale (death) include un evento intermedio (illness). Volendo confrontare gli azzardi di morte prima e dopo illness, una possibilità è l'uso del test di Mantel-Byar, un'estensione del logrank test che tiene conto della natura tempo-dipendente di illness. Tuttavia tale approccio è valido solo per processi markoviani poichè il tempo è sempre misurato a partire dallo stato iniziale. Proponiamo quindi un metodo alternativo, sempre basato sul logrank test che, utilizzando una scala temporale che parte dallo stato intermedio, consente di valutare l'impatto dell'evento intermedio in scenari non markoviani. I due metodi sono messi a confronto tramite un protocollo di simulazione.*

Key words: Illness-death model, Mantel-Byar test, Markov property

1 Introduction

Situations where subjects start from an initial condition (state 0) and then can possibly develop a final event (state 2 or *death*), either directly or passing through another intermediate condition (state 1 or *illness*), may be described by the simple *illness-death* multistate model [5], as depicted in Figure 1. This framework may be applied also in situations where the transition to the intermediate state does not consist in the occurrence of a disease but instead represents the administration of a therapeutic intervention. Consider, as an example, patients affected by end-stage cardiomyopathy that enter a waiting list (state 0) to receive heart transplant: they may die (state 2) while still on list or they can indeed be transplanted (state 1) after some time.

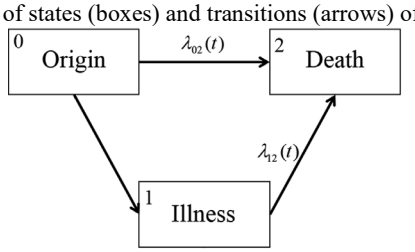
In this context, a key issue is often to assess the impact of the intermediate event on the hazard of mortality which is done, in practice, by comparing two transition hazards: the hazard from state 0 to state 2 $\lambda_{02}(t)$ and the hazard from state 1 to state 2 $\lambda_{12}(t)$. A key aspect to consider to this end is the choice of the scale used to measure time [2]. The most obvious one is the original (or "clock forward") time scale, where time is always measured starting from the entry into the initial state 0. As an alternative, one may resort to the "clock reset" scale, where time is set back to 0 as patients enter the intermediate state 1. In practice, for those who experience the intermediate event, the observation time since origin (denoted as t) can be split in two parts: time elapsed while in state 0 (waiting time to intermediate event, denoted as r) and time elapsed while in state 1 (time since intermediate event, denoted as d).

Depending on the relation between hazards and time scales, three types of data generating process can be defined [6]: Markov, semi-Markov and extended semi-Markov. The process is Markovian if the value of $\lambda_{12}(t)$ for $t>r$ depends only on time t from origin. This means, in other words, that the value of $\lambda_{12}(t)$ depends on time d after intermediate event and on the fixed covariate time to intermediate event r only through their sum $d+r=t$ and not on the values d and r taken separately. The clock forward time scale alone can be conveniently used to measure time even after the intermediate event and the notation $\lambda_{12}(t)$ can be kept, meaning that in this case the hazard depends only on t. The process is semi-Markovian if the value $\lambda_{12}(t)$ for $t>r$ depends only on time d after intermediate event. Thus, the clock reset time scale alone can be conveniently used to measure time after the intermediate event and the new notation $\lambda_{12}(d)$ for $d>0$ is set, meaning that time is measured on the clock reset scale. The process is extended semi-Markovian if the value of $\lambda_{12}(t)$ for $t>r$ depends on time d after intermediate event and on the fixed covariate time to intermediate event r, taken separately. The time d after intermediate event, and thus the clock reset time scale, becomes again the natural way to measure time after the intermediate event and one can set the new notation $\lambda_{12}(r,d)$ meaning that time is measured on the clock reset scale and r has an impact on the hazard $\lambda_{12}(r,d)$ for $d>0$.

In this work we review an extension of the logrank test, namely the Mantel-Byar test, to compare the hazards between two time-dependent groups and show that it is suitable only for markovian processes. Moreover, we propose an alternative method,

based again on the logrank test, that is suitable for non-markovian scenarios. The performance of the two methods is compared in a simulation protocol.

Figure 1: Representation of states (boxes) and transitions (arrows) of the *illness-death model*.



2 Methods

The logrank test is a standard non-parametric tool to compare the hazard of failure between two time-fixed groups, e.g. A and B. Under the null hypothesis H_0: $\lambda_A(t)= \lambda_B(t)$, the distribution of the observed frequency of failures d_{Aj} at each distinct event time $j=1,...,J$ is hypergeometric with $E(d_{Aj})=d_j n_{Aj}/n_j$ and $Var(d_{Aj})= (d_j n_{Aj}/n_j)(1-d_j/n_j)[(n_j - n_{Aj})/(n_j -1)]$. The following test statistics can thus be considered: $Q = U^2/Var(U) = \{\Sigma_j [d_{Aj} – E(d_{Aj})]\}^2/ \Sigma_j[Var(d_{Aj})]$ which follows a Chi-square distribution with 1 degree of freedom.

When the two groups are described by a time-dependent binary indicator, as in the case of an *illness-death model* where patients may enter state 1 after some waiting time, alternative approaches should be considered.

2.1 Mantel-Byar test

An extension of the logrank test to deal with time-dependent groups was proposed back in 1974 by Mantel and Byar [3] in the context of heart-transplant. Time is always measured using the original scale t (time since entry in state 0). At time 0 all patients are in state 0 and thus the risk-set of the intermediate event (i.e. transplant) group is empty.

Suppose a patient is transplanted at time $r=t^*$, since then he/she is moved to the transplant risk-set of the transplanted group. In other words, the observation of that patient is split in two parts: *i)* from time 0 to t^* the patient is ascribed to the waiting-list group and the observation is censored at t^*; *ii)* from t^* onwards the patient is ascribed to the transplanted group and the observation is left-truncated at t^*. If the process is markovian, the hazard of mortality under transplant, after t time units since entry in the waiting list, does not depend on the waiting time to transplant r nor on the time since transplant d. Thus, under markovianity, the Mantel-Byar test is suitable to compare the hazard of mortality of a patient in waiting list with the

hazard of an hypothetical patient transplanted at an arbitrary time r (e.g. at $r=0$). The null hypothesis can be written as H_0: $\lambda_{02}(t) = \lambda_{12;r=0}(t)$.

If the process is not markovian, however, there is an impact of time since transplant d (semi-Markov process) and possibly also of time to transplant r (extended semi-Markov process). In these scenarios, the Mantel-Byar test is not suitable to test the above null hypothesis because the hazard after transplant is calculated by averaging hazards of patients at t time units since entry in list, when patients have spent a different amount of time on list and after transplant [1].

2.2 "Clock reset logrank-type" test

For semi-markovian processes, a simple modification to the Mantel-Byar test can be applied by adopting a double time scale to measure time: the original time scale t before transplant and the clock reset scale d after transplant.

Again, the observation of a patient transplanted at $r=t^*$ is split in two parts: *i)* from time $t=0$ to $t=t^*$ the patient is ascribed to the waiting-list group and the observation is censored at t^*; *ii)* from time $d=0$ onwards the patient is ascribed to the transplanted group. Under the semi-Markov property, the hazard of mortality at time d since transplant does not depend on the waiting time to transplant r. Using this "clock reset logrank-type" test, the hazard after transplant is calculated by averaging hazards of patients at d time units since transplant, disregarding that they spent a different amount of time on list. Thus, under semi-markovianity, the test is suitable to compare the hazard of mortality of a patient on waiting list with the hazard of an hypothetical patient transplanted at an arbitrary time r (e.g. at $r=0$). The null hypothesis can be written as H_0: $\lambda_{02}(t) = \lambda_{12;r=0}(d)$.

When the waiting time on list r has an impact on the hazard after transplant (extended semi-Markov process), this has to be taken into account. Thus, we propose the following two-steps approach. First, fit a Cox model only on post-transplant data to check the impact of time to transplant r on the hazard of mortality after transplant (measured using the clock reset scale) [4]. Then, use the estimated coefficient β_r of r to adjust the size of the risk-set in the transplanted group (n_{12j}) within the "clock reset logrank-type" test. This is done by substituting n_{12j} with $n^*_{12j} = \Sigma_i [exp(\beta_r r_i)]$ (i.e. sum over subjects $i=1,\ldots, n_{12j}$ at risk at time $d=j$) which resembles the expected counts one would observe if patients were all transplanted at $r=0$.

Table 1: Details of the distributions of the transition times used in the simulation protocol. In every scenario: 1000 samples of size 150 were generated; uniform independent censoring was considered; the time to the final state T_{02} was generated from a *Weibull*(0.6;0.7); the time to *illness* R was generated from an *Exponential*(0.5).

Scenario	***D***	***$\beta_r(t)$***
1. H_0: $\lambda_{02}(t) = \lambda_{12;r=0}(d)$	*Weibull*(0.6exp(β_rr/0.7);0.7)	0.5
2. H_0: $\lambda_{02}(t) = \lambda_{12;r=0}(d)$	*Weibull*(0.6exp($\beta_r(t)$r/0.7);0.7)	0.5*log(t/10)
3. H_1: $\beta_{ill} = -log(3)$	*Weibull*(0.6exp(β_{ill}/0.7)exp($\beta_r(t)$r/0.7);0.7)	0.5
4. H_1: $\beta_{ill}(t) \neq 0$	*Weibull*(0.5exp(β_rr/0.5);0.5)	0.5

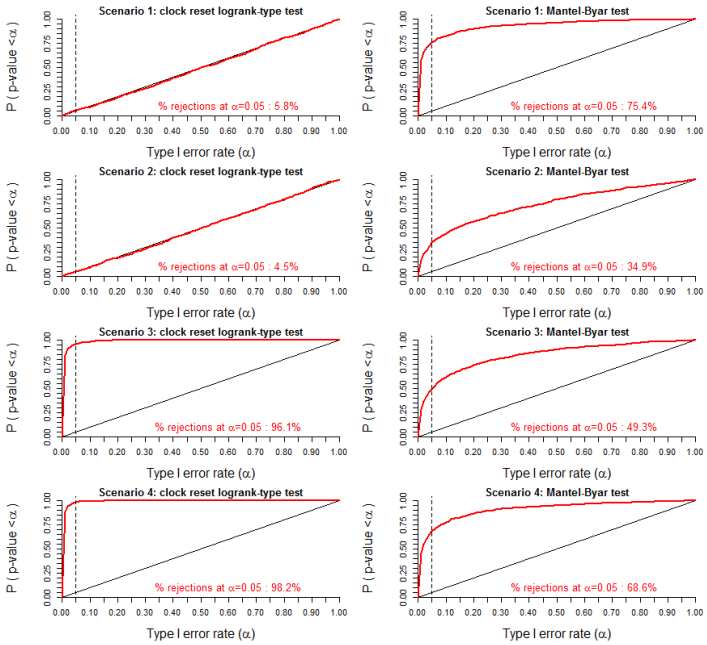
2.3 Simulation protocol

We compared the performance of the Mantel-Byar test vs the "clock reset logrank-type" test in four scenarios under the extended semi-Markov property. In the first two scenarios data are generated under the null hypothesis of equality of the hazards of mortality before and after intermediate event but in scenario 1 the effect of the time to intermediate event *r* is time-fixed while in scenario 2 it is time-dependent. In the last two scenarios data are generated under an alternative hypothesis where the intermediate event has a beneficial effect on mortality but in scenario 3 the effect of *"illness"* is proportional (coefficient β_{ill} is constant) while in scenario 4 it is non-proportional (coefficient β_{ill} is time-dependent). More details are shown in Table 1.

3 Results

The results of the simulation protocol are reported in Figure 2. Under the null hypothesis (scenarios 1 and 2), the percentage of rejections with the "clock reset logrank-type" test are close to the nominal level, while the Mantel-Byar test tends to reject the null too often. Moreover, the "clock reset logrank-type" test has a higher power than the Mantel-Byar test, as shown by the higher percentage of rejections under an alternative hypothesis (scenarios 3 and 4).

Figure 2: Results of the simulation protocol. The R Software (version 3.6.2) was used for the analyses.



4 Concluding remarks

The impact of the occurrence of illness on the hazard of death can be investigated non-parametrically with logrank-type tests.

The null hypothesis H_0: $\lambda_{02}(t) = \lambda_{12;r=0}(t)$ can be tested by the Mantel-Byar test only when the process is Markovian. For non-Markov processes, we proposed a test based on the clock reset time scale (thus suitable for semi-Markov scenarios) that can possibly account for the effect of the time to illness r (thus becoming suitable also for extended semi-Markov scenarios). In our simulation protocol, due space reasons, we only considered an extended semi-Markov data generating process and we only compared two methods: the "classic" Mantel-Byar approach vs the "clock reset logrank-type" test accounting for time to illness. Within this framework, we considered four scenarios to check the performance of the methods under the null (scenarios 1 and 2) or an alternative hypothesis (scenarios 3 and 4) and in the absence (scenarios 1 and 3) or presence (scenarios 2 and 4) of time dependent effects.

As an alternative, one can consider a Cox model where time after transition to state 1 is measured using the clock reset scale and where the time-dependent indicator of transition to state 1 and the fixed time to state 1 are included in the model as covariates [6]. This latter solution is not directly suitable for situations where hazards are not proportional.

Big data and AI: challenges and opportunities in healthcare

Big data e Intelligenza Artificiale: sfide e opportunità in sanità

Vieri Emiliani, Gian Luca Cattani, Fabrizio Selmi[1]

Abstract The sustainability of healthcare systems is put at risk by the increase of health and long-term care demand of an aging population. So far, information technology has failed to delivery in healthcare the benefits in terms of efficiency that has been able to provide to other sectors. Conversely, several studies relate the adoption of Electronic Health Records with decreased professional satisfaction and increased risk of professional exhaustion. Big Data and Artificial Intelligence are among the technologies that are driving the so-called digital transformation. The aim of this paper is to provide an overview on how a broader adoption of these new technologies could help addressing these issues, using a first-hand case study to illustrate the results that can be achieved.

Abstract *La crescita della domanda per servizi di cura e salute dovuta all'invecchiamento della popolazione sta mettendo a rischio la sostenibilità dei sistemi sanitari. Ad oggi, l'information technology in sanità ha fallito nel produrre i benefici in termini di efficienza che è stata in grado di realizzare in altri settori. Al contrario, alcuni studi correlano l'introduzione di EHR a un calo della soddisfazione professionale e a un aumento del rischio di burnout. Big Data e Intelligenza Artificiale sono tra le tecnologie che guidano la cosiddetta digital transformation. Lo scopo di questo articolo è fornire un inquadramento di come l'adozione di queste nuove tecnologie può contribuire ad indirizzare questi problemi, usando un caso studio per illustrare i risultati che è possibile raggiungere.*

1 Introduction

Advances in medicine and healthcare contribute to increase life expectancy. As a result, the population of the elderly in most countries is increasing, leading to a growing demand of health and long-term care services. The number of Europeans aged 65 or over, reached in 2018 100 million [1]. Eurostat forecasts that people over 65 will grow to 23.9% in 2030, adding 23 million of elderly people that will require complex and expensive care treatments and services. European high standards in providing affordable, accessible and high-quality health systems come at a cost: EU healthcare expenditure relative to GDP in 2016 was already close to 10% [2], while in Italy the total spending for healthcare amounts to 149.5 billion of Euro (8.9% of Italian GDP), 75% of which is covered by public funds [3].

"A radical redesign of health is needed to meet these challenges" [4]. Big Data and Artificial Intelligence (AI) applications are supporting the innovation in many traditional sectors. Our aim is to contribute to the discussion on how these technologies can help to ensure the future sustainability of our health systems by delivering greater efficiency, lower costs and better health outcomes.

The remainder of this paper is structured as follows: in Section 2 we provide an overview of the IT context in healthcare, current issues and how a broader adoption of Big Data and AI could help to address some of them. In Section 3 we present a case study where such technologies have been used to improve the efficiency of allocation of diagnostic procedures in an Italian Local Health Authority. Finally, challenges and barriers that need to be addressed are discussed as our conclusions.

2 Context

From autonomous vehicle control to drone-based aerial intelligence to identify crop pests, insurance claims processing, movie recommendation, fraud detection, Big Data and AI lead this innovation stream called digital transformation. In the last decade, the vast amount of data generated and collected by sensors, mobile phones and computerised systems, combined with the increase of computational power and the commoditisation of data storage, enabled the application of well-known algorithms [5] to a multitude of new use cases that now permeate our lives.

Big Data [6][7] and AI [8][9] research is also very dynamic in Healthcare. AI-powered algorithms outperform physicians in several diagnosis tasks. In 2018 only, more than 1500 papers were published on the topic of AI applied to radiology [10], while in the last year VC firms invested almost $4 billion in Healthcare AI start-ups [11]. Despite this hype, these technologies are not widely applied. 84% of health professionals in Europe either do not use AI tools or are not aware of it, and 59% do not have plans to adopt AI tools over the next 1-3 years [12].

It is acknowledged that adoption of IT tools in healthcare is at least 10 years behind most other sectors [4]. IT systems designed for administrative and management purposes have contributed to a transactional health care model, where poor usability

and rigid workflows limit the efficiency of health care professionals, causing distress and increasing risk of burnout [13],[14].

Healthcare processes are complex, as complex is the data they manage. Industry consensus is that approximately 80% of all healthcare data are unstructured [15]. Computer Vision and Natural Language Processing (NLP) techniques can be applied to convert unstructured data in valuable information for data driven processes, enabling a true digital transformation of healthcare systems [16]. Having tools for the automatic conversion of images and narrative texts in actionable information would relief physicians from the tedious, error prone task of manually encoding diagnoses and procedures and speed up the task of reporting in digital imaging, improving the efficiency of the clinical processes while increasing reliability of the administrative ones (for a review of possible applications please refer to [8]).

In the next section we will illustrate, by means of a first-hand case, how the combination of healthcare data digitisation with the transforming potential of AI have helped a long-term initiative of an Italian Local Health Authority (LHA) in managing quality and appropriateness of referrals for diagnostic tests. In fact, leveraging the availability of referrals in digital format, we fully automated the appropriateness evaluation process, extending the outreach of the initiative from a small fraction of the referrals to their totality, and helped to ensure a more efficient allocation of a scarce and costly resource such as diagnostic imaging.

3 Case study

Inappropriate referral for diagnostic imaging is a worldwide problem for healthcare systems, leading to a waste of resources, increased costs and longer waiting lists, while unnecessarily overexposing patients to radiations. Diagnostic imaging is a co-operative process between the referring clinicians, and the radiologists. The quality of the outcome is strongly influenced by the quality of the diagnostic question and by the appropriateness of the requested diagnostic procedure. Communication challenges, limited knowledge and defensive medicine are all factors that contribute to inappropriate use of diagnostic procedures (DP).

Since 2008, Reggio Emilia LHA (hereafter also AUSL RE) has put in place an initiative targeted to improve the appropriateness of DP referrals. A multi-disciplinary task force developed a set of guidelines for several families of DPs, defining the clinical conditions that are appropriate for referring to a specific DP, and the corresponding level of urgency (priority). The program includes the distribution of educational materials and retraining sessions for the referring physicians.

To provide feedback to doctors, an ex-post review of the referral against the provided guidelines was required. This implies assessing each referral to verify if, given the provided information (gender, age, diagnostic question, diagnostic procedure and priority), it was compliant with the provided criteria. Due to the large number of referrals (more than 90,000 in 2011), this was a daunting task to be performed manually, and therefore only a small sample of the referrals was assessed.

With the digitisation of referrals, an opportunity to automate their assessment using a software tool arose. This led to the development of a software solution, Clinika VAP [17], that analyses the text of the diagnostic question and, given the test and the priority requested, verify the compliance of the referral against the corresponding guidelines. At the core of Clinika VAP there are two main components: first, a patented semantic engine that uses Machine Learning and NLP algorithms to analyse the unstructured clinical information contained in a narrative text. Second, a powerful rule engine that, using a domain specific language, can represent the guidelines criteria and reason about them, to verify if the diagnostic condition is one of those admitted by the referral guideline.

Referral guidelines implementation in Clinika VAP has been progressive, with Neuro MRI being the first to be deployed in 2012, and the others following between 2013 and 2016. Once a guideline is deployed, the LHA can systematically assess all the referral forms, to provide feedback to the GPs, and carry out targeted interventions. In order to measure the effectiveness of the system, more than 400,000 electronic referral forms related to 6 families of DPs have been collected and analysed. For this analysis, a referral was considered as appropriate if and only if both the requested DP and priority were in accordance with the guidelines. The appropriateness trend by referral guideline from 2011 to 2017 is reported in Table 1.

Table 1: Percentage of appropriate referrals by referral guideline, from 2011 to 2017.

		Year *(in grey years preceding guideline implementation)*						
Referral guideline	**Deploy**	**2011**	**2012**	**2013**	**2014**	**2015**	**2016**	**2017**
Neuro MRI	*2012*	29%	61%	67%	68%	71%	71%	71%
Musculoskeletal MRI	*2013*	28%	64%	70%	71%	75%	73%	74%
Colonoscopy	*2014*	27%	54%	57%	59%	65%	70%	70%
Gastroscopy	*2014*	16%	38%	43%	44%	47%	50%	50%
Neuro CT	*2015*	17%	41%	45%	46%	47%	47%	46%
Musculoskeletal CT	*2015*	13%	32%	35%	42%	44%	52%	58%

Overall, the results show the effectiveness of the adoption of a computerised system for the systematic assessment of referrals. The improvement of the appropriateness rate between 2011 and 2017 ranges from 29% for Neuro CT to 46% for Musculoskeletal RMI, with relative improvements ranging from +145% (Neuro MRI) to +346% (Musculoskeletal CT).

In a recent work [18], the Epidemiology Department of AUSL RE analysed a similar dataset to identify the determinants of inappropriate reporting for a group of imaging and endoscopy DPs, using multivariate log-binomial regression models. Their results confirm that even though "the variability between GPs was the greatest source of inappropriateness variation, promising improvement was observed over time for all procedures under study, consistent with the implementation of several measures of training, shared protocol definition and administrative control".

4 Opportunities and challenges

Big Data and AI could act as a transformational force in healthcare, helping to recovery part of the errors made in the past in the digitisation of healthcare processes. First, by automating the process of extracting meaningful information from vast droves of unstructured data at speed. Second, by systematizing repetitive tasks and by ensuring that all the available knowledge, guidelines and protocols are steadily applied in case management. This would enable a complete redesign of healthcare IT systems, that instead of focussing on the process of data recording, could finally support healthcare professionals in the delivery of care. To deliver these promises, several tough challenges need to be tackled.

Since at the core of this transformation we have data, we need to ensure a transparent and accountable access to it. Given its sensitivity, it is essential to develop policies to balance access to data with individual privacy, to ensure data protection and security, and to restore user control of personal data [19]. New models of data ownership, supported by secure by design data platforms, a clear regulatory framework, establishing strong safeguards and a stable market environment, and increased public awareness on how data are collected and used are among the suggested actions by the EU eHealth Task Force.

Another challenge is posed by the lack of interoperability. Health data are usually siloed in departmental, legacy software such as EHR and EMR software for clinical records, RIS and PACS for radiology, etc. Systems that may use different technologies with limited-to-none interoperability. Despite several initiatives at national [20] and European level [21], lack of technical interoperability and heterogeneity of electronic health record are identified as the major barriers to electronic sharing of health data [22].

The Estonian digital transformation project e-Estonia [23] demonstrates that some of these challenges can be successfully tackled. e-Estonia has digitised over 3000 government services, from tax payments to voting. The Estonian National Health Information System integrates data from all the different healthcare providers in a unified record structure and, since 2015, 99% of health data has been digitised. Patients are in control of their data, managing who can access them, while doctors share a common view on their patients. Whether this approach can be effectively transferred to other countries, or scale at cross-national level remains to be seen.

Statistical methodology for volume-outcome studies

Metodologia statistica per studi di volume

Marta Fiocco and Floor van Oudenhoven

Abstract The recurrent marked point process is used to study a longitudinal volume-outcome association of clustered data. Methodological issues in the selection of aggregate and non-aggregate and yearly measures for hospital volume are considered. An additional aspect associated with hospital volume data, concerns the presence of informative cluster size, where outcome depends on cluster size conditional on covariates. The concept of informative cluster size within a volume-outcome study presents a unique situation since hospital volume is both the covariate of primary interest under study and it is closely linked to cluster size. A new method suitable for volume-outcome studies in which informative cluster size is presented. A simulation study to assess the performance of the method is performed.

Abstract *II recurrent marked point process viene utilizzato per studiare un'associazione longitudinale con il volume nei dati di cluster. Misure aggregate, non aggregate e annuali riguardanti il volume degli ospedali vengono discusse. I risultati sui dati sul volume dipendono dalle dimensioni del cluster in base alle covariate. Il concetto di dimensione informativa dei cluster all'interno di uno studio sul volume presenta una situazione unica poiché il volume dell'ospedale non solo è la covariata di interesse primario oggetto di studio, ma è anche strettamente associato alla dimensione dei cluster. Un nuovo metodo adatto per studi di volume in cui viene considerata la dimensione informativa del cluster viene presentato. Uno studio di simulazione è stato condotto.*

Key words: Volume-outcome , Recurrent marked point process, Informative cluster size

1 Introduction

A growing body of literature studies the association between measures of hospital volume and patient outcomes to evaluate whether hospitals with large case volumes are associated with better outcomes. Applying the appropriate statistical methodology to volume-outcome studies erases several challenges such as the selection of a longitudinal estimation method and the specification of an appropriate measure for hospital volume. In daily practice hospital volume is analysed as a categorical variable, neglecting its time-dependent nature. The recurrent marked point process to approach a longitudinal volume- outcome analysis of clustered data is used in this work. Statistical issues in the selection of both non-aggregate and yearly aggregate measures for hospital volume are considered. An additional aspect sometimes associated with clustered data concerns the presence of informative cluster size, where outcome depends on cluster size conditional on covariates. The concept of informative cluster size within a volume-outcome study presents a unique situation since hospital volume is both the covariate of primary interest under study and it is closely linked to cluster size. Within cluster resampling (WCR) is an appropriate method to analyse informative cluster size data. The novelty of this work is to apply WCR in the framework of a recurrent marked point process to study a longitudinal volume-outcome association. A simulation study has been performed to asses the performance of the proposed method and to evaluate whether the use of aggregate measures for hospital volume leads to bias in the estimation of the volume- outcome association.

2 Data description

Data from the Netherlands Cancer institute for patients after oesophageal cancer surgery between 1989 and 2010, covering all hospitals in the country, is used. To improve survival, it is suggested that surgery should be performed in specialized centres with adequate annual volume.

All 10,0025 patients in the dataset underwent oesophageal cancer surgery performed at 148 different hospitals. The outcome of interest is death from any cause within 6 months since surgery. A binary outcome variable is modelled, indicating whether or not the patient is still alive, by using logistic models. Figure 1 shows observed patients' outcomes after 6 months follow-up since surgery per different categories of cumulative hospital size. This figure suggests a possible association between cumulative hospital size and post-treatment outcome. Although many

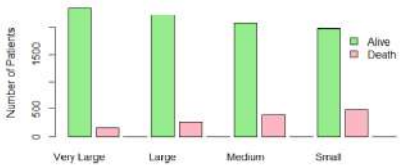

Fig. 1: Observed patient outcome (dead or alive) after 6 months since surgery for each category of cumulative hospital size.

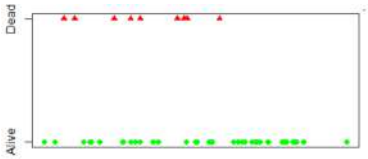

Fig. 2: Marked point process for a specific hospitals with mark space M=Alive, Dead.

volume-outcome studies analyse hospital volume as a categorical variable, this strategy requires great caution. Here hospital volume is analyzed as a continuos variable.

3 Application of a recurrent marked point process

The recurrent marked point process is used as an approach to model volume-outcome associations [1]. This process may be a suitable approach since patients outcome are only observed for patients who underwent surgery. This means that marks are only observed at point locations. Since an outcome only exists when an event of surgery takes place, measurement times differ considerably between hospitals. A recurrent marked point process can cope with different time points, whereas observations in traditional longitudinal data analysis are usually at fixed time points. Use of a recurrent marked point process enables us to interpret the case under study as a point process in one dimension (i.e. time). In this context, surgeries can be seen as ”points” and the corresponding point locations capture information about time the surgery is performed. Figure 2 represents marked point processes for a specific hospitals in the population under study.

Regression methods such as Generalized Estimating Equations (GEE) and Generalized Linear Mixed Models (GLMM) can be used to provide estimates under the recurrent marked point process setting by taking into account the dependence within hospitals. However, an assumption of independence between previous outcome and future number of events is required for covariance weighted methods to provide unbiased estimates.

3.1 Fitting a recurrent marked point process model

Different measures for hospital volume are considered. Non-aggregate specification for hospital volume, defined as the cumulative number of surgeries performed at

hospital i through time t, are available at each surgery time. Yearly aggregate measures, defined in three different ways (yearly total volume; cumulative yearly total volume and running average volume), are only available at the end of each year. Figure 3 shows different volume measures over time for a specific hospital in the population under study. Volume specification is the primary challenge of a volume-outcome study [1].

3.2 Statistical model

Let $Y_i(t)$, $X_i(t)$ and $N_i(t)$ denote patient outcome (i.e. mark), covariates and hospital volume respectively, for hospital i $(i = 1,\ldots,n)$ at time point t $(t = 1,\ldots,T)$. According to a marked point process approach a surgery event must occur for an outcome to exist. A surgery which took place at time point t is denoted as $\Delta N_i(t) = N_i(t) - N_i(t-1) = 1$. The complete history is as follows

$$\chi_i(t) = \{X_i(s)|s \le t\};\ \mathscr{N}_i(t) = \{N_i(s)|s \le t\ \};\ \mathscr{Y}_i(t) = \{Y_i(s)|s \le t\}. \qquad (1)$$

A marginal regression model which describes the association between hospital volume and the average outcome among patients satisfying the criteria $\Delta N_i(t) = 1$ is fitted. The partly conditional model which quantify the marginal association between the complete history of the event-time process and the mark process after adjusting for a full history of the covariate process is estimated. The logit link function is used This may be represented as

$$\mu_i(t) = E[Y_i(t)|\Delta N_i(t) = 1, \chi_i(t), \mathscr{N}_i(t)] = g^{-1}(\beta_0 + \beta_1 X_i(t) + \beta_2 N_i(t)) \qquad (2)$$

The parameters β_1 and β_2 quantify the association between the covariate and event-time processes and the average outcome among patients for whom an event of surgery takes place. The model is fitted by Independent Estimating Equation (IEE) and GEE by assuming an exchangeable correlation structure. Both IEE and GEE are fitted by using the `R` package `gee`. A GLMM with hospital specific random intercepts (GLMM-RI), and a GLMM with hospital specific random intercepts and slopes for hospital volume (GLMM-RS) are fitted by using the package `lme4`.

3.3 Results

The table below shows estimated associations between different measures for hospital volume and the odds-ratio of dying within 6 months since surgery for ten-patient increase. Results based on IEE and GEE are population-averaged parameters, quantifying the average volume-outcome associations among the whole population of patients. Results from GLMM-RI (random intercept) and GLMM-RS (random slope) are hospital-specific, assessing the average volume-outcome associations among a

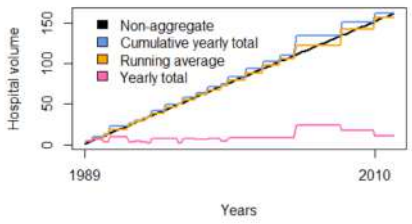

Fig. 3: Volume measures over time for a specific hospital in the population under study.

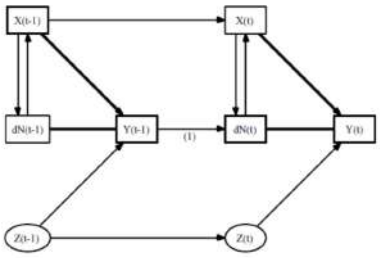

Fig. 4: Underlying framework for the simulation study

population of hospitals. Discrepancies in results might be the consequence of bias, induced in the estimation process because of violation of the assumption about independence between previous patient-outcome and future number of events. In this context the cluster (hospital) size is informative. For the non aggregate cumulative total volume the odds ratio for IEE, GEE. GLMM-RI and GLMM-RS are 0.984(0.979-0.989), 0.997(0.994-1.000), 0.993(0.987-0.999) and 0.958(0.945-0.971) respectively.

4 New approach: within cluster resampling in combination with recurrent marked point process

Within cluster resampling (WCR) [2] is a proper method to analyse informative cluster size data due to one-per-cluster sampling scheme. The novelty of this work is to use WCR in the framework of a recurrent marked point process to study a longitudinal volume-outcome association. The proposed method consists of the following steps

Step 1: Repeatedly (Q times) sample one observation from each cluster I, forming Q resampled datasets.

Step 2: Fit the marginal model on each of the Q resampled datasets, quantifying the volume-outcome associations between hospital volume $N_i(t)$ and patient outcome Yi(t). The estimated parameter $\hat{\beta}_q$ represents the average volume-outcome association within the Q resampled dataset. The variance estimators can take negative values when number of clusters (i.e. hospitals) is too small for the asymptotic variance approximation to hold. This is a drawback of using WCR.

Step 3: The WCR parameter is obtained by taking the average $\widehat{\beta}_{WCR} = \frac{1}{Q}\sum_{q=1}^{Q}\hat{\beta}_q$. WCR is a method suitable to analyse informative cluster size data due to one-per-cluster sampling scheme.

5 Simulation Study

For each hospital i, at each time point t, it is simulated whether or not an event occurs. In case a event takes place a patient-level covariate $X_i(t)$, denoting patient's risk and outcome $Y_i(t)$ are generated. Figure 4 shows conditional relations between patient's risk, the event-time process, patient's outcome and unmeasured error $Z_i(t)$ [3]. Unmeasured error includes serial correlation $W_i(t)$, hospital specific random effects $\gamma_i(t)$ and measurement error $\varepsilon_i(t)$. For each iteration, 1000 hospitals, together with their corresponding patients' risk and outcomes at time t $(1,\ldots,100)$ are randomly selected and volume-outcome analysis is performed. Special focus is on the parameter β_2 since this parameter in the mark process quantifies the effect of hospital volume on patient outcome. WCR, based on 5000 resamplings, is used to obtain mean point estimates for the regression parameter β_2, along with the corresponding mean squared error (MSE), mean standard error, empirical standard error and estimated coverage of 95% confidence intervals. Simulations show that when informative cluster size is present, the proposed method estimates the parameter for volume with small bias. Bias might be introduced when an aggregate measure for present hospital volume is used. Code for simulations study is written in the `R`-software environment and is available upon request.

6 Conclusion

Statistical issues in the specification of both aggregate and non-aggregate measures were considered. Different estimation methods are used to provide volume-outcome estimates under the recurrent marked point process. Results showed an inverse relation between hospital volume and patient mortality, many of them being significant.

Specification of an appropriate measure for hospital volume which takes into account the time-dependent character and bias that may occur in the estimation process when assumptions are violated are also discussed in this work. A new method suitable for volume-outcome studies when informative cluster size is present is proposed. In this research within cluster resampling is used within the framework of the recurrent marked point process, providing cluster-based parameters.

Advances in textual data mining

Distance measures for exploring pairs of novels in a large corpus of Italian literature

Misure di distanza per l'analisi di coppie di romanzi di un grande corpus di letteratura italiana

Matilde Trevisani and Arjuna Tuzzi[1]

Abstract In text clustering most distance-based methods summarize the occurrences of a set of linguistic features to obtain a distance. It should decrease when texts are written by the same author, however, there are further properties that might influence the result: gender of the authors, their age, their geographical origin, publication date of the novels, their size, etc. In this study, regression analyses compare the performance of three distances and highlight, among available covariates, the preeminent effect of the author's hand but also interesting patterns in the effect of novels' size.

Abstract *Nel text clustering la maggior parte dei metodi distance-based sfruttano le occorrenze di un insieme di caratteristiche linguistiche per ottenere una distanza, che dovrebbe diminuire quando i testi sono scritti dallo stesso autore, ma ci sono ulteriori proprietà che potrebbero influenzarne il risultato: il genere degli autori, l'età, le origini, la data di pubblicazione dei romanzi, le dimensioni del testo, etc. Questo studio attraverso analisi di regressione confronta tre distanze ed evidenzia come, tra le variabili a disposizione, il fattore autore sia predominante, ma anche pattern interessanti nell'effetto della dimensione dei romanzi.*

Key words: text distances, large corpora, subset selection, average marginal effects, relative importance of regressors

1 Introduction and data

In text mining the classification task plays a relevant role in the exploration of text corpora. The most common distance-based methods include strategies to summarize

[1] Matilde Trevisani, Università di Trieste; email: matilde.trevisani@deams.units.it
Arjuna Tuzzi, Università di Padova; email: arjuna.tuzzi@unipd.it

the occurrences of a set of linguistic features in order to obtain a distance for each pair of texts [8,9]. A distance measure should significantly decrease when a pair of texts have been written by the same author, however, there are potentially further properties that might influence the result: gender of the two authors, their age, their geographical origin, publication date of the novels, their size, etc. Within the specific frame of bag-of-words approaches, this study aims at comparing the performance of three measures to identify what properties of the pair of texts they are able to detect.

In addition to the distance, further choices concerning how many (e.g. all words in the vocabulary or a limited number of most frequent words) and which lexical features (e.g. words, 2-grams, content words) should be considered. Each distance should be tested in different settings thus leading to a large number of comparisons. In this study the distances between pairs of novels have been calculated by three text distances and in settings that involve a large number of words. By means of regression models we started a first exploration of data to understand which properties of the pair of texts emerge as significant in the examples considered.

The corpus of this study represents a reduced version of a large corpus of Italian contemporary literature that has been exploited in previous studies [10]. It includes 143 novels by 39 authors born from 1920 to 1982 in several cities and regions.

A distance matrix is obtained by choosing from three distances: Labbé [5], Delta [1], and Cosine [3]. Delta and Cosine are calculated on most frequent words with at least 143 occurrences (at least one per novel on average) and Labbé has been tested in four variants: the basic version with frequency threshold set to 1 (Labbé-1) and without threshold (Labbé-0), the iterative version [2] based on 200 replications of measures computed on equal-sized text chunks of 5,000 tokens, considering either the whole vocabulary (Labbé) or grammatical words only (Labbé-gramm). Combining novel data (on author: name, gender, year/ city/ region of birth, age at text publication; on text: year of publication, number of word-tokens (N), size (*large* if N>100,000, *small* otherwise)) and distance matrix, a derived matrix is obtained which, for each (unique) pair (a,b) of texts (10,153), records: *y*: distance; *dauthor*: *same* if texts are by the same author, *differ* otherwise; *diffyear*: difference between publication years; *dyear*: *similar* if texts were published in the same period (i.e., *diffyear*<10 years), *diss* otherwise; *dgender*: *same* if gender of authors is the same, *differ* otherwise; *diffbirth*: difference of authors' age; *dbirth*: *similar* if authors are of the same generation (i.e., *diffage*<10 years), *diss* otherwise; *diffage*: age difference between authors at publication date (*diffyear*±*diffage*); *dage*: *similar* if age difference between authors at pubblication date<10 years, *diss* otherwise; *dregion*: *same* if authors are from the same region, *differ* otherwise; *dcity*: *same* if authors are from the same city, *differ* otherwise; *diffN*: difference (in absolute value) of number of word-tokens ($|N_a - N_b|$); *diffN_r*: relative difference in number of word-tokens ($|N_a - N_b| / (N_a + N_b)$); *dsize*: *similar* if texts have similar size category (which can be *large* or *short*, see above), *diss* otherwise; *ratioN*: $\min(N_a, N_b)/\max(N_a, N_b)$.

2 Text distances at comparison

A linear regression model has been tuned for each distance method by a step-wise procedure. (A) Because of high multicollinearity, a preliminary reduction of design matrix *X* has been performed by carrying out an exhaustive subset selection with each regressor forced-in at time across subsets of any size: besides of the goodness-of-fit (R^2) of regression model, sign consistency and significance (*p*-value) of coefficient estimate as well as variance inflation factor (VIF) for regressor have been jointly analyzed to decide which regressors should be removed in sequence. (B) Variable transformation has been opportunely carried out to linearize the relationship between *y* and *X* (Labbé-gramm and Cosine distances as well as all continuous covariates have been square-root transformed due to moderate to serious positive skewness). (C) An exhaustive subset selection is carried out on the reduced *X* to fit the best model without as well as (D) with interaction effects with *dauthor*.

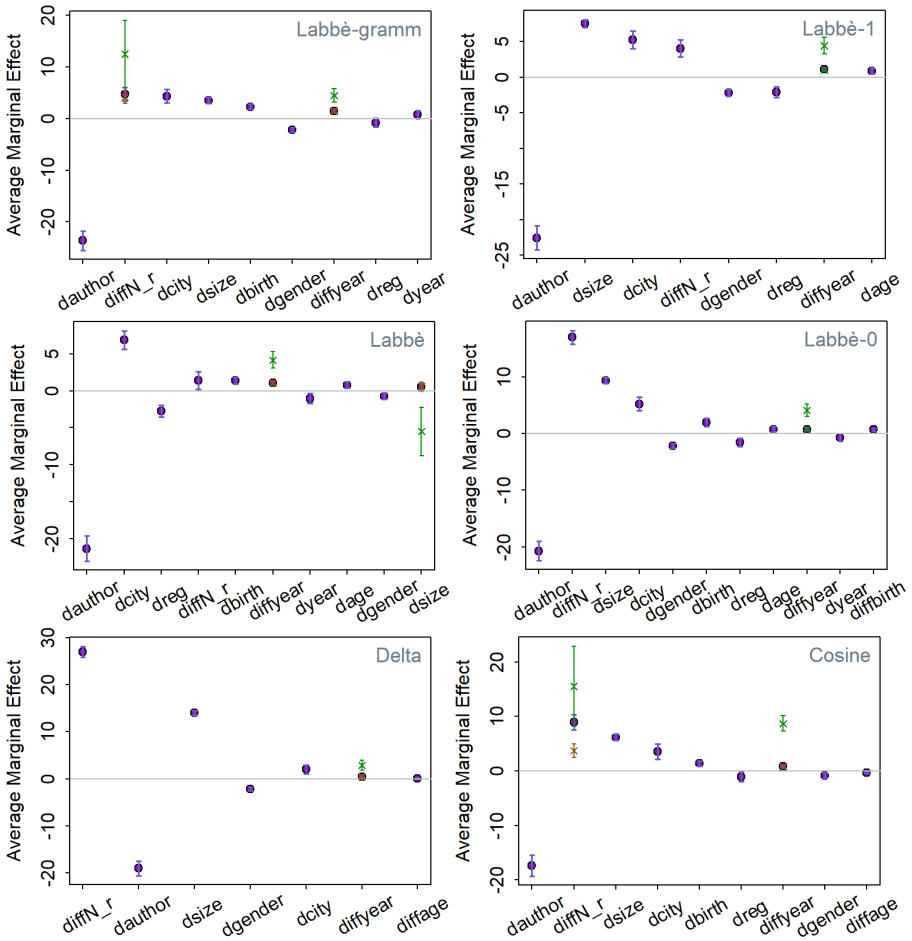
Two measures have been used to compare the effectiveness of distance methods to grasp the author's hand: (1) Average Marginal Effects (AMEs) - average derivative/change (by changing infinitesimally a continuous variable or by 1 an indicator variable) at the values of the covariates as they were observed [6]; (2) relative importance of regressors [4] as measured by LMG method - R^2 partitioned by averaging over orders [7]. AME is useful when model contains non only main effects but more complicate relationships like polynomial (e.g., a quadratic form for *diffN_r* is needed with Delta, Cosine and Labbé-0 distances) or interaction effects (see (D) above). Notice that to compare distances having different ranges, marginal effects have been calculated as % of distance range. LMG overcomes the issue of calculating partial R^2 given the order of regressors' inclusion. To complete the comparison, First - each regressor contribution when included first, which is just the squared covariance between *y* and the regressor - has been added although it is a rawer measure of comparison. In Table 1, rankings of text distances have been highlighted by colouring metric value with different intensity. Adjusted R^2 (R^2_a) summarizes the overall importance of regressors to explain *y* variation.

Table 1: AME %, LMG, First for dauthor, R^2_a for the selected model

Measure/Distance	Labbé-gr	Labbé-1	Labbé	Labbé-0	Delta	Cosine
AME %	23.6	22.5	21.3	20.7	19.0	17.3
LMG	6.1	6.2	5.7	5.6	4.7	3.3
First	6.6	7.0	5.9	6.8	5.7	3.5
R^2_a	11.4	17.1	10.3	20.8	30.6	8.9

In Figure 1, regressors have been ordered according to AME (note that *p*-values are not proper: a statistically significant result may not be practically significant, however, predictors are significant almost everywhere - see 95% CI). Interaction effects are indicated wherever present in the final model selected in (D). In Figure 2, regressors are ordered according to their relative importance in the final model selected in (C).

Figure 1: AMEs with 95% CI (% of distance range). Distances are ordered according to AME-based ranking (from top-left to bottom-right). Interaction effects are added wherever present (green if texts are written by the same author, orange if written by different authors).

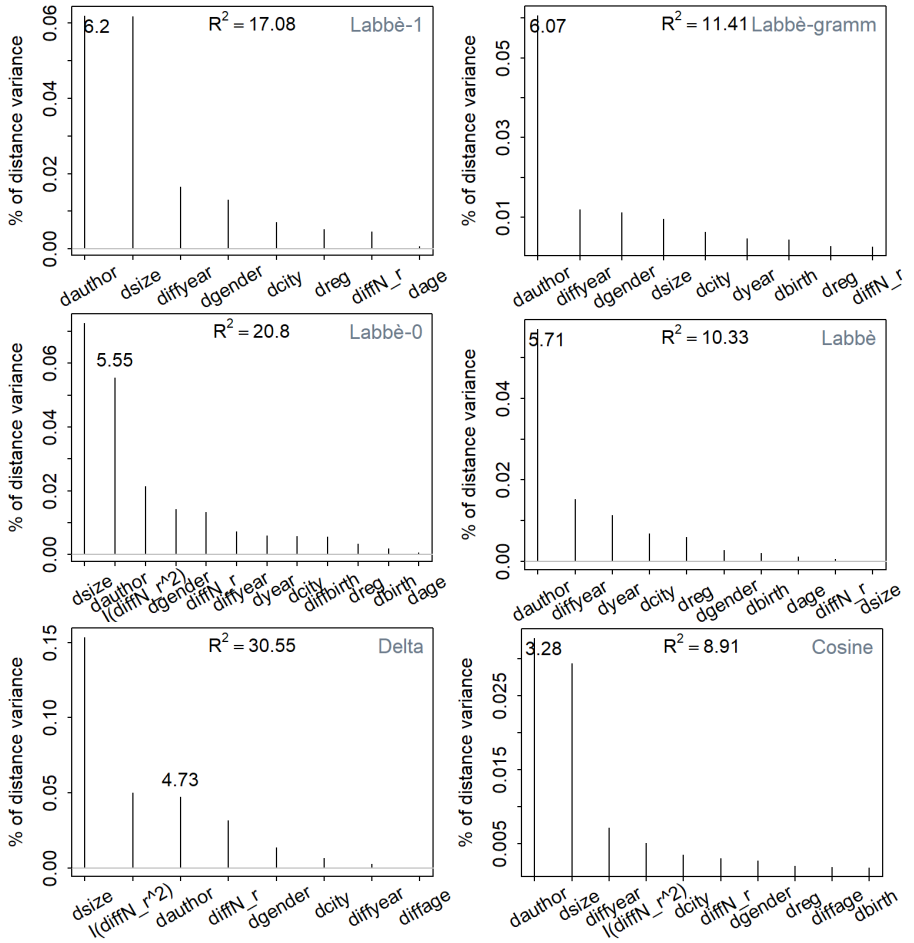


In general, the author factor is highly significant for all distance methods (Figure 1), with a degrading effect from Labbé-gramm (distance drops by -24%, Table 1) to Cosine (-17%). Moreover, relative importance of regressors highlights how the author factor is the most important one in almost all cases (Figure 2), confirming once again a ranking of methods: from about 6% for Labbé-gramm and Labbé-1 down to 3% for Cosine (Table 1). Notice also that the relative importance of author factor weights differently on the overall distance variation explained by the model (R^2_a): more than half for Labbé-gramm and Labbé down to less than one sixth for Delta (passing through one third for Labbé-1 and Cosine and a quarter for Labbé-0).

Another regressor that (except for Labbé and Labbé-gramm) plays a relevant role in explaining distance is text size (in particular for Delta where it is the most

important regressor). The difference in publication year as well as authors' gender and place of birth show a moderate influence almost everywhere. For novels by the same author, difference in year publication – always – and text size – in half of the cases – affect distance (see interaction effects superimposed in Figure 1, AMEs for same author are higher).

Figure 2: Relative importance of effects (LMG method). Distances are ordered according to LMG-based ranking (from top-left to bottom-right).



3 Conclusions

In almost all distance methods the author factor is the most important among the regressors. However, Labbé methods show to be the most effective in detecting the

author's hand (with Labbé-gramm and Labbé-1 at the top), Delta being at an intermediate position, and leaving Cosine as the last choice. Cosine also appears as the distance least explained by the overall factors hypothesised as important (R^2_a≈9%). On the opposite side there is Delta (R^2_a≈31%), Labbé-0 and Labbé-1 are intermediate (≈20%), while Labbé-gramm and Labbé (≈11% and ≈10%) appear to be almost totally explained by the sole author factor (Figure 2). Text size emerges as a second preeminent factor, difference in year publication as well as author's gender and place of birth play a not negligible role. Distance between texts written by the same author is significantly affected by their temporal distance (difference in year publication) and, for some methods, by text size.

This is only a first step in a territory that has been already explored with many methods but needs further systematic investigation. Moving from these first results the future direction of this explorative study consists in increasing the number of distances under investigation and testing their performances in different settings and with different text genres.

Supervised vs Unsupervised Latent Dirichlet Allocation: topic detection in lyrics

Allocazione di Dirichlet latente supervisionata vs. non supervisionata: identificazione di topic da testi musicali

Mariangela Sciandra, Alessandro Albano, Irene Carola Spera

Abstract Topic modeling is a type of statistical modeling for discovering the abstract "topics" that occur in a collection of documents. Latent Dirichlet Allocation (LDA) is an example of topic model and is used to classify text in a document to a particular topic. It builds a fixed number of topics starting from words in each document modeled according to a Dirichlet distribution. In this work we are going to apply LDA to a set of songs from four famous Italian songwriters and split them into topics. This work studies the use of themes in lyrics using statistical analysis to detect topics. Aim of the work is to underline the main limits of the standard unsupervised LDA and to propose a supervised extension based on the Correspondence Analysis (CA) association theory.

Abstract *Il topic modeling è un metodo analitico per estrarre gruppi lessicali chiamati "topic" da un insieme di documenti sulla base di calcoli statistico-probabilistici. La Latent Dirichlet Allocation (LDA) è un esempio di topic model che viene usata per analizzare dei testi che si riferiscono ad argomenti specifici. Questo metodo individua un numero fissato di "topic" a partire dalle parole in ogni testo, assumendo una distribuzione Dirichlet. In questo lavoro applichiamo la procedura LDA ad un dataset costituito dalle canzoni di quattro famosi cantautori italiani. Lo scopo del lavoro è sottolineare i limiti principali della procedura LDA standard non supervisionata e proporre un'estensione supervisionata basata sulla Correspondence Analysis (CA).*

Key words: Topic modeling, LDA, Correspondence Analysis, Music mining

1 Introduction

Nowadays our collective knowledge is mainly based on extracting information from different written resources in the form of news, blogs, Web pages, scientific articles, books, images, but also from sound, video, and social networks. This large amount of document corpora that can be easily stored is leading to a growing need to analyze large collections of electronic text and makes more difficult the search of what we are looking for. New computational tools are then necessary in order to organize, search, and understand these vast amounts of information. This has led to considerable interest in applying statistical methods able in deriving high-quality information from text. Typical tasks of this process, also known as text mining or text data mining, include text categorization, text clustering, production of taxonomies and sentiment analysis [7]. A common step of all these procedures consists, essentially, in turning text into data for analysis, via application of Natural Language Processing (NLP) [5], different types of algorithms and analytical methods [4]. The final goal this process is the interpretation of the gathered information. The process of learning, recognizing, and extracting meaning hierarchically from words to sentences to paragraphs to documents is known as "*topic modeling*" [1]. Topic models are algorithms for discovering the latent semantic structure ("topics") that pervade a large and otherwise unstructured collection of documents. Once topics have been detected the collection can be organized according to the discovered themes. There are multiple methods of going about doing this in the NLP framework but in this work we will focus on the Latent Dirichlet Allocation (LDA) [3]. LDA is a topic model which assumes that the words of each document arise from a mixture of topics. The topics are shared by all documents in the collection; the topic proportions are document-specific and randomly drawn from a Dirichlet distribution.
Topic modeling algorithms can be adapted to many kinds of data. In this work we apply the standard unsupervised LDA procedure to find patterns in lyrics from different songwriters and we address a limitation of the procedure in making predictions on singers starting from the topics detected on a set of songs. To avoid this problem we propose a supervised LDA obtained by combining standard LDA with a correspondence analysis applied on the LDA results (LDA-CA).
The article is structured as follows: after this introduction, section 2 explains the method employed, followed by section 3, where the main results are described and discussed trough an example on real Genius data.

2 Topic models: unsupervised and supervised approach

Topic modeling is part of a class of text analysis methods that analyze "bags" or groups of words together—instead of counting them individually–in order to capture how the meaning of words is dependent upon the broader context in which they are used in natural language. The starting assumption is that documents have latent semantic structure ("topics") and the challenge is to infer them from word–document

co-occurrences. This depends heavily on the quality of text preprocessing and the strategy of finding the optimal number of topics that is out of the interest of this work. Formally, a topic is a probability distribution over terms in a vocabulary. To introduce the notation let $Pr(z)$ be the probability distribution of topics in a particular document, $Pr(w|z)$ be the probability distribution given a topic z;$Pr(z_i = j)$ will be the probability that the j-th topic will be extracted for the i-th word and $Pr(w_i|z_i = j)$ the probability of the word under topic j. The following distribution of words in a document is derived:

$$Pr(w_i) = \sum_{j=1} Pr(w|z = j)Pr(z = j) \tag{1}$$

Equ. (1) shows as the topic model uses a Bayesian approach: the probability of finding a word in a text comes from the product between the probability of finding a certain topic, $P(z)$, and the probability of finding the same word conditioning on the chosen topic, $P(w|z)$.

2.1 Latent Dirichlet Allocation

The LDA model is a topic modelling technique that was first described by Blei, Ng and Jordan in 2003 [2]. In the LDA model topics are considered to be probability distributions over the finite vocabulary. We denote by V the vocabulary of the corpus and $W_1, W_2, \ldots, W_D$ the documents in the corpus (each assumed to contain N_d words). We denote by $W_{d,n}$ (for $1 \leq d \leq D$; $1 \leq n \leq N_d$) the n-th entry in W_d, i.e. the n-th word in the d-th document of the corpus. Furthermore, we denote the (n-1)-simplex by Δ^{n-1} and $\theta_1, \ldots, \theta_D \in \Delta^{K-1}$ are the K topic proportions (which are distributions over the K topics): an n-vector θ lies in the $(n-1)$- simplex if $\theta_i \geq 0$, $\sum_{i=1}^{n} \theta_i = 1$; let $\beta_1, \ldots, \beta_k \in \Delta^{V-1}$ be the topics (which are distributions over words), and $Z_{d,n} \in 1, \ldots, K$ for $1 \leq d \leq D$, $1 \leq n \leq N$, the topic of word n in document d. Standard LDA assumes that producing a document is a random process described by the following generative model:

1. Choose topics β_1, β_2, …, $\beta_K \sim Dir(\eta)$, where $\eta \in \mathbb{R}^+$ a parameter .
2. For $d = 1, \ldots, D$, choose the topic distribution of document $d \sim Dir(\alpha)$, as:
   (a) Choose the topic of the n-th word, $Z_{d,n} \sim$ Multinomial(θ_d).
   (b) Choose the n-th word, $W_{d,n} \sim$ Multinomial($\beta_{Z_{d,n}}$).

2.2 Latent Dirichlet Allocation-CA

Standard LDA can be considered an 'unsupervised' machine learning process because it does not require a predefined list of tags or training data that has been previously classified by researchers. However, its main limit is that it cannot guarantee

final accurate results, which is why many users opt to invest in *topic classification models*. As opposed to text modeling, topic classification needs to know the topics of a set of texts before analyzing them and so they can be considered "supervised" techniques. In this work we propose a supervised LDA procedure that uses the topics identified in a first standard LDA and then it applies a Correspondence Analysis (CA) [6] that takes advantage of the *a priori* information about clusters. The proposed procedure is named $LDA-CA$ as it consists of this two main steps:

1. Find topics $\beta_1, \beta_2, \ldots, \beta_K$ by applying a standard unsupervised LDA procedure;
2. Use a classical Correspondence Analysis to explore relationships among topics identified by the LDA and the known cluster information (where M is the number of real clusters). In particular:
   a. Read in the M (rows) by K (columns) data matrix, L. Note that the elements of K must be non-negative and that none of the row or column totals is zero.
   b. Compute the proportion matrix, P, by dividing the elements of K by the total of all numbers in K. Mathematically, we write $P = \{p_{ij}\} = \{k_{ij}/k_{..}\}$.
   c. Compute the totals of the rows of P and the columns of P, putting the results in the vectors r and c that will be respectively the row and column profiles on which distances will be calculated once coordinates on the reduced space will be evaluated.

Although topic classification is more complex, this topic analysis technique delivers more accurate results than unsupervised techniques, which means more valuable cluster predictions could be derived.

3 LDA-CA in practice: topics in lyrics

The dataset is made up of 100 lyric songs extracted from genius Web API of 4 famous Italian songwriters (25 songs per singer): Antonacci, Battiato, Ligabue e Nomadi. The corpus was preprocessed and after a tokenization it was cleaned by removing stop words. Table 1 shows the final number of words used by each author:

Antonacci	Battiato	Ligabue	Nomadi	Total
2245	1396	1730	1696	7067

Table 1: Number of words per songwriter.

Then next step is to put together all the 100 songs in a unique corpus such that the individual songs are unlabeled. LDA was applied to discover how songs cluster into distinct topics, each of them presumably representing a specific songwriter. In this example, each document d is represented by a single song. The aim is to know how topics are associated with each document, starting from the per-document-per-topic estimated probabilities $\hat{\theta}_i$.

Topic from the LDA are plotted in Fig. 1 (word-clouds showing the 25 most important words).

(a) Topic 1 (b) Topic 2 (c) Topic 3 (d) Topic 4

Fig. 1: Wordclouds of Topics

Except for topic 1, the word "Amore" is the most common frequent word.
For each song, we get an estimated proportion of words that are generated from the identified topics. Fig. 2 shows the distributions of words in each of the four topics conditioning on the four singers. It could give an idea about how well our unsupervised learning works: the ideal situation should be the one in which songs from a songwriter belong to the same topic.

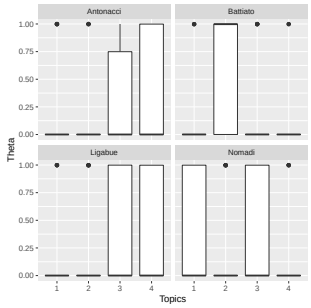

Fig. 2: The θ probabilities for each song within each songwriter.

Unfortunately we notice that almost all of the songs by Antonacci, Ligabue and Nomadi do not not belong to unique topic; on the contrary, Battiato is mostly identified with topic 2. Crossing the topic information from LDA and the known singer clustering we obtain contingency Table 2 that we use as starting point of the CA.

	Topic			
Songwriter	1	2	3	4
Antonacci	414	349	615	867
Battiato	146	792	335	123
Ligabue	297	383	546	504
Nomadi	526	396	470	304

Table 2: Number of words per songwriter and topic.

A global view of CA results useful for interpretation is shown in Fig. 3:

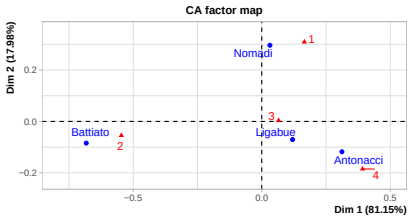

Fig. 3: CA biplot from data in Tab. 2.

Songwriter	Dim 1	Dim 2	Dim 3
Antonacci	25.2	16.0	27.0
Battiato	72.2	5.6	2.5
Ligabue	2.5	3.6	69.5
Nomadi	0.1	74.8	1.0

Table 3: Singer contributions to the CA dimensions.

Fig 3 confirms the goodness of CA results showing the association between topic clustering and songwriters: the percentage of variance explained by Dimension 1 is very high (81.15%). In particular, the result is due to Battiato's songs, for the first dimension, and to Nomadi for the second one.

Conclusions

In conclusion, our method can be used for predicting song classification once topics have been generated. Future work will be addressed in quantifying total classification error and comparing the proposed procedure with a classification tree approach.

Automated Land Cover Maps from Satellite Imagery by Deep Learning

Mappe di Copertura del Suolo Automatiche da Immagini Satellitari mediante Deep Learning

Fabrizio De Fausti, Francesco Pugliese and Diego Zardetto

Abstract The Italian National Institute of Statistics (Istat) is currently investigating whether Deep Learning methods could be used to derive automated Land Cover estimates of satisfactory quality from Sentinel-2 satellite images. A prototype software system is being developed within the scope of this research. This paper focuses on "automated land cover maps", a very relevant output artefact of the system.
Abstract *Istat sta studiando se sia possibile derivare stime automatizzate di Copertura del Suolo di qualità accettabile da immagini satellitari Sentinel-2 processate con metodi di Deep Learning. Nell'ambito del progetto è in via di sviluppo un sistema software. Questo articolo si concentra su un importante output del sistema: le mappe di Copertura del Suolo automatiche.*

Key words: Land Cover, Satellite Imagery, Deep Learning, Convolutional Neural Networks

1 Introduction

Timely and frequently updated Land Cover (LC) information is of paramount importance to modern National Statistical Institutes (NSI).

As far as Europe is concerned, two flagship LC projects exist: CORINE [2, 3], currently run by the Copernicus Program, and LUCAS [1, 4], managed by Eurostat. Despite these projects address the study of land cover very differently – CORINE in a cartography (i.e. full-coverage) perspective, LUCAS in a statistical estimation (i.e. sample survey) perspective – they suffer common shortcomings. Both are very costly, have very complex production pipelines, rely heavily on clerical work, and produce their outputs with a rather low time frequency. Most of the shortcomings affecting CORINE and LUCAS depend on the huge amount of *human workload* they require. It is, therefore, very tempting to try to overcome these shortcomings through *process automation*. Given an input satellite image depicting a portion of territory, a fully automatic system should ideally be able to (i) *classify* the territory according to some standard LC taxonomy, and to (ii) *quantify* the area (or the proportion) of territory covered by each LC class, without any human intervention.

[1] Fabrizio De Fausti, Istat; defausti@istat.it
Francesco Pugliese, Istat; frpuglie@istat.it
Diego Zardetto, Istat; zardetto@istat.it

The Italian National Institute of Statistics (Istat) is currently investigating whether Deep Learning [5] methods could be used to derive automated Land Cover estimates of satisfactory quality from Sentinel-2 satellite images. A prototype software system is being developed within the scope of this research. This paper focuses on "automated land cover maps", a very relevant – though quite specific – output artefact of the system.

2 Methodology

Istat research goal is to design and develop an automatic LC estimation system. Such a system should be able to take as input a satellite image depicting a portion of territory, and to return as output a table of LC statistics.

Although LC estimation is a quantification problem rather than a classification one, we decided to implement our system according to a 'classify-and-count' design. The main driver of this design choice was to incorporate into our system a Convolutional Neural Network (CNN), so as to take advantage of its tremendous performance in image classification tasks. CNNs [7, 8] are cutting edge Deep Learning architectures that have recently reached superhuman accuracy in many Computer Vision tasks and whose topology was originally inspired by the organization of the visual cortex of mammals.

Without going into technical details, our classify-and-count design can be summarized as follows:

(0) Train a CNN to predict the LC class of a satellite image 'tile' (i.e. a small, fixed-size sub-image).

(1) Divide the satellite images covering a 'target area' (i.e. the territory for which LC statistics have to be computed) into tiles.

(2) Use the trained CNN to predict the LC class of all the generated tiles.

(3) Obtain LC statistics for the target area by simply computing the relative frequencies of predicted LC classes.

It ought to be clear that phases (1), (2), (3) have to be repeated each time LC statistics are requested for a new target area, whereas the CNN's training phase is carried out only once (whence the (0) index in the list).

3 Training Data

We decided to adopt the EuroSAT dataset [8] as training set for our CNN. EuroSAT contains 27,000 manually labelled image patches of size 64 x 64 pixels. These patches have been cropped from carefully selected Sentinel-2 satellite images covering 34 European countries. EuroSAT images are multispectral (all 13 Sentinel-2 bands are provided) but we have so far restricted our interest to Red, Green and Blue bands only (i.e. to RGB color images). Since the resolution of Sentinel-2 images in the R, G and B bands is 10 meters per pixel, each 64 x 64 EuroSAT patch represents a ground area of 640^2 square meters, i.e. about 41 hectares.

The LC classification according to which EuroSAT patches have been manually labelled entails 10 classes: 1) 'Annual Crop', 2) 'Forest', 3) 'Herbaceous Vegetation', 4) 'Highway', 5) 'Industrial', 6) 'Pasture', 7) 'Permanent Crop', 8) 'Residential', 9) 'River', 10) 'Sea & Lake'. EuroSAT authors have defined this LC taxonomy following the principle that the

patterns of each class should be visible at the resolution of 10 meters per pixel. The dataset is roughly balanced with respect to the 10 classes, as class cardinalities range from 2,000 to 3,000 patches.

4 CNN Model Training and Accuracy

To implement the classification engine of the system, we are currently using a cutting-edge, highly sophisticated CNN model named Inception-V3 [9], which we customized and trained on the EuroSAT dataset. As far as the training stage is concerned, we randomly split the EuroSAT data into training set and test set according to a 75/25 proportion. The generated training set and the test set contain 20,250 and 6,750 image patches, respectively.

Fig. 1 below reports the Confusion Matrix obtained contrasting the LC classes predicted by our best model and the true LC labels of the 6,750 image patches belonging to the test set. We achieved an accuracy of 98.43%.

PRED. / TRUE	Ann. Crop	Forest	Herb. Veg.	Highway	Industrial	Pasture	Perm. Crop	Residential	River	Sea Lake
Ann. Crop	740	0	1	1	0	4	4	0	0	0
Forest	0	747	2	0	0	0	0	0	0	1
Herb. Veg.	0	3	738	0	0	2	7	0	0	0
Highway	1	1	0	613	1	1	0	2	6	0
Industrial	0	0	0	1	621	0	1	2	0	0
Pasture	6	0	11	0	0	479	3	0	0	1
Perm. Crop	13	0	12	0	0	2	598	0	0	0
Residential	0	0	1	0	1	0	0	748	0	0
River	1	1	0	8	0	1	0	1	613	0
Sea Lake	1	0	0	0	0	1	0	0	1	747

Figure 1: The Confusion Matrix obtained contrasting the LC classes predicted by our Inception-V3 model and the true LC labels of the 6,750 image patches belonging to the test set. The trace of the matrix gives the overall number of exact predictions (i.e. 6,644), which implies an accuracy of 6,644/6,750, i.e. 98.43%.

5 Land Cover Estimation Algorithm

Once the CNN has been trained on the EuroSAT dataset, our automatic LC estimation system can be fed with a satellite image and return LC statistics for the corresponding territory. To do so, a classify-and-count algorithm is used, whose main logical steps can be summarized as follows:

S1) The input Sentinel-2 image is split into a set of (possibly overlapping) tiles of size 64 x 64 pixels. These tiles are generated by cropping the input image along a regular spatial grid, through a 'sliding window' algorithm.

S2) The trained CNN classifies one tile at a time and logically links the predicted LC class to the corresponding area of the original image. The output of the whole process is a 'classification matrix': each element of this matrix corresponds to a tile of the original image and stores its predicted LC class.

S3) The area share of each LC class for the whole territory depicted in the input satellite image is estimated by the relative frequency of the corresponding label within the classification matrix.

S4) A land cover map of the territory depicted in the input satellite image is obtained by rendering the classification matrix as a raster image.

The working mechanism of the sliding window algorithm mentioned in **S1)** is schematically illustrated in Fig. 3. Basically, a window of 64 x 64 pixels slides horizontally and vertically over the input image with a stride (i.e. step length) of *s* pixels, starting from its upper-left corner. For each step of the window, one tile is generated by cropping the area of the input image that is framed by the window. This way, the algorithm actually produces a *systematic spatial sample* of tiles drawn from the input image. Note that, since each generated tile corresponds to a specific area of the input image, the output sample has an intrinsic geometrical structure. More specifically, the generated tiles are naturally arranged according to a regular spatial grid (see Fig. 2).

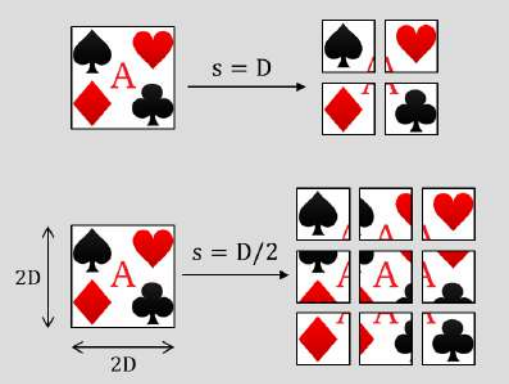

Figure 2: Illustration of the sliding window algorithm. A convenience image of size 2D x 2D is split into tiles of size D x D. In the upper panel, the window slides horizontally and vertically with a stride of length D, giving rise to 4 non-overlapping tiles arranged according to a 2 x 2 grid. In the lower panel, the stride is reduced to D/2: this generates 9 partially overlapping tiles arranged along a 3 x 3 grid. Note that reducing the stride from D to D/2 allowed to resolve more image details: for instance the red 'A', which in the upper panel was not framed in any tile of the grid, now pops up in the central tile of the lower panel grid.

In **S2)** the trained CNN is used to predict the LC class of all the tiles generated in **S1)**. Note, incidentally, that different tiles can be processed independently, allowing our system to take advantage of high-performance parallel computing architectures (GPUs).

In **S3)** the system calculates output LC statistics from the classification matrix. In accordance with our classify-and-count approach, this is accomplished by simply computing class frequencies. If we indicate with W and H the input image width and height in pixels, with c a generic LC class and with f_c the proportion of class c within the classification matrix, then the corresponding area and area share are estimated by:

$$\begin{cases} Area_c = (f_c \cdot W \cdot H) \cdot 100m^2 \\ AreaShare_c = f_c \end{cases} \quad (1)$$

Note that in the upper equation of (1) we took into account that the resolution of the satellite images processed by our system is 10 meters per pixel.

While the LC statistics calculated in **S3)** have to be regarded as the main output of our system, a further interesting artefact can be distilled, as a by-product, from the classification matrix. Indeed, as mentioned in **S4)**, a land cover map can be produced by simply rendering the classification matrix as a raster image. It is worth stressing that this is only possible because of

the geometric structure of the systematic spatial sample of tiles generated by the sliding window algorithm. Clearly, the smaller the stride, the larger will be the dimension of the classification matrix and, therefore, the resolution of the obtained land cover map.

6 Automated Land Cover Maps

We tested and validated our system on several Sentinel-2 images representing quite different Italian territories. Test images have been cropped from Sentinel-2 products downloaded from Copernicus Open Access Hub, namely TCI (True Color Image) objects encoded in JPEG2000 format. Due to space limitations, we focus here on just one test image, which we will refer to as the *"Lecce image"*. We briefly analyze here the automated LC maps that our system generated from the Lecce image as by-products of LC estimation. Recall that our system produces LC maps by simply rendering as a raster image the classification matrix computed for LC estimation. The success of this approach entirely rests on the inherent spatial structure of the sample of tiles determined by the sliding window algorithm (Section 5). Since both the LC estimates and the LC maps produced by our system improve as the stride of the sliding window decreases, we provide here results obtained by setting the stride to its minimum value of 1 pixel. This setting generated (39 x 47) = 1,833 tiles for the Lecce image.

Fig. 3 shows the Lecce image (left panel) and its automated LC map (right panel). Overall, the map exhibits a high degree of spatial consistency, in that the main structures (urban centers, industrial areas, highways, crops and vegetation) have been correctly detected and nicely reconstructed.

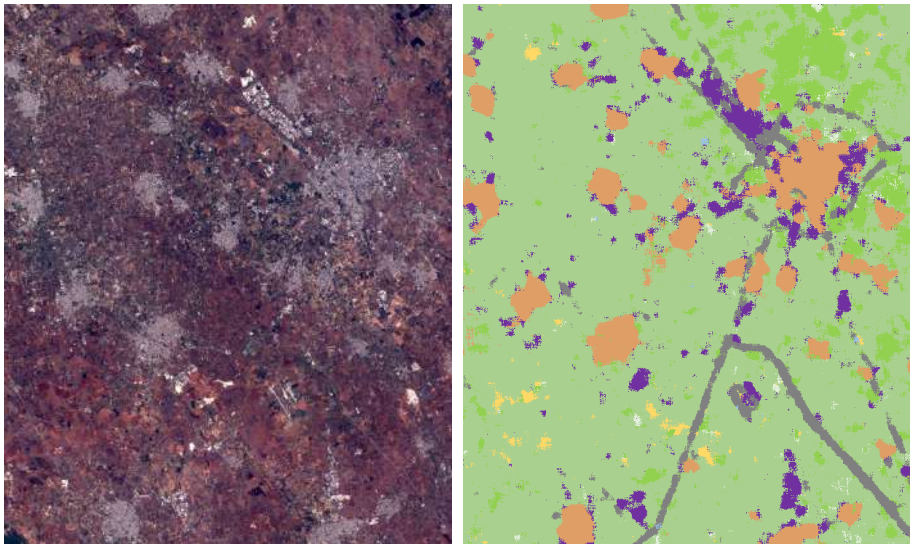

Figure 3: Automated LC map (right panel) of the territory depicted in the Lecce image (left panel).

For instance, focusing on residential areas (brown pixels on the map) and comparing visually the map with the original image, one can observe that the sizes, the shapes and the relative positions of cities are all described fairly well by the map.

Fig. 4 offers an easier way to appreciate the spatial consistency of our LC map with respect to urban areas. To build the left panel of this figure, we first extracted the edge of the

'Residential' areas from the LC map using the Canny Edge Detector algorithm. Then, we overlaid the obtained edges on the Lecce image using a GIS. Evidently, the green edge-line outlines with remarkable accuracy all the cities that are visible in the Lecce image.

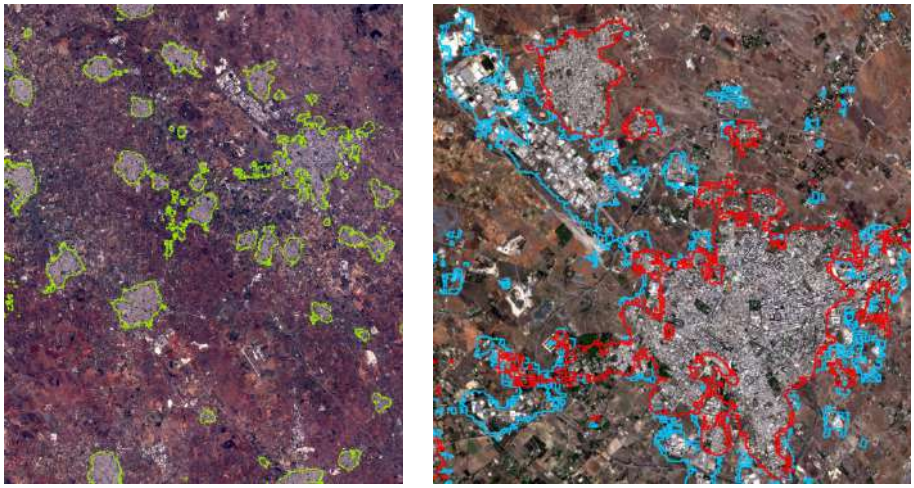

Figure 4: Left panel: the Lecce image overlaid with the edge of the 'Residential' class (green line) extracted from the automated LC map in Fig. 3. Right panel: a detailed view of the city of Lecce overlaid with the edges of the 'Residential' (red line) and 'Industrial' (blue line) classes extracted from the automated LC map in Fig. 3.

The right panel of the figure shows a detailed view of Lecce (taken, of course, from the input satellite image) overlaid this time with two edge-lines: the red one for the 'Residential' class and the blue one for the 'Industrial' class. The segmentation ability of our system emerges very neatly.

CROWD4SDG: Crowdsourcing for sustainable developments goals

CROWD4SDG: Crowdsourcing per gli obiettivi di sviluppo sostenibile

Barbara Pernici

Abstract While a set of measurable indicators has been defined for Sustainable Development Goals (SDG), in some cases the collection of data is problematic. The CROWD4SDG project proposes to support this data collection using Citizen Science. The project is based on three pillars: research for Citizen Science based on new IT tools, research by Citizen Science to facilitate the generation of bottom-up projects, and research on Citizen Science for the development of high-quality Citizen Science projects identifying best practices. The CROWD4SDG project will focus on a set of SDGs, centering on Climate action goals, in particular targeting climate hazards, in combination with SDGs on gender equality, sustainable cities, and rights. The project will exploit also the research results obtained in the E2mC project, which developed an approach to information extraction from social media based on geographic information management, AI, and crowdsourcing in the context of emergency situations after natural disasters.

Abstract *Mentre è stata definita una serie di indicatori misurabili per gli Obiettivi di sviluppo sostenibile (SDG), la raccolta dei dati per valutare questi indicatori è in alcuni casi problematica. Il progetto CROWD4SDG propone di supportare questa raccolta di dati utilizzando la Citizen Science o Scienza dei cittadini. Il progetto CROWD4SDG si basa su tre pilastri: ricerca per la Citizen Science basata sullo sviluppo di nuovi strumenti IT, ricerca con la Citizen Science per facilitare la generazione di progetti bottom-up e ricerca su Citizen Science per lo sviluppo di progetti di Citizen Science di alta qualità con l'identificazione di best-practice nel settore. Il progetto si concentrerà su una serie di obiettivi di sviluppo sostenibile, incentrati sugli obiettivi per il cambiamento climatico, in combinazione con obiettivi di sviluppo sostenibile sulla uguaglianza di genere, sulle città sostenibili e sui diritti. Il progetto si baserà anche sui risultati delle ricerche del precedente progetto E2mC che ha portato allo sviluppo di un approccio per l'estrazione di informazioni dai social media basata sulla gestione delle informazioni geografiche, l'intelligenza*

artificiale e il crowdsourcing nel contesto di situazioni di emergenza dopo catastrofi naturali.

Key words: Crowdsourcing, social media, SDG, climate change, natural disasters

1 Introduction

The 17 Sustainable Development Goals (SDG) defined by the United Nations[1] were adopted by "all United Nations Member States in 2015, as a call for action by all countries to promote prosperity while protecting the environment". A set of Measurable indicators[2] has been defined in association to the SDG goals and their targets, however in some cases the collection of relevant data is problematic and further sources of data are needed. The goal of the CROWD4SDG is to propose to develop new IT tools and methodological approaches using a Citizen Science approach.

Citizen Science has been advocated as a resources for collecting information to assess SDG [4]. In fact, it can improve coverage and frequency of data collection, allow managing spatial variations across a country, and support the veracity of information. Several citizen-generated projects are emerging, and as reported by SciStarter.org, several activities in Europe address also climate issues.

In particular, CROWD4SDG will focus on SDG 13 climate action, and in particular target 13.1 Strengthen resilience and adaptive capacity to climate-related hazards and natural disasters in all countries, with the following indicators: "13.1.3 Proportion of local governments that adopt and implement local disaster risk reduction strategies in line with national disaster risk reduction strategies; 13.1.1 Number of deaths, missing persons and persons affected by disaster per 100,000 people; 13.1.2 Number of countries with national and local disaster risk reduction strategies". SDG 13 will be analyzed in different yearly rounds, focusing each year on a specific combination with another goal: SDG 11 Sustainable cities and communities; SDG 5 Gender equality; SDG 16 Promote peaceful and inclusive societies for sustainable development, provide access to justice for all and build effective, accountable and inclusive institutions at all levels, focusing on rights.

In fact, the impact of climate change in not only limited to environmental issues but it has a deep impact on society, as discussed in detail in [2], that discusses how climate change and weather-related disasters impact on gender-based violence and discrimination and inequality.

In CROWD4SDG the goal is both to collect information to assess SDG indicators and also to collect from Citizens proposals for actionable actions to achieve SDGs.

In Section 2, we illustrate the methodological approach of CROWD4SDG; in Section 3, we illustrate the results achieved in a previous project, E2mC, combining

[1] https://sustainabledevelopment.un.org

[2] https://unstats.un.org/sdgs/indicators/indicators-list/

different approaches to collect first hand information in the first hours after natural disasters, and finally we conclude with open issues and future developments.

2 The Crowd4SDG approach

The project is based on three pillars:

- *Research for Citizen Science based on new IT tools*. Starting from previous research of the participants in the project, tools for organizing online communities, discussion platforms, and mining information from social media will be enhanced with AI-based modules. In particular, we will focus on facilitating the community participant interactions in large communities and in learning from crowdsourced information to improve data mining.
- *Research by Citizen Science* to facilitate the generation of bottom-up projects will start from the experience of the OpenSeventeen challenges (O17)[3], to generate challenges and select interesting projects related to SDGs and guiding the selection of tools to support crowdsourced activities.
- *Research on Citizen Science* for the development of high-quality Citizen Science projects identifying best practices and developing new methodological approaches.

3 Mining social media with the support of AI and crowdsourcing

In the project, in particular in the initial phases, the focus is on climate changes and natural disasters, in particular in urban settings. In this context, the project will be based on the research results obtained in the E2mC[4] project, using information extraction from social media based on geographic information management, AI, and crowdsourcing in the context of emergency situations after natural disasters. In E2mC, a set of tools have been developed to select and analyze information from social media or contributed through crowdsourcing tools and display them on a WebGIS interface [6], [7].

In particular, social media crawlers have been developed to select information, and in particular images relevant to a natural disaster, from social media [6], using data mining with topic extracting for Twitter posts and mining through triangulation techniques and clustering to extract keywords from one social media such as Flicker and apply them in another source, such as for instance YouTube [1]. Automatic geolocation of images is performed analyzing the text of posts with Natural Language Processing techniques and locations are disambiguated using OpenStreetMap [5]

[3] http://openseventeen.org/

[4] https://www.e2mc-project.eu/

and the CIME disambiguation algorithm developed in the project [7]. Kernel density analysis can be then performed to define hot spots for an event [9]. In addition to data mining techniques, evaluation of the relevance selected images and the precision of the geolocation can be assessed using crowdsourcing, in conjuction with crowd information evaluation techniques [8].

Starting from the E2mC results, the CROWD4EMS project will emphasize AI techniques, to improve crowd results evaluation [3] and for learning new keywords from crowdsourcing results and for improving the precision of the geolocation of posted images, using also image analysis techniques to extract relevant features to identify useful images.

4 Open challenges and future work

Several research challenges are open in providing AI enhanced tools to Citizen Science projects. In addition to tools availability and stability, it is important to provide a basis for the agile deployment of an environment in case of new emergency events, tailoring the tools to the specific needs of each situation in a very short time.

We will further enhance existing tools with AI and ML mechanisms, in particular to benefit from the information that can be gathered from the crowdsourcing activities. However, we will also need to study some of the issues emerging from the use of such tools in particular in the case of vulnerable populations, following and advancing the guidelines provided in [10], which discusses the use of AI in those contexts.

Permanent Population Census: evaluation of the effects of regional strategies on the process efficiency. The direct experience of Tuscany

Il Censimento Permanente della Popolazione: valutazione delle strategie regionali sull'efficienza del processo

L. Porciani, L. Francovich, L. Faustini, A. Valentini

Abstract The current challenges of Official Statistic are related to various global changes interesting also social behaviors; and conducting a Population Census is a public and social action has several interconnections with the features of the societies in which it is planned. This work has the main aim to identify some best practices in the management of a complex and completely new statistical process such as the Permanent Population Census (PPC) at regional level, in Tuscany. The analysis were conducted using paradata extracted by the Survey Management System, a web system implemented by the Italian National Statistical Institute (Istat) to manage the survey process.

Abstract *Le attuali sfide della Statistica Ufficiale sono legate a cambiamenti globali che impattono anche sui comportamenti sociali: condurre un censimento della Popolazione è un'azione pubblica che implica la considerazione delle caratteristiche delle società in cui esso viene realizzato. Questo lavoro ha l'obiettivo principale di individuare alcune buone pratiche nella gestione di un processo statistico complesso e completamente nuovo, come il Censimento Permanente della Popolazione, a partire dall'esperienza della Regione Toscana. L'analisi è stata condotta utilizzando i paradata estratti dal Sistema di Gestione delle Indagine, un sistema web implementato da Istat per la gestione del processo di indagine.*

1 Introduction

Istat introduced Permanent Population Census (PPC) in Italy in 2018, after two pilots survey in 2015 and 2017. PPC represents one of the core data collection process of the new course proposed in the ESS visions strategy 2020[1], based primarily on the Integration of data sources for Official Statistic in order to reduce response rate, response burden and costs and to increase timeliness. In addition, the project of a complex process, such as a PPC, has to take into consideration the impact of social changes on statistical process due to the globalization era[2]. The general decrease in trusting institutions could be one of the reasons for the continuous reduction in response rate; the huge increase of data producers of the criticalities of the response burden; and the widespread of the sentiment of uncertainty of the growing request of a primary attention to the right of privacy and data confidentiality[3]. These elements affect the statistical process, pushing the National Statistical Institute towards the improvement of the evaluation process and, consequently, to share good practices to figure out the major criticalities.
In this perspective, this work has the main aim to identify some strengths (and weakness) of the management of a complex and completely new statistical process such as the PPC, starting from the regional experience of the Istat office of Tuscany.

2 Data and methods

PPC in Italy has been projected on 4 years survey process (2018-21) and on two simultaneous sampling- surveys – namely Areal Survey (AS) and List Survey (LS) – performed every year (roughly) from October to December[4]. Both have a strategy sampling based on a first step of Municipalities and on a different second step: AS is based on an area frame sampling strategy (the initial population is composed by the addresses), whereas LS has a traditional list frame sampling strategy (the initial population is composed by the households extracted from Population Register). In terms of number, the sample counts at national level almost 2800 Municipalities (on more than 8000 ones), 40% of them involved every year, and 1,4 millions of households (2/3 in the LS and 1/3 estimated in AS). In Tuscany region, 120 Municipalities are sampled (69 every year), for almost 110000 households (74% for LS and the rest for AS).

Their routinely implementation requires to respect a very detailed and mandatory scheduling that greatly affect the organizational effort of the Regional Census Office for Tuscany (RCOT) both in terms of training of census network operators and in terms of timely interventions to sustain response.

The present analyse was conducted on three aspect of RCOT work:

a) the main strategies adopted at regional level to improve the data quality and the efficiency of the process;
b) the profile of the field operators to evaluate the effects of some socio demographic features on the quality of the field work;
c) the tempus and quantum of response rate through a statistical model based.

The analysis used paradata[1] derived from the Survey Management System (SMS): a web system created to manage the PPC by the side of the census operators. The SMS collect information on process related variables such as: empty houses, non respondents, not eligible families for health problems or relocation, on-going (not finished) interviews, refusals, number of appointments for having an interview and so on.

3 Preliminary results

3.1 Istat regional strategies

RCOT main strategies could be structured into three type of actions aimed to improve the efficiency of the statistical process and to guarantee the data quality: training process, interinstitutional relationships and steady support to the network census.

a) The guidelines of training process has organized at national level: it changed from 2018 to 2019 following to the results of the 2018 evaluation survey. In the current year, the training process passed from 2 days in presence and a general e-learning session, to 1 day in presence and a customised e-learning session. In this framework, in Tuscany the training session were organized depending on the role of the actors in the Census (responsible and coordinator and interviewers) and on the geographically location of the operators. Seven persons managed 37 classes, composed by a mean number of 25 operators (min. 12 , max. 55). The training process took places from June to September 2019 in all the 10 chief town, from 0 to

[1] Kreuter F. (eds), 2013, Improving Surveys with Paradata. Analytic Uses in Process Information, University of Maryland, Wiley Series in Survey Methodology, J.W. and sons, Canada.

140 km away from the Istat Regional Office. Almost 1000 operators where trained in total.

b) The building of a strong interinstitutional network through coordinated actions to reach a unique objective: a good response rate combined with data quality. Several meetings in persons between RCOT and Provincial Offices of Ministry of Interiors were organized and a weekly follow up of the survey process was shared, in order to identify rapidly the criticalities and to figure out them with mixed modes of interventions. The combined actions affected the increase of response rate.

c) RCOT assaulted time resources in the reinforcement of a steady support to the different nodes of the census network. It sent specific email Notes in order to recall process deadlines, the delay of some of them, or to suggest some specific actions to respect the process guidelines (17 Notes). In addition, RCOT managed a direct assistance by email (about 500 assisted email).

3.2 The operators profile

Regarding 2019 wave, on the field were active 319 men (37,3%) and 538 women (62,7%). The mean age was 45,8 years for men ad almost the same (45,2) for women (min. 26 – max. 60 years old). Two thirds of them (68%) were interviewers, the rest were coordinators, chief of the census office or back office operators. Almost half of them have a high school certificate, and 43,1% a university degree; women are more educated: 47.0% have an university degree (men 36,3%).
During the work on the field for the AS, operators had a mean of 33,4 expected families to be contacted: at the end of the survey period each operator completed 26 questionnaires on average[1].

Table 1 - *Work field - AS- Tuscany 2018 and 2019. Mean value*

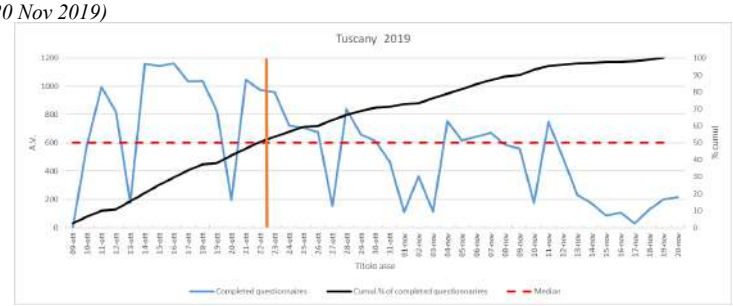
	No. addresses	***Estimated families***	***Contacted Families***	***Questionnaires***
2019	***23,2***	***33,5***	***39,1***	***25,9***
2018	***19,7***	***24,3***	***23,9***	***21,9***

3.3 The statistical model based evaluation of the tempus and quantum of response rate

[1] The same analyse will be conducted for LS.

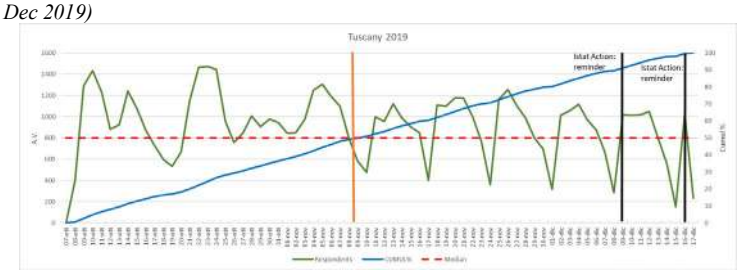
The timing of the two surveys is crucial for the success of the PPC. To evaluate the goodness of the process, it is essential to consider separately AS and LS, because in AS process, the most of the work is up to the operators (09 Oct. – 20 Nov), whereas the LS has a mixed mode data collection strategy: CAWI (7 Oct - 13 Dec), CAPI and CATI (8 Nov - 20 Dec). For the AS, an analysis of the timing shows that the median value of the distribution of the completed questionnaires in Tuscany drop on the 14th day of fieldwork (on a span of 42 days available)[1] represented by an orange bar on Figure 1[2]. After 25 days, 75% of the questionnaires were compiled. The RCOT entered actively in the process through a series of punctual emails and calls to specific municipalities, and with a final reminder on the 19 of November, keeping them to the end of the survey with around 100% of successful contacts (for AS 84,5% of the estimated families – 89,8% in 2018 - and 98,9% in the LS– 96,1% in 2018).

Figure 1 – *Distribution of the questionnaires (absolute values and % cumulated distribution) of the AS (8 Oct - 20 Nov 2019)*



As regards the LS, in the Figures 2 and 3[3], it is evident the spontaneous and non-spontaneous response rate. The median drop on the 34th day on a span of 72 days.

Figure 2 – *Distribution of the respondents (absolute values and % cumulated distribution) of the LS (7 Oct – 17 Dec 2019)*



Two active actions were taken by RCOT at the end of the period to stimulate the operators in order to close the work in time (black vertical line).

A second exploratory analysis has been conducted on the available variables of the SMS 2018 using a logistic regression model approach with the aim to identify elements affecting the quality of the process, more than some proxies of non-

[1] Provincial analyses will be conducted.
[2] In 2018 was the 26th day, mainly due to an interruption for technical problem of SSM.
[3] In Additional Figures file uploaded in the SIS website.

sampling errors. The response variable, Y, is calculated on the median number of days elapsed to get a final solution for a specific survey unit by municipality: 1 in case the median number of days for a municipality is lower than the regional one and zero in the opposite case. The regional median value is 26 days. The explanatory variables selected are the following, the amount of survey units per municipality (x1); number of census operators by municipality (x2); the average number of records for operator per municipality (x3); being in Union of Municipalities (x4); percentage of not completed surveyed units (x5); percentage of completed surveyed units (x6). The selected variables could be ascribed to three main thematic areas: the structure of the Municipality Bureau of Census (x1,x2,x4), the census operator effort (x3) and the general territorial context (x5,x6). Preliminary results show that the local context appears to play a key role in promoting the data collection process (x6), followed by the efforts of Municipal Census Bureau (x1), underlying the centrality of local actors in the complex process of PPC[1].

Capture-recapture methods

Bayesian Model Averaging for Latent Class Models in Capture–Recapture

Model Averaging Bayesiano per Modelli a Classi Latenti in Cattura-Ricattura

Davide Di Cecco

Abstract Model selection appears to be crucial in capture-recapture problems as it is common that different models with an equally good level of adaptation to the observed data lead to rather different estimates of the undercounts. We consider log–linear Latent Class Models as our capture-recapture model and propose Bayesian model averaging to overcome the difficulties of model selection within this class. We show that, by focusing on graphical decomposable models, we can design a simple Gibbs–based MCMC to sample over the space of eligible models.
Abstract *In problemi di cattura–ricattura, la selezione del modello risulta essere un aspetto delicato e difficoltoso. Non è inusuale, infatti, trovare modelli con valori di bontà di adattamento molto simili tra di loro che conducono a delle stime del numero di unità non catturate molto diverse. In questo lavoro trattiamo una famiglia estesa di modelli a classi latenti che rilassa l'ipotesi di indipendenza condizionata modellando le interazioni tra le variabili attraverso un modello log–lineare con una variabile latente. Per superare la difficoltà di scelta del modello all'interno di questa classe ampliata, proponiamo un model averaging Bayesiano. Mostriamo come, se ci limitiamo a considerare i modelli log-lineari decomponibili, è possibile costruire un semplice Gibbs sampler per ottenere la distribuzione a posteriori della numerosità della popolazione d'interesse.*

Key words: Bayesian Model Averaging, Latent Class Models, Capture-Recapture

1 Introduction

As pointed out by many authors, see, e.g., [4], the problem of estimating the size of a population in a capture-recapture model is essentially a problem of forecasting. As a consequence, it is not unusual that different models with a comparable level of

Davide Di Cecco
Sapienza University, viale del Castro Laurenziano 9, e-mail: davide.dicecco@uniroma1.it

goodness of fit lead to rather different estimates of the total population count. Given the lack of specific criteria for model choice, and the impossibility to validate the estimates, it is not unusual in capture-recapture practice to simply rule out a model resulting in unrealistic estimates. We think that a reliable procedure to deal with model selection in a more automatic way would certainly be of interest.

We treat the case of Multiple Record System, that is, the data consists of a set of capturing lists, usually originating from different sources, reporting partial listing of the same target population. In this setting it is common to assume different capture probabilities for the various sources. As a consequence, log-linear models are the tool of choice in capture–recapture modeling, and Latent Class Models (LCM) represent the natural extension when one wants to include unobserved heterogeneity. The use of LCM in capture–recapture dates back at least to [1] with many developments thereafter. The simplest formulation of LCM envisages the conditional independence assumption (CIA) which appears to be too restrictive in many situations. There are many proposals in literature to relax the CIA resulting in more flexible models. We focus on log-linear LCM where the additional dependencies are directly modeled by interaction parameters. Previous works on this class include [3], [13], [12]. We propose a Bayesian approach to the class as previously introduced in [6] and [7]. To overcome the difficulty of model selection within this class, we propose Bayesian model averaging to analyze the posterior distribution of the population count over a set of eligible models. Usually a full Bayesian approach to model averaging requires the use of a Reversible Jump algorithm ([8]) which is in general hard to implement. See [11] for an example of use of the algorithm within the class of log-linear models (without a latent variable). We show that, if we restrict ourselves to the subclass of decomposable models, it is possible to implement a simple Gibbs–based MCMC. Some preliminary results on simulated data (not shown in this work for space limitation), seem to indicate that the restriction to that subclass does not affect the efficacy of the procedure.

2 The model

Consider k capturing variables $\mathbf{Y} = (Y_1, \ldots, Y_k)$, where $Y_i = 1$ if a certain unit is listed in the i-th source and 0 otherwise, and let X be the latent variable taking values in $\{1, \ldots, m\}$ identifying the latent classes of our population. The LCM under the CIA can be equivalently expressed as the mixture model

$$P(\mathbf{Y} = \mathbf{y}) = p_{\mathbf{y}} = \sum_{x=1}^{m} p_x \prod_{i=1}^{k} p_{y_i|x}, \tag{1}$$

where $p_{y_i|x}$ indicates the conditional probability $P(Y_i = y_i|X = x)$, or as the log-linear model

$$[XY_1][XY_2]\cdots[XY_k], \tag{2}$$

where we use the classic notation reporting only the higher order interactions (generators) of the model. The dependence graph of this model is a star–shaped graph, where the node representing X is connected to all other nodes, like the one in Figure 1 on the left. Any additional interaction term with respect to (2), (i.e. any additional arc in the graph), constitutes a relaxation of the CIA.

Denote the number of observed units as n_{obs}, and the number of units presenting the capture profile $\mathbf{y} \in \{0,1\}^k$ as $n_{\mathbf{y}}$. Let $n_{x,\mathbf{y}}$ be the number of units having that profile which belong to latent class x, so that $\sum_x n_{x,\mathbf{y}} = n_{\mathbf{y}}$, and $n_{\mathbf{x},\mathbf{y}}$ be the vector $(n_{x,\mathbf{y}})_{x=1,\ldots,m}$. Let $n_{\mathbf{0}}$ be the number of uncaptured units to be estimated and N the total population count such that $\sum_{\mathbf{y}} n_{\mathbf{y}} + n_{\mathbf{0}} = N$. Let M be the (random variable associated to) the model to be chosen in a pre determined set $\mathscr{M}$, and Θ_M the set of parameters associated to model M.

2.1 Prior distributions

Obviously, the choice of a prior on the set of models $\mathscr{M}$, as on any other parameter, is subjectively arbitrary. However, we usually just want to exclude some cases, and set a uniform prior on all remaining cases. As we have said, we focus on decomposable models and, as an elementary additional criterion, we rule out all unidentifiable models. In [14] we can find a necessary and sufficient condition for the identifiability of any graphical model (hence of any decomposable model too).

In practice, to utilize the proposed methodology, we have to list out all possible models for a given number of variables. That is, all identifiable models represented by decomposable graphs containing the star–shaped graph relative to the CIA. Consider the case $k = 4$: in Figure 1 we have all decomposable graphs grouped by isomorphism. This leaves us with 19 eligible models. When $k = 5$ the number of identifiable decomposable models goes up to 355.

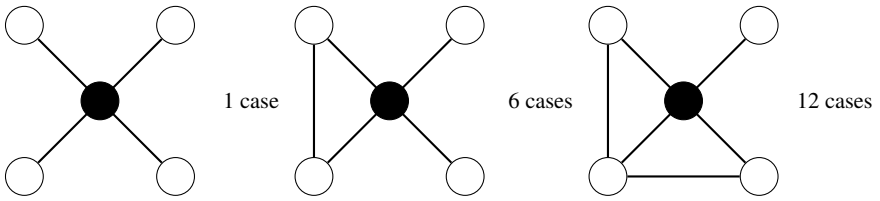

Fig. 1 Identifiable decomposable graph models with 4 manifests (empty nodes) and a latent (black node) grouped by classes of isomorphism

As for the prior distributions over the parameters Θ_M of each model M, we utilize the Hyper Dirichlet distribution described in [5]. Such a choice allows us to exploit

the result of [9] giving an analytical formula for the posterior probabilities of the models given the data.

3 Model averaging

We analyze the posterior distribution of N given the observed data $\{n_{\mathbf{y}}\}$ with $\mathbf{y} \neq \mathbf{0}$,

$$\pi(N \mid \{n_{\mathbf{y}}\}) = \sum_{M \in \mathscr{M}} \pi(N \mid M, \{n_{\mathbf{y}}\})\, \pi(M \mid \{n_{\mathbf{y}}\}).$$

The posterior probability of model M is given by:

$$\pi(M \mid \{n_{\mathbf{y}}\}) \propto \pi(M)\pi(\{n_{\mathbf{y}}\} \mid M) = \pi(M) \int \pi(\{n_{\mathbf{y}}\} \mid M, \Theta_M)\pi(\Theta_M \mid M) d\Theta_M.$$

In practice, given the computational complexity of calculating the last integral quantity, one can settle for the simplest (first order) approximation of the marginal likelihood of a model based on the Bayesian Information Criteria (BIC), that is, $\exp(-BIC/2)$, which, given equal prior probabilities for the models, leads to the following approximation of the weights $\pi(M \mid \{n_{\mathbf{y}}\})$:

$$\frac{\exp(-BIC_M/2)}{\sum_{M \in \mathscr{M}} \exp(-BIC_M/2)}, \tag{3}$$

where BIC_M is the BIC of model M. Then, one can use those weights in computing the averaged mean

$$E[N \mid \{n_{\mathbf{y}}\}] = \sum_{M \in \mathscr{M}} \widehat{N}_M\, \pi(M \mid \{n_{\mathbf{y}}\}), \tag{4}$$

where $\widehat{N}_M$ is the posterior mean of N under model M.

By using formula (4), one should keep in mind that the approximation quality can be poor in some cases, and, in any case, we limit ourselves to a point estimate of N. A full Bayesian approach to the problem, on the other hand, would result in an estimate of the whole posterior distribution of N marginalized over $\mathscr{M}$.

4 The Gibbs sampler

In this section we outline a Gibbs–based MCMC algorithm to sample from the joint distribution of $(N, N_{\mathbf{x},\mathbf{y}}, M, \Theta_M)$, conditioned on the observed data $\{n_{\mathbf{y}}\}$. Note that we cannot obtain the full conditionals for all terms: as pointed out in [2] and in [10], given $n_{\mathbf{x},\mathbf{0}}$, the value of N is deterministically defined. As a workaround, they propose to consider the conditional distribution of the couple $N, N_{\mathbf{x},\mathbf{0}}$ conditionally

on the rest. Similarly, we cannot obtain the conditional distribution of M given the parameters Θ_M. For these reasons, the algorithm loops over the following steps:

1) sample $n^{(t)}_{\mathbf{x},\mathbf{y}}$ from $\pi(N_{\mathbf{x},\mathbf{y}} \,|\, N, M, \Theta_M, \{n_{\mathbf{y}}\})$, for all $\mathbf{y} \neq \mathbf{0}$,

$$N_{\mathbf{x},\mathbf{y}} \sim Mult\left(n_{\mathbf{y}}, p_{\mathbf{x}|\mathbf{y}}\right),$$

where the $p_{\mathbf{x}|\mathbf{y}}$ are calculated according to the current value of M and Θ_M;

2) sample a couple $\left(N^{(t)}, n^{(t)}_{\mathbf{x},\mathbf{0}}\right)$ from

$$\pi(N, N_{\mathbf{x},\mathbf{0}} \,|\, M, \Theta_M, \{n_{\mathbf{x},\mathbf{y}}\}) = \pi(N \,|\, M, \Theta_M, \{n_{\mathbf{x},\mathbf{y}}\})\, \pi(N_{\mathbf{x},\mathbf{0}} \,|\, N, M, \Theta_M, \{n_{\mathbf{x},\mathbf{y}}\}).$$

Note that

$$\pi(N \,|\, M, \Theta_M, \{n_{\mathbf{x},\mathbf{y}}\}) = \pi(N \,|\, M, \Theta_M, n_{obs}) \propto \pi(N) \binom{N}{n_{obs}} p_{\mathbf{0}}^{N-n_{obs}} (1-p_{\mathbf{0}})^{n_{obs}},$$

then, if we choose the improper prior $\pi(N) \propto 1/N$, the conditional distribution of N results in a Negative Binomial distribution, and we simply have to

- sample $N^{(t)}$ from $NegBin\,(n_{obs}, 1-p_{\mathbf{0}})$;
- sample $n^{(t)}_{\mathbf{x},\mathbf{0}}$ from $Mult\big((N^{(t)} - n_{obs}), p_{\mathbf{x}|\mathbf{0}}\big)$.

where $p_{\mathbf{x}|\mathbf{0}}$ and $p_{\mathbf{0}}$ are calculated according to the current value of M and Θ_M;

3) sample from $\pi(M, \Theta_M \,|\, \{n_{\mathbf{x},\mathbf{0}}\}, \{n_{\mathbf{x},\mathbf{y}}\}) = \pi(\Theta_M \,|\, M, \{n_{\mathbf{x},\mathbf{0}}\}, \{n_{\mathbf{x},\mathbf{y}}\})\, \pi(M \,|\, \{n_{\mathbf{x},\mathbf{0}}\}, \{n_{\mathbf{x},\mathbf{y}}\})$. That is,

- calculate the posterior probability of each eligible decomposable model and sample $M^{(t)}$ from $\pi(M \,|\, \{n_{\mathbf{x},\mathbf{0}}\}, \{n_{\mathbf{x},\mathbf{y}}\})$. The posterior probability of each model M is defined as a product of Gamma functions (see [9]);
- then sample all parameters $\Theta^{(t)}_M$ from their posterior conditional distribution $\pi(\Theta_M \,|\, M, \{n_{\mathbf{x},\mathbf{0}}\}, \{n_{\mathbf{x},\mathbf{y}}\})$, which is a product of Dirichlet distributions.

5 Conclusions

The proposed algorithm can be just used for model selection by simply inspecting the generated values of M, as the relative frequency of each model constitutes an estimate of its posterior probability, and select the best model accordingly. However, model averaging seems to be the best choice in capture-recapture problems. Compared to the usual approximation techniques, our estimates should be more accurate, and allow to inspect the whole posterior distribution of N at the cost of some additional computational effort which appears nonetheless reasonable. The restriction to decomposable models may seem a severe limiting factor, as they constitutes a minority fraction of the possible models, and many frequently used models, such as the one with all second order and no higher order interactions, are left out. How-

ever, some preliminary results based on simulations (not shown in this work for space limitation), appears to be encouraging. In fact, the proposed approach seems to work well even when used on data generated from non decomposable models.

Combining "signs of life" and survey data through latent class models to consider over-coverage in Capture-Recapture estimates of population counts

Un modello a classi latenti per combinare segnali di presenza e dati di indagine nel contesto di stima cattura-ricattura dei conteggi di popolazione in presenza di sovra-copertura

Marco Fortini, Antonella Bernardini, Marco Caputi, Nicoletta Cibella[1]

Abstract The new permanent census strategy integrates population registers with sample surveys to obtain the counts of the usual resident population at a reference date, in such a way clearing Census counts of coverage errors affecting the register. A Lincoln-Petersen estimator is used after adjusting for people erroneously included in the register (over-coverage). We show a latent class model integrating the 2018 survey data affected by both missing values and response errors with administrative signals of job and school education (signs of life) in order to estimate over-coverage rates. We apply the model to a random sample of municipalities of Piedmont. We will see how and to what extent the signs of life are useful in determining usual residence of individuals and differences between Italians and foreigners in terms of over-coverage errors.

Abstract *La nuova strategia di censimento permanente integra il registro della popolazione con indagini campionarie per ottenere i conteggi della popolazione abitualmente dimorante alla data di riferimento, in modo da eliminare dal conteggio del censimento gli errori di copertura del registro. Viene utilizzato uno stimatore Lincoln-Petersen dopo l'aggiustamento per le persone erroneamente incluse nel registro (sovra copertura). In questo lavoro mostriamo un modello a classi latenti che integra i dati del censimento del 2018, affetti da valori mancanti ed errori di risposta, con segnali amministrativi di lavoro e di istruzione scolastica (segnali di presenza) al fine di stimare i tassi di sovra copertura. Il modello è applicato a un campione casuale di comuni piemontesi. Vedremo come, e in che misura, i segnali di presenza sono utili per determinare la dimora abituale delle persone e le differenze tra italiani e stranieri in termini di errori di sovra copertura.*

1. Introduction

The new permanent census of the Italian population integrates administrative data and surveys. It will be carried out every year on a sample of Municipalities and households and its aim is updating data contained in the integrated system of registers, taking into account for possible coverage errors affecting them. Two types of errors are considered, called over- and under-coverage, which can cause bias in population counts when they are not perfectly balanced each other. Although the coverage error affects population counts across all territorial levels, the adjustment at the municipal level is considered here, which is the most detailed territorial domain reported in the census figures. In this way, the estimate of coverage errors only relates to this level of detail, while the corrected population at higher levels is obtained as a sum from the corrected municipal-level counts.

An estimate of corrected (Nirel and Glickman, 2009) population count $\widehat{N}_{ch}$ for stratum h and municipality c is obtained starting from the corresponding register count R_{ch} and the error estimation components as

$$\widehat{N}_{ch} = R_{ch} \frac{\hat{p}_{D|Rch}}{\hat{p}_{R|Dch}}$$

where $\hat{p}_{D|Rch}$and $\hat{p}_{R|Dch}$ are, respectively, the proportions of actual residents among people rostered by register and of those included into the register among people surveyed on the field. A sample of individuals drawn from the register and subsequently checked on the field can estimate the first error component while the second one is estimated by people found in the register among those enumerated in a random sample of municipal areas (first stage sample units), under the conditions of validity of the Lincoln-Petersen estimator.

Here we focus on determining $\hat{p}_{D|Rch}$ when some of the units assigned to the enumerator cannot be determined with certainty. In practice, while the interviewer is quite certain of the respondent's usual residence, the status of "not more dwelling" for deceased or moved people is less reliable, being it communicated by a family member or neighbour and not directly verifiable at the survey date. Even more, the status remains unknown when the interviewer cannot obtain information on the actual residence of the subjects due to a lack of contact.

Since a simple exclusion of undetermined cases from the analysis can cause severe bias on estimates, external information coming from administrative data is collected in order to build a secondary variable representing the so called 'signs of life', which can offer clues on the actual presence of the units on the field.

These two variables can be used as indicators of individual's dwellings, both affected by error, and included in a latent class model (Biemer, 2011). A dichotomous latent variable represents in this case the true dwelling status of the individuals. Further descriptive variables, such as the citizenship (Italian or foreign), age class and membership of a single or multi-component family have also been considered in the analysis with the dual aim to better investigate the phenomenon and make the model identifiable. In the following, we describe the data used, then we introduce the latent class model and finally show some results concerning a sample of municipalities in the Piedmont region.

2. Data settings

The new Census is designed as a two phases Master Sample (MS), based on two balanced

and coordinated sampling surveys, called L and A survey respectively[2]. It is planned for supporting the Istat Population Register (PR) in order to increase the amount of provided statistical information and to improve the level of coverage and quality.
With the aim of identifying the "usual resident population", ISTAT linked the PR to subject-specific administrative sources (Labour and Education registers, Tax Returns register, Earnings, Retired, and Non-Pension Benefits registers, Permits to Stay archive). As a results of this trial, an Integrated Archive of Usual Resident Population (AIDA) was obtained. This Archive allows for the assessment of coverage measures of the permanent census and could be used to correct the population counts estimates by using individuals' "signs of life" on the Italian territory (ONS, 2019). Whereas the absence of signals for people in the population register could denote over-coverage cases, it is possible to assume that, in case of strong association between administrative data and Census survey, "signs of life" can be used to predict or to correct the results of the Census survey for the estimation phase. This approach can reduce the possible under coverage of the survey without inflating over-coverage of the PR in Census results.
In this paper the focus is on the L survey of the MS, the list sample, which is designed on a list of households and has the purpose of producing the thematic integration of surveys and registers so as to estimate the hypercube [3] which cannot be obtained using the replaceable information coming from registers. The L component is based on a yearly sample, with the size of about 950,000 households, drawn from 2,850 municipalities out of 7,950 of which around 1,150 are self-representative; in four years' time all the Italian municipalities will be selected. The analysis is conducted on a sample of 205 municipalities in the region Piedmont, further sampled so to select 141,241 individuals within them.
For each individual, the residence status is based on the field contact results and the corresponding signs of life from administrative sources are compared to detect possible errors in the survey results.
Table 1[4] shows the unweighted frequency distribution of the individuals, according to their municipality and the dwelling status identified by the surveyor at the time of the survey.
The variables considered for data analysis have been classified as follows:
C – Residence status from field contact (1, Usual resident; 2, moved or deceased; 3, Undetermined)
Signs of life (SOL from now on), which are specifically relative to labour and education, are classified on the basis of the number of distinct months with at least one signal during 2017, the year preceding the survey, as: Strong (8-12 months), Medium (4-7 months) and Weak (1-3 months).
The variable S summarises the kind of administrative signals associated to an individual as follows:
1 - No signals at all or person living abroad
2 - Strong SOL and all of the administrative signals are geo-referenced in the Labour Area Market (LAM) of residence
3 - Strong SOL, but not all of the administrative signals are in the LAM of residence or some information is missing

[2] L survey adds variables not already available from administrative sources while A survey aims to correct population counts for under-coverage affecting the PR.
[3] Census hypercubes: census tables for the cross classification of the set of variables.
[4] All tables and figures of the present contribution are available online as supplementary material at the following url: https://doi.org/10.6084/m9.figshare.12471707.

4 - Medium SOL or university students and all of the administrative signals are geo-referenced in the LAM of residence
5 - Medium SOL or university students but some of the administrative signals are not in the LAM of residence or some information is missing
6 - Dependent family members resident in the same municipality of their own tax declarant
7 - Retired persons having the administrative source reporting the same municipality of official residence
8 - Weak SOL
9 - No SOL but other administrative signals
The variable is built sequentially so, except for the residual class 1, once an individual is classified with a lower number he cannot be further classified with a higher number.
Other variables considered in the analysis are: E for age classes (0-19; 20-34; 35-64; 65+), F for family size (1 if the individual is a single-member family; 0 otherwise), N for citizenship (1 if the individual is foreigner; 0 otherwise), P for the size of the municipality (<2,000 inhabitants; 2,001-5,000 inhabitants; 5,001-20,000 inhabitants; 20,000-50,000 inhabitants; >50,000 inhabitants).
The latent variable X represents the true residence status and has been categorised as 1 for "not dwelling" and 2 for "dwelling in" the same municipality of their official residence.

3. The statistical model

We applied a log linear model with latent variables on the 141.241 sample units where manifest variables are those listed above while the latent variable is with the true residence status X. For practical reasons the model has not been weighted with inclusion probabilities for sample units. The observed data distribution is factorised by the following path analysis model:

$$\Pr(C,S,F,E,N,P) = \sum_X \Pr(C|X,P)\Pr(S|X,E)\Pr(X|F,E,N,P)\Pr(F,E,N,P)$$

where $\{PFE, PFN, PEN, FEN\}$ are interaction terms considered for the hierarchical log-linear component. We also imposed a structural zero in table {FE} to consider absence of cases in the "0-19 years old" and "single component household". Concerning the logit model describing structural effect of manifest variables on the latent variable we imposed {XPE, XPN, XF} interactions, while marginal effects {SX, SE} and {CX, CP} were considered for logits implied by the two measurement models $\Pr(C|X,P)$ and $\Pr(S|X,E)$. Finally, a structural zero has been considered for people found by interviewer as resident at the address (C=1) being not dwelling at the same address of its official residence (X=1), since such an error by the interviewer is supposed markedly rare.
Data analysis was accomplished with the LEM software (Vermunt, 1997). The model definition followed a forward search strategy where interactions in logit and log-linear models have been tested by a compromise between BIC and index of dissimilarity, the latter given by the sum of absolute differences between the observed and the expected frequency cells, divided by twice the number of statistical units. The final model uses 145 parameters leaving 2014 DoF and getting a dissimilarity index of 0.06975.

[5] A value under 0.1 is generally considered as a good fitting.

4. Main results

While the use of the model for the purpose of the permanent census is mainly for forecasting purposes, the approach here will be more explanatory. The data showed here refer only to the L survey sample and therefore it is noted that the (unweighted) average values reported cannot be directly extended to the entire Piedmont population. From the structural component of the model we obtain the conditional probabilities that people are not truly dwelling (X=1) although they result resident in the municipality's population register.

Model fitting appears satisfactory as shown by the plot of expected against observed frequencies in figure 1.

Figure 2 shows the log-odds of being a dweller given age category and class of population size for people that hold the residence in the municipality. It is apparent that risk of over-coverage is higher for large cities and in the "20-34" age class. Older people show a low and almost equal risk across municipalities.

Figure 3 describes the log-odds of being a dweller given citizenship and municipality population class of people's residence. It comes out that being a foreigner person is by far the most important risk factor for over-coverage.

Figure 4 highlights the higher risk of over-coverage for people that live in single-sized households than those living in larger ones. As expected, the risk also depends on population size.

The measurement model also allows to evaluate the effectiveness of field contact and signs of life in identifying the over-coverage. As far as field contact is concerned, a constraint imposed on the model required that all individuals identified by the interviewer as dwellers should be considered as such with certainty. This information helps to determine the meaning of the latent classes and by assumption assigns to dwellers the 90% of the whole sample.

Figure 5 shows the log odds (LO) of field contact outcomes for dwellers vs non dwellers, given class of municipality population size. An arbitrary value of 3 in the graph was assigned to LLR1 to people found as resident at home during the field contact, which would have been instead infinite given the structural zero considered in the model.

As expected, both the other contact outcomes are clues of not being resident. However, the information provided by a proxy about the move or death of not surveyed individuals seems no more informative than the non-contact differently from what it is expected. In this sense, it could be interesting to consider cases where proxy respondent is a family member from those where information is given by a municipality officer or an acquaintance of the subject (e.g. a next-door neighbour or the doorman).

Concerning LO in figure 6 for signs of life and four age classes, they seem definitely accurate in identify dwellers when there is a strong evidence of work or school attendance in the same LMA (2) or retired persons resulting in the same municipality of the official residence (7). Strong signals outside LMA of the official residence municipality (3) continues to weakly support for the actual presence of people at their actual residence, meaning perhaps that many people keep their life centre around their official residence even when their job is far than this place. This effect could concern people returning to their families at the end of the working week and should be better investigated.

By contrast, evidence supporting for not dwelling at the official residence is given for people without signals or with signal of living abroad (1), people with weak signals in LMA of their official residence municipality (8) and people with residual and not geo-referenced signs of

life (9). In addition, class 4 (medium-level signals in LMA), 5 (medium-level signals outside LMA) and 6 (dependent relatives) are not very informative in this case and need further refinement on the basis of the collected evidence. Finally we performed a cross validation by randomly excluding 40 municipalities with less than 20,000 inhabitants and then estimating the model on the remaining 165 municipalities, with 107,402 statistical units. In doing so, we then estimated the model fitting at municipality level for those retained in analysis, while we evaluated the predictive power of the model on the 40 excluded municipalities. The observed people classified by the result of field contact in each municipality are plotted in figure 7 against their correspondent expected numbers, representing the excluded municipalities by red dots. The graphs show that both the fitting of the model and its predictive power seem acceptable for the higher frequencies, while they are less reliable for small frequencies. Since, as hoped, the lower frequencies concern the case of missing information, for these we notice a greater variability.

Finally in figure 8 we compare the coverage rates estimated by the model for each municipality with corresponding rates computed under the missing at random (MAR) assumption after the exclusion of not contacts (C=3). Again, red dots are municipalities excluded from the model estimation phase and used only during the prediction stage.

While we cannot see remarkable differences for "predicted" municipalities when compared to those involved into model estimation, a general improvement of coverage rate is obtained by latent class model as revealed by position of almost all the dots at the right of the 'equivalence' line with the MAR estimates.

5. Final remarks

Latent structure models are useful tools when a phenomenon is measured by multiple indicators affected by errors or that relates to different aspects of the same fact. Here this approach has been applied to the check of usual residence on a sample of residents in the Piedmont municipalities, in order to overcome the non-contact issue by interviewers using information coming from administrative sources. The model provides coherent and reasonable results and could be used both to interpret the components related to over-coverage and within a population estimation strategy based on capture-recapture models. However, the analyses carried out here need to be repeated in different census social and territorial contexts before they can be reliably used for direct estimation in official statistics. This will help to understand the strength and limitations of administrative signals on the territory and how they can be used to support statistical surveys. Furthermore, it is essential to continue to refine the model given its sensitivity, well known in the literature, in order to clarify how it can be better integrated into a production and quality control perspective.

Population size estimation with interval censored counts and external information

Stima della numerositá di una popolazione in presenza di conteggi con censura intervallare e informazioni esogene

Alessio Farcomeni

Abstract We discuss Bayesian log-linear models for incomplete contingency tables with both missing and interval censored cells, with the aim of obtaining reliable population size estimates. External information on the censoring probability may substantially reduce uncertainty. We are motivated by an original example on estimation of prevalence of multiple sclerosis in the metropolitan area of Rome; where five out of six lists have interval censored counts. External information comes from mortality rates.

Abstract *Introduciamo modelli log-lineari per tabelle di contingenza incomplete in cui siano presenti sia celle mancanti che con censura intervallare. Lo scopo é ottenere una stima della somma di tutte le celle. Mostriamo come usare informazioni esogene sul meccanismo di censura, riducendo sostanzialmente l'incertezza. La motivazione nasce dal stima della prevalenza di sclerosi multipla nell'area metropolitana di Roma. Cinque liste su sei sono censorate. Le informazioni esogene riguardano i tassi di mortalitá.*

Key words: Incomplete tables; capture-recapture; external information; left-censored counts; right-censored counts.

1 Introduction

Population size estimation often involves specifying a log-linear model for the incomplete contingency table of cross-counts, where the cell(s) corresponding to exclusion from all lists is (are) missing. The parameter of interest is the population size N, which corresponds to the sum of observed and unobserved counts (Fienberg, 1972; Cormack, 1989; Fienberg et al, 1999; Farcomeni, 2016). In this work we fo-

Alessio Farcomeni
Department of Economics and Finance, University of Rome "Tor Vergata", Via Columbia, 2, Roma, Italy, e-mail: alessio.farcomeni@uniroma2.it

cus on the case in which observed counts are censored, that is, they only provide an upper bound for the true underlying counts. This happens for instance when some individuals not belonging to the population of interest might have been included. This situation is rather common in epidemiology and social sciences research, but it is oftentimes overlooked. Formally, we extend works by Overstall et al (2014); Overstall and King (2014); Alunni Fegatelli et al (2017), which deal with right-censored counts in one list, to the case of more than one list, interval-censored counts, and possible presence of external information. Surprisingly enough, use of external information can be advantageous even when it is somehow misspecified (Dotto and Farcomeni, 2018). Our motivating example comes from an original study on the prevalence of MS in the metropolitan area of Rome (Farcomeni et al, 2018). Six centers provided us with lists of their patients, and several patients appear in more than one list. All centers also provided us with information regarding gender, age at prevalence date, date of last visit. The prevalence date was set at the last day of December, 2015. One center (MS unit of Fondazione Santa Lucia) has also carefully verified that patients were alive at the prevalence date, but the other ones have not. For patients not included in the Santa Lucia list we can only note that subjects whose last visit occurred after the prevalence date were clearly alive at the prevalence date. For the other patients, we can not confirm this. We thus have five out of six lists with some censored counts. True counts therefore have both upper (the total number of patients in the list) and lower (the total number of patients that could be confirmed to be alive at the prevalence date) bounds. Source code to implement the proposed approaches, and the data set, are available as Supporting Information in the accompanying paper (Farcomeni, 2020).

2 Method

Suppose there are n cells in an incomplete contingency table, of which n_O are observed precisely, n_U are completely unobserved, and n_C are censored. Denote with Y_{U_j}, $j = 1,\ldots,n_U$, the counts, to be estimated, in the unobserved cells and Y_{C_j} the true but unobserved cell counts in the censored cells. The observed counts in the censored cells are denoted Z_{C_j}, $j = 1,\ldots,n_C$. Finally, Y_{O_j}, $j = 1,\ldots,n_O$ denote the precisely observed counts. For each censored cell we also have an upper and a lower bound, so that $L_{C_j} \leq Y_{C_j} \leq U_{C_j}$ for $j = 1,\ldots,n_C$. In the most simple scenario, $L_{C_j} = 0$ and $U_{C_j} = Z_{C_j}$, the observed left-censored count. We denote with $Y = (Y_O, Y_C, Y_U) = (Y_1,\ldots,Y_n)$ the collection of true (observed, censored, and unobserved) cell counts. Common assumptions on Y include that they are Poisson or multinomial distributed. In order to make inference we follow a Bayesian framework. Note that the observed data is given by uncensored observed counts Y_O, and by lower and upper bounds L_C and U_C. After some algebra and using obvious conditional independence assumptions (see Farcomeni (2020) for more details) it can be seen that

$$\pi(Y_U, Y_C, \beta | Y_O, L_C, U_C) \propto \pi(Y|\beta)\pi(\beta)\pi(U_C, L_C | Y_C, \beta); \quad (1)$$

which can be simply marginalized to obtain $\pi(Y_U, Y_C | Y_O, L_C, U_C)$. A simple assumption for the last factor in (1) is that U_{C_i} and L_{C_i} are conditionally independent, and that U_{C_i} is uniformly distributed in the interval $[Y_{C_i}, \infty)$, while L_{C_i} is uniformly distributed in the interval $[0, Y_{C_i}]$. As prior for the β parameters we use $\beta_{-0} \sim N(0, n(X'_{-1}X_{-1})^{-1})$, which is a restricted unit information prior (Ntzoufras et al, 2003) (UIP), where β_{-0} indicates all parameters except the intercept and X_{-1} the design matrix without the first column of ones. The model will not in general be known *a priori*. Model selection can be performed using Stochastic Search Variable Selection (SSVS) (George and McCulloch, 1993, 1997; Ntzoufras et al, 2000). Let γ denote a binary vector. We assume

$$\beta_{-0} \sim N(0, \Gamma n(X'_{-1}X_{-1})^{-1}\Gamma), \quad (2)$$

with $\Gamma = \text{diag}\left(\sqrt{\gamma_j \tau_{1j}^2 + (1-\gamma_j)\tau_{0j}^2}\right)$. In this work we fix $\tau_{1j} = 1$ for all j so that when an effect is included in the model, it follows the UIP marginally; and $\tau_{0j} = 1e-3$. For γ we assume prior independence and $\Pr(\gamma_j = 1) = 0.5$. The posterior distribution for the population size is a direct by-product of the MCMC sampling scheme we describe below. Indeed, $\Pr(N|Y_O, L_C, U_C) = \Pr(\sum_j Y_{C_j} + \sum_j Y_{U_j} = N - \sum_j Y_{O_j} | Y_O, L_C, U_C)$. Since with SSVS more than one design matrix is used throghout the algorithm, the final resulting population size estimate can be obtained either via model averaging (Hoeting et al, 1999) (that is, averaging over all sampled models), or after model selection. In this case we suggest including all effects with a posterior probability of inclusion larger than 50%, the so called median model, which has been shown to be optimal from a predictive perspective (Barbieri and Berger, 2004) and model consistent under mild assumptions (Farcomeni, 2010).

In order to generate an MCMC sample from the posterior distribution (1) we employ a data augmentation procedure, where the missing data Y_U and Y_C is sampled at each iteration conditionally on the current value of the parameters. A Metropolis-within-Gibbs allows us to sample from the full conditional for β. When the model is not fixed the inclusion indicators are then sampled from their full conditional distribution, which is a Bernoulli. Finally, in order to update the unobserved cell entries we use their full conditional distribution, which simply corresponds to a Poisson. Similarly, the full conditional distribution for censored cells corresponds to a Poisson distribution restricted to the support given by lower and upper bounds.

We conclude this section by discussing external information on the probability of censoring, which in some cases is available. We suggest that external information is seen as an aggregated data measurement D (as in Bayesian meta-analysis, for instance). A consequence is that external information induces conditional independence between Y_{C_j} and β. Hence, $\pi(Y_{C_j} = x | D, L, U, \beta) = \pi(Y_{C_j} = x | D, L, U)$, with support $x = L_{C_j}, L_{C_j} + 1, \ldots, U_{C_j}$. These probabilities can be computed as sums of probability of censoring for the $U_{C_j} - L_{C_j}$ uncertain individuals, which under independence correspond to a Poisson-binomial (a binomial under further assumptions of homogeneity).

3 Simulations

We generate data fixing $S = 6$ lists and $N = 5000$, with 5 censored lists. The full simulation study can be found in Farcomeni (2020). Upper bounds are obtained by adding a binomial random variable with maximum value five times the true unobserved count, and success probability p_s. Lower bounds by subtraction of an independent identically distributed binomial. When we use wrong external information we further misspecify the censoring probability p_x by sampling it from a uniform in the interval $(p_x * 0.8, \min(p_x * 1.2, 0.995))$. We report the square root of the median squared error (RMSE) when estimating the true N. Results are in Table 1.

Table 1 RMSE for $\hat{N}$ for different approaches and success probabilities for censoring counts (p_s). The first 5 lists are censored. INC-C (Overstall et al, 2014) only uses upper bound information, IGN-C treats censored counts as truly observed, INC-B-C uses our lower and upper bound plus SSVS approach, INC-B-EXT-C additionally uses external information, INC-B-EXT-C (Wrong) uses wrong external information. Results are averaged over $B = 1000$ replicates.

p_s	INC-C	IGN-C	INC-B-C	INC-B-EXT-C	INC-B-EXT-C (Wrong)
0.10	1746.61	2039.75	1658.60	43.50	401.22
0.25	4676.05	5103.40	4579.26	110.50	377.43
0.33	6234.28	6736.40	6136.06	144.90	393.43

The simulation results clearly indicate that INC-B-C outperforms INC-C and IGN-C in all settings. Use of external information can additionally dramatically improve the performance of INC-B-C, even when this is somehow misspecified; as noted also in a different context in Dotto and Farcomeni (2018).

4 Data analysis

According to official (even if outdated) prevalence estimates the total number of patients with MS in the metropolitan area of Rome is slightly above 4,000. Results obtained with our data (i) ignoring the issue of censored counts, and (ii) using log-linear models with unobserved heterogeneity in a frequentist framework, lead to $\hat{N} = 4,610$ (Farcomeni et al, 2018). The resulting estimated prevalence would be 143 per 100,000. As external information we use official age-gender-specific mortality rates for the general Italian population as published by ISTAT, the national statistical agency, adjusted using standardized mortality ratios specific to multiple sclerosis (Scalfari et al, 2013). In our analysis we will compare, in addition to INC-C and IGN-C, with classical Chao estimators and Generalized Chao (GC) estimators with covariates (Böhning et al, 2013; Farcomeni, 2018); both ignoring the censoring problem (IGN- methods) and restricting only to subjects guaranteed to be alive (LB-methods). Results are reported in Table 2.

Our approach with use of lower bounds leads to very reasonable and stable estimates, regardless of the use of covariates and external information. Our fi-

Table 2 Population size estimates $\hat{N}$ with 95% Credibility Intervals (CI) for different approaches applied to the multiple sclerosis data set. IGN- methods treat censored cells as truly observed, INC-C methods use upper bound information, LB-C fix censored counts at their lower bounds, INC-B-C use both lower and upper bound information as proposed and -EXT- use also external information. Finally -Covs methods additionally stratify on gender and age class.

Method	$\hat{N}$	CI-low	CI-up
IGN-C	4612	3767	5665
INC-C	224	180	420
LB-C	1012	1007	1043
IGN-Chao	4813	4544	5082
LB-Chao	1320	1188	1453
IGN-C-Covs	4655	3777	5736
INC-C-Covs	NA	NA	NA
LB-C-Covs	312	308	328
IGN-Chao-Covs	5003	4715	5290
LB-Chao-Covs	1380	1237	1523
INC-B-C	4212	4036	4347
INC-B-C-Covs	4188	4042	4375
INC-B-EXT-C	4227	4115	4338
INC-B-EXT-C-Covs	4225	4111	4339

nal estimates are indeed more credible than the previously published figure (Farcomeni et al, 2018) and have reasonably narrow 95%CI. Our final estimate for the prevalence of MS in the metropolitan area of Rome is then 131.2 per 100,000 $(95\%CI : 127.6 - 134.8)$. We note that previously published $\hat{N} = 4,610$ lies outside all credibility intervals obtained with our method; hence this estimate might be deemed to have included dead patients in the prevalence estimate.

Changes in environment extremes and their impacts

FPCA Clustering of rainfall events

Classificazione di dati pluviometrici basata su FPCA

Gianluca Sottile, Antonio Francipane, Leonardo Noto, Giada Adelfio

Abstract The increasing occurrence of flood events in some areas of the Southern Mediterranean area (e.g., Sicily), over the last few years, has contributed to raise the importance of characterizing such events and identifying their causes. Since most of these events can be related to high-intensity rainfalls due to convective events, it is very important to understand which factors could be recognized as drivers of such extreme rainfalls. Nevertheless, the way to distinguish between convective and stratiform rainfall is still today an open issue and not easy to solve. With this regard, starting from precipitation time series recorded at different rain gauge stations of Sicily, which is the greatest island of the Mediterranean Sea, this work proposes an algorithm capable to classify precipitation distinguishing between their convective and stratiform components.

Abstract *Negli ultimi anni si sono osservati sempre più eventi pluviometrici di natura estrema anche nell'area del Sud Mediterraneo. Sembra pertnato necessario un maggiore approfondimento delle loro caratteristiche e delle principali cause. Ad oggi la distinzione tra eventi convettivi e stratiforme è ancora un problema aperto. In questo lavoro si presenta un algoritmo basato sulla natura funzionale dei dati al fine di classificare e caratterizzare gli eventi osservati in una regione dell'area analizzata.*

1 Introduction

Since the impacts of climate change on the environment have been constantly rising over the last decades, scientists have paid much attention to understand the effects of this phenomenon (Kunkel et al. 1999). Climate change leads to different kinds of extremes, such as heavy rainfall events, characterized by short duration and high intensity, and drought, which can cause the problem of water scarcity over a certain area. These types of extreme events cause several damages for the affected areas since they can result in loss of human lives and economic damages. Heavy rainfall events, for example, because of their characteristics, especially when they hit small catchments with low times of concentration, may result in flash floods (Aronica et al. 2012; Forestieri et al. 2016) and cause economic damages and, more relevantly, human lives losses. Because of their high intensity and short duration, these kind of events are often associated to convective rainfalls. In the last years, the increase of occurrence of these kinds of phenomena in many areas of Europe, including Sicily, which is the largest island of the Mediterranean Sea, has contributed to raising the importance of understanding which factors could be recognized as drivers of these events. Arnone et al. (2013) studied the changes in rainfall statistics over Sicily, finding out an increasing trend in the occurrence of shortest-duration rainfall events. Nonetheless the distinction between convective and stratiform precipitation is a very important task today, it is not easy to deal with and still today a big challenge to face (Kyselý et al. 2016). In fact, such a distinction is connected with the characteristics of rainfall events, such as the rain rate and duration, which are usually different for a convective and a stratiform precipitation (Liu et al. 2013). Still today, despite some studies tried to set up different criterions to make a net distinction between the convective and the stratiform rainfall events (Fiori et al. 2014; Rulfová and Kyselý 2013), others affirm that in some cases there could be a coexistence of these two kinds of events (Houze 1997; Liu et al. 2013). As an example, Houze (1997) affirmed that, in some cases, convective phenomena are embedded in stratiform regions. In this case, the spatial patterns are similar to those of a stratiform precipitation, even though they also present a convective component. It is clear, then, that a clear-cut separation of the events in only two classes is improper and difficult to carry out and then, with this regard, Rulfová and Kyselý (2013) introduced a class of mixed/unresolved events to classify all of those events.

In this paper a k-means clustering algorithm denoted FPCAC and based on principal component analysis rotation of curves data is proposed to overcome the limitation of the cross-correlation, as well as an alternative to methods based on the interpolation of data by splines or linear fitting (Sangalli et al. (2010), Adelfio et al. (2011), Garcìa-Escudero and Gordaliza (2005)). This technique is applied to rainfall data collected from 2003 to 2018 in Sicily, from six rain gauge stations more or less uniformly distributed over the region.

The rest of the paper is organized as it follows. In section 2 a brief description of the characteristics of pluviometric events in Sicily is reported. In section 3 functional data analysis basic notation, focusing on PCA for functional data and the proposed clustering approach are reviewed. The application of the proposed clus-

tering approach to highlight common characteristics of rainfall data is proposed in section 4. Some conclusions are provided in section 5.

2 Pluviometric events in Sicily

Sicily (Italy) is the largest island of the Mediterranean Sea and covers an area of about 25,000 km^2. The elevation varies a lot across the island, ranging from 0 m a.s.l. along the coast to more than 3,000 m a.s.l. at the volcano Etna. Sicily has always experimented a high spatial and temporal variability of precipitation. With regard to the spatial variability, Di Piazza et al. (2011) obtained a spatial distribution of the mean annual precipitation (MAP) over Sicily with higher MAP recorded in the northeast of the region, where it reaches about 1,900 *mm*, and lower MAP in the southeastern part of the island (about 360 *mm*). The overall mean of the MAP is about 700 *mm*. With reference to the temporal variability, instead, rainfall is mostly concentrated in winter, whilst the summer season (i.e., June, July, and August) is usually rainless. With regard to air temperature, Sicily is a region with a temperate-mesothermal (Mediterranean) climate, with a dry summer, having an average temperature in the hottest month greater than 22°C, with a precipitation regime more intense in the coldest season. The highest values of mean annual temperature (MAT) are around 18.5 ± 19.5°C along the coast, while the lowest values ($10.5/13.5$°C) characterize higher elevations, with a minimum above the Etna volcano. The warmest areas are the flat lands in the North West nearby the city of Trapani and in the South East close to the city of Catania, both with a relevant agricultural tradition. In the last years many areas of the island have been experiencing some very intense rainfall events, usually concentrated in between the end of the summer and the beginning of the autumn, that cause urban floods and flash floods with consequent economic damages and, sometimes, human lives losses.

3 Clustering of rainfall data by FDA

When data are observed as functions of time we refer to as functional data, referring to n pairs (t_i, y_i) where y_i is the value of an observable variable x at time t_i, and focusing on a set of functions defined on $[0,T]$, such that:

$$\{y_i = x_i(t); i = 1,2,\cdots,I; 0 \leq t \leq T\} \tag{1}$$

Therefore, assuming that a functional for replication i can be represented by a set of discrete measured values $y_{i1}, y_{i2}, \cdots, y_{in}$ the first task is to convert these values to a function x_i with values $x_i(t)$ computable for any t, called functional objects. In the functional context the counterparts of variable values are functional values $x_l(t), l = 1, \cdots, p$ and the discrete index j in the multivariate context is now replaced

by the continuous index s, such that:

$$f_l = \int_{\Omega_s} \beta(s) x_l(s) ds \tag{2}$$

with $\beta(s)$ weight functions and Ω_s a subset of R. In the literature, the term harmonic is used to refer to principal component of variation in curves analysis (see Ramsey and Silverman (2006) for more details).

The functional PCA-based clustering approach, denoted as the FPCAC algorithm and proposed by Adelfio et al. (2011), introduces a variation of the trimmed k-means Robust Curve Clustering (RCC) algorithm (Garcìa-Escudero and Gordaliza, 2005), that is a kind of robust version of k-means methodology through a trimming procedure.

In particular, FPCAC looks for clusters of functions according to the direction of largest variance, finding a linear approximation of each curve by a finite p dimensional vector of coefficients defined by the FPCA scores, assigning event to the cluster on the basis of a distance measure, considering the matrix of FPCA scores instead of the coefficients of a linear fitting to B-spline bases.

4 FPCAC for rainfal data

A dataset from the regional agency SIAS (Servizio Informativo Agrometeorologico Siciliano - Agro-meteorological Information Service of Sicily) has been used because of its high temporal resolution, quality, and availability of up-to-date data. The database includes more than 100 rain gauge stations distributed over the entire island that collect the data with a temporal resolution of 10 minutes. Specifically, data from six rain gauge stations (i.e., Enna, Montalbano Elicona, Palermo, Ragusa, Sciacca e Trapani Fontanasalsa), more or less uniformly distributed over the region, have been collected for the period 2003 – 2018 (Figure 1). For each rain gauge, starting from the original dataset, the rainfall events have been identified and extracted within the observation period providing, for each event, the duration (hours) and depth (*mm*). Two subsequent rainfall events have been defined as different if they are separated by at least equal to three hours and have a total depth of at least equal to 1 mm.

For each of the six rain gauge stations across the Sicily, we applied the FPCA clustering algorithm using 5 harmonics to discriminate the identified rainfall events between convective and stratiform precipitations. In figure 2, just as an example, we provide results of the clustering method for Palermo.

In table 1, we reported the numbers of rainfall events classified as stratiform and convective precipitations; minimum, average (standard deviation) and maximum rainfall intensity (mm/hr).

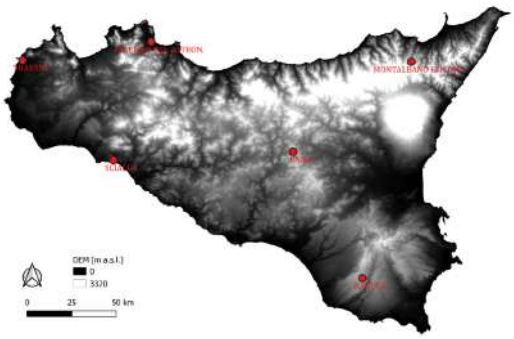

Fig. 1 Location of the considered SIAS rain gauge stations.

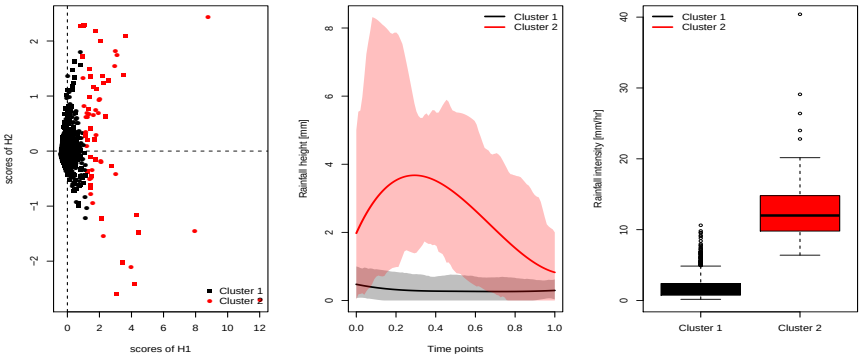

Fig. 2 FPCA clustering method applied to Palermo rain gauge station. Black and red color refer to stratiform and convective precipitation. The left panel shows scores of the first harmonic vs the second one; middle panel shows mean rainfall height in mm of the two clusters and the interquartile range for each normalized time point; the right panel compares boxplots of rainfall intensity (mm/hr)

Table 1 Descriptive statistics of the stratiform and convective precipitations identified applying the FPCAC method to the six rain gauge stations.

Stations	Stratiform				Convective			
	N.	Min	Avg (SD)	Max	N.	Min	Avg (SD)	Max
Enna	1155	0.13	2.17 (2.64)	19.31	20	15.84	26.70 (11.59)	63.60
Montalbano Elicona	1343	0.13	1.47 (1.20)	10.00	43	5.00	11.23 (6.22)	32.64
Palermo	1402	0.17	1.81 (1.55)	10.62	65	6.40	13.62 (7.02)	45.60
Ragusa	1121	0.11	2.02 (2.03)	16.20	29	9.60	22.45 (11.52)	64.80
Sciacca	1216	0.16	1.99 (2.08)	15.90	28	8.70	18.50 (7.57)	46.60
Trapani Fontanasalsa	1319	0.16	1.79 (1.62)	13.52	53	6.40	14.38 (7.39)	43.20

5 Discussion and conclusion

The proposed algorithm seems to clearly distinguish the two precipitation components. However, deeper analysis could be carried out in order to individuate the main causes and features of these two components, based on dependence models accounting for spatial information.

The results in table 1 suggest that the stratiform precipitations have a similar behaviour among the six rain gauge stations, whilst the convective ones are more heterogeneous, as a function of the geographical site.

Finally, one of the advantages of the procedure is related to an immediate use of PCA for functional data avoiding some objective choices related to the splines fitting.

Trends in rainfall extremes in the Venice lagoon catchment

Tendenze nelle precipitazioni estreme nel bacino scolante della laguna di Venezia

Ilaria Prosdocimi and Carlo Gaetan

Abstract A high number of unprecedented extreme weather events have occurred in recent years in the Venice lagoon and the surrounding region. These events have triggered the questions of whether such large events are linked to climate change. In this study we analyse daily rainfall records from long-term gauging stations in the Venice lagoon catchment. The records are analysed using extreme value model based on the peaks-over-threshold approach: several models are employed to investigate the presence of changes in the extreme rainfall in the catchment. The impact of the parametrisation of the suggested models on the representation of change in high quantiles of the rainfall distribution is investigated.

Abstract La laguna di Venezia e la regione circostante sono state colpite negli ultimi anni da molti eventi climatici estremi. La possibilità che la frequenza e intensità di questi eventi sia legata al cambiamento climatico è quindi di interesse. In questo studio vengono analizzate serie temporali di accumulazioni di piogge misurate da pluviometri in funzione da lungo tempo nel bacino scolante della laguna di Venezia. Vengono in particolare utilizzati modelli di analisi dei valori estremi basati sui picchi sopra una soglia che permettano di caratterizzare il cambiamento nella distribuzione delle piogge estreme. Quindi, viene studiato l'impatto della parametrizzazione utilizzata sulla caratterizzazione del cambiamenti dei quantili.

1 Extreme value analysis for risk assessment

To manage risk related to natural hazards one needs to quantify the relationship between magnitude and frequency of intense events. This relationship is quantified by means of the quantile function: $q(1-p) = x_p$, so that $P(X \leq x_p) = 1-p$, where X denotes the random variable of interest, e.g. daily rainfall accumulation. Typically the distribution of X is unknown and needs to be determined statistically. Further, when assessing risks connected to natural hazards such as rainfall, the interest lies in the frequency of extreme events: the statistical characterisation of X is therefore carried out using only the part of the record which can be considered in some way extreme and for which extreme value theory results hold. In this work we focus on the peaks over threshold approach: only rainfall events which exceed a certain high threshold are considered to be extreme and used to estimate the distribution of extreme daily rainfall. Denoting with X the daily rainfall accumulation and with u a fixed high threshold it can be shown that $X-u$, conditional on X being larger than u, is approximated by a Generalised Pareto (GP) distribution [2]. Denoting with $Y = X-u$ the threshold exceedances we have that: $(Y|X > u) \sim GP(\sigma, \xi)$, with CDF: $F(y) = 1-(1+\xi y/\sigma)$, where $\sigma > 0$ and $\xi \in \mathbb{R}$ are the scale and shape parameter of the distribution. Notice that when $\xi = 0$ the GP distribution reduces to an exponential distribution.

The quantile function for the Generalised Pareto (GP) distribution has the form:

$$q(1-p;u,\sigma,\xi) = \begin{cases} u + \frac{\sigma}{\xi}\left(p^{-\xi}-1\right) & for \xi \neq 0 \\ u + \sigma \log p & for \xi = 0 \end{cases} \quad (1)$$

Once suitable estimates are found for σ and ξ the quantile function is used to estimate the relationship between rainfall totals and the probability of such totals to be exceeded. In engineering, the quantiles of interest are typically denoted by their annual exceedance probability (AEP) $p = P(X > x_p)$ and the closely related return period T, which is the expected time between two events larger than x_p. If the distribution of X is unchanged in time and rainfall events are independent of each other the return period T is the reciprocal of the AEP: $T = 1/p$.

When assessing risk using the peaks over threshold approach one typically assumes that the variable of interest X_i is recorded for a long period of time, with recordings at time t_i independent of other recordings at time t_j ($i \neq j$). For a large threshold u, $Y_i = X_i - u$ is approximated by a GP distribution, and it is typically assumed that Y_i and Y_j are iid. Nevertheless, the increasing evidence of global changes in the climate, puts the assumption that climate variables are identically distributed in time into question. Therefore models which allow for the distribution to change as a function of time or some other forcing variable (e.g. CO_2 emissions, temperature, etc.) have been proposed. For the peaks over threshold approach these mostly consist of two types of models: models which allow the GP parameters or the threshold u to change [2, 1, 3].

In this work four time varying models are employed to investigate whether the distribution of rainfall extremes in the Venice lagoon catchment has changed:

1. a model in which the threshold is constant and the scale parameter for the GP distribution changes linearly in time: $Y_i = (X_i - u) \sim GP(\sigma_0 + \sigma_1 t_i, \xi)$;
2. a model in which the threshold changes linearly in time and the scale parameter for the GP distribution is constant: $Y_i = (X_i - (\alpha + \beta t_i)) \sim GP(\sigma, \xi)$;
3. a model in which the threshold and scale parameter change linearly in time independently of each other: $Y_i = (X_i - (\alpha + \beta t_i)) \sim GP(\sigma_0 + \sigma_1 t_i, \xi)$;
4. a model in which the threshold changes linearly in time and with the scale parameter for the GP distribution changes proportionally to the threshold: $Y_i = (X_i - (\alpha + \beta t_i)) \sim GP(\tau(\alpha + \beta t_i), \xi)$.

All models keep a constant shape parameter in time: the shape parameter is a often found to have high variability and it is rarely allowed to change [2]. Notice also that when estimating the models in practice one needs to ensure that the threshold and the scale functions are positive. While model 1. to 3. have already been employed in the literature the last model has not been used for the detection of trends, but has the advantage of being a parsimonious model to describe changes in both the threshold and the scale parameter of the GP distribution. Further the model has the advantage of implying changes in the quantile function which are constant for all return periods and therefore easy to interpret.

When assessing changes in environmental extremes, the interest often lies in how the distribution quantiles, rather than the parameters, are changing. The different time varying models imply different functional forms of change over time for the quantile function. These can be characterised by taking the ratio of the quantile function estimated at different points in time, say $(t_0 + \Delta t)$ and t_0:

$$M(p, t_0, \Delta t) = \frac{q(p; u(t_0 + \Delta t), \sigma(t_0 + \Delta t), \xi)}{q(p; u(t_0), \sigma(t_0), \xi)}. \tag{2}$$

For example, the ratio of the quantile function on 01/01/2015 over the value on the 01/01/2005 could be of interest to assess what changes have occurred in ten years. When the scale is allowed to change proportionally to the threshold (model 4.), the relative change is constant across all return periods, i.e. all exceedance probabilities p, since the ratio in (2) can be determined to be $M(p, t_0, \Delta t) = 1 + \beta \Delta t / (\alpha + \beta t_0)$.

2 Data

The data analysed in this study have been provided by the Veneto regional environment protection agency (ARPAV). In particular, daily rainfall accumulation records from rain gauges located in the Venice lagoon catchment were made available. From all available records only stations which were operational till the end of 2018 and which have at least 20 years of valid recordings have been kept. A year was deemed to have valid recordings if at least 274 days in the year had a record. In total 20

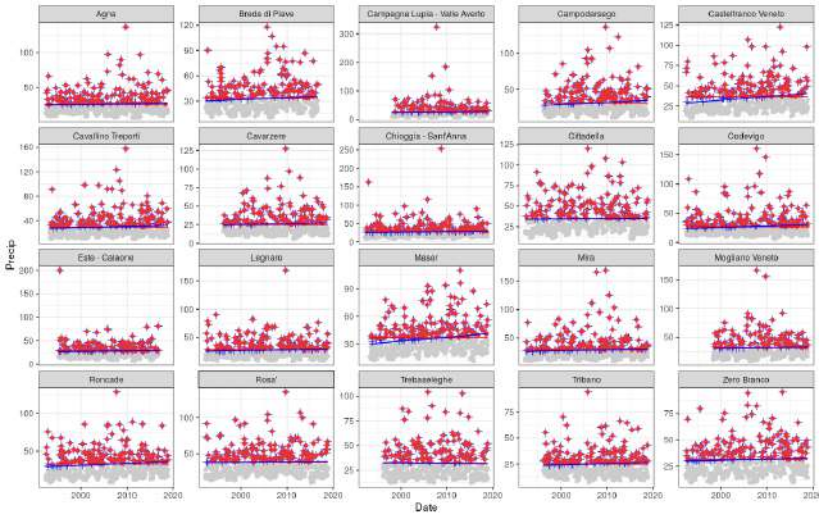

Fig. 1 High daily rainfall data with thresholds and peaks over threshold. Red lines and dots indicate the case of constant threshold. Blue lines and crosses indicate the case of varying threshold.

stations are included in the study and the models are fitted to each station separately, using a constant and a time varying thresholds. At each station, the constant threshold u is selected such that an average of 5 independent peaks in a year is extracted from the daily records. Peaks are considered to be independent when they are separated by at least 5 days. Additionally, a time varying threshold $u_i = u(t_i)$ was determined by means of quantile regression [4] allowing rainfall accumulation quantiles to change as a linear function of time. The varying threshold was also chosen so that an average of 5 independent peaks per year are extracted.

Figure 1 shows the top 20 independent events per year at each station included in the study, together with the constant and varying threshold and the selected peaks. Notice that for each station when using a constant or a varying threshold different peaks are included in the analysis. From the Figure it is clear that some stations have been operating for a longer period of time with several stations starting in 1992.

3 Results

Figure 1 shows that most varying threshold are increasing in time. Only the station in Trebaseleghe shows a slightly negative change in the higher quantile. Nevertheless, the quantile regression slope was found to be significantly different from zero at the 10% level only for one station of the 20 under study (Maser). A map showing the test statistic for trend in the quantile regression (i.e. the estimated slope divided by

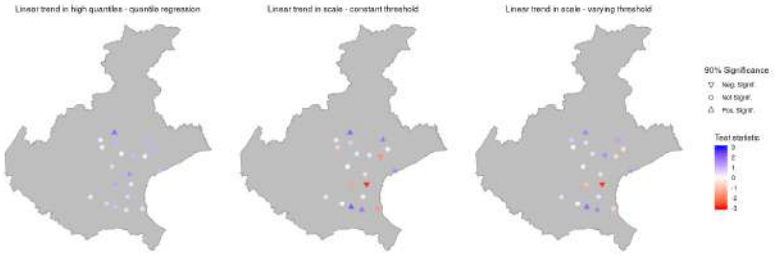

Fig. 2 Left panel: map of test statistic for trend in high quantile - quantile regression. Central panel: map of test statistic for trend in the scale parameter - model with constant threshold. Right panel: map of test statistic for trend in the scale parameter - model with a varying threshold.

its estimated standard deviation) is shown in Figure 2. The test statistic for trend for the scale parameter in model 1. is also shown in the central panel. The model (as all other GP models) was fitted via the maximum likelihood approach. Some increasing and decreasing trends are visible, with two significant decreasing trend and four significantly increasing trends (at the 10% significance level). A similarly scattered result is also found when both the threshold and the scale parameter are allowed to change independently, although only three stations exhibit slopes which are significantly different from zero. The evidence for changing behaviour of rainfall extremes when analysing stations independently is weak.

Figure 3 shows the relative change between the estimated quantiles for the year 2015 and 2005 for the four models at each rainfall station. The changes derived in models in which the scale is allowed to change (in the left panels) tend to be more variable across the different return periods compared to the other models. The relative change for events with higher return period appear to be larger: when rainfall accumulations have been predicted to increase (decrease) in time large events are estimated to increase (decrease) relatively more than frequent events. When only the threshold is allowed to change, little variability can be seen in the implied relative changes in quantiles across return periods.When the threshold, rather than the scale is allowed to change, the long return period events appear to be increasing relatively less than the frequent, low magnitude events. When the scale is allowed to change proportionally to the threshold, the relative change is constant across all return periods, with a fairly high variability across the different stations.

4 Conclusions and perspectives

A peaks-over-threshold analysis of potential changes in rainfall daily accumulation in the Venice lagoon catchment finds little evidence of change in the distribution of extreme rainfall. Several models were employed: significant changes were identified

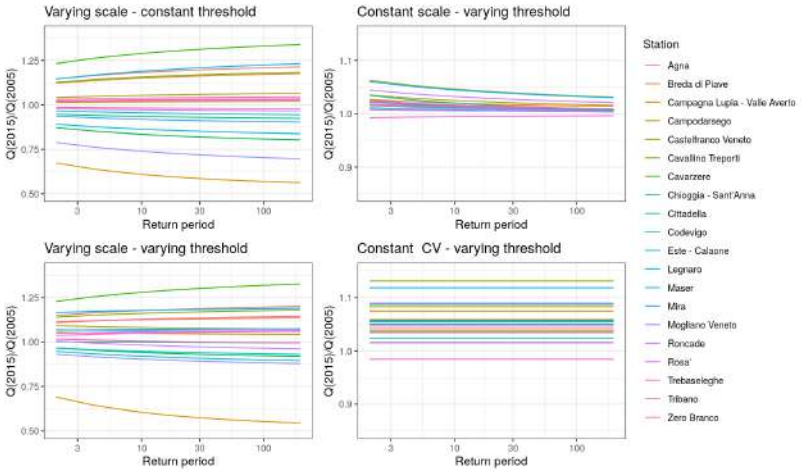

Fig. 3 Relative change across return period (in log scale) for the four different time varying models. Changes are over a ten year period between 2005 and 2015.

only in a handful of stations, with no clear pattern of changes in the area. Further work will focus on a spatial analysis, rather than the separate study of each station.

It is proposed that when comparing the suitability of regression models to describe changes in extremes, measures based on changes implied in the quantile function might be useful. A model is proposed in which the scale parameter changes proportionally to the threshold. The model implies constant relative changes across return periods: this feature improves the interpretability of the derived changes in quantiles. The applicability of the model, and the suitability of its assumptions will be further explored in other applications.

Copulas: models and inference

Analysis of district heating demand through different copula-based approaches

Analisi della domanda del teleriscaldamento attraverso diversi approcci basati sulla copula

F. Marta L. Di Lascio and Andrea Menapace

Abstract The main purpose of this paper is to investigate the multivariate dependence relationship between meteorological variables and thermal energy demand through copula modelling. In order to keep into account both the multivariate dependence structure and the diverse bivariate relationships observed in the data, mainly two approaches can be followed. One is to adopt a mixture of copulas that allows us to combine different copula families and to generate complex dependence structures not captured by the existing models. The other way is to use vine copulas that make it possible to analyse multivariate probability distributions through bivariate and conditional bivariate copulas organised in a suitable tree. A comparison of the two approaches is discussed.

Abstract *Lo scopo principale del presente contributo è quello di proporre uno studio sulla dipendenza multivariata tra la domanda di calore e le variabili meteo attraverso modelli copula. Al fine di tenere in considerazione sia la struttura di dipendenza multivariata che le relazioni bivariate osservate, è possibile seguire diversi approcci. Un primo approccio si basa sulle misture di copulae che permettono di combinare diversi modelli copula per generare strutture di dipendenza complessa non appartenenti a modelli noti. Un secondo approccio riguarda l'uso delle copulae vine che permettono di analizzare distribuzioni di probabilità multivariate utilizzando copulae bivariate e copulae bivariate condizionate organizzate in strutture ad albero. Un confronto tra questi due approcci è discusso.*

1 Introduction

The European Green Deal recently presented by the European Commission aims at transforming Europe in the "first climate-neutral continent by 2050". To achieve this purpose, investments in green technologies and sustainable solutions, like the district heating (DH hereafter) that should be designed to efficiently distribute thermal energy through smart grids for any heat request in the urban area [5], are crucial. The efficient planning and managing a DH system requires an in-depth knowledge of the relationship between thermal energy demand (ED hereafter) and meteorological variables. [2] and [3] are the only studies that address this issue using copulas [8, 9] to keep into account the complex multivariate dependence structure underlying the data generator process. Copula models have been successfully used for analysing several engineering phenomena, e.g. for environmental risk assessment [7], food processes controlling [1], and energy production and demand analyses [10].

In this paper, we present a copula-based analysis between the ED of a DH system and the weather conditions, specifically outdoor temperature (OT hereafter) and solar radiation (SR hereafter). We start from the analyses presented in [3] and investigate the performance of R-vine copula models in capturing a three-variate dependence with different kinds of pair dependencies. We, hence, analyse the dataset used in [3] and compare the goodness of fit of our approach with that used in [3], which is based on mixture copulas.

The rest of the paper presents the problem statement in Section 2, the dependence modelling through R-vine copula in Section 3, and final remarks in Section 4.

2 Problem statement

The main purpose of [3] is to develop a statistical model able to keep into account the relationships between thermal energy demand and meteorological variables with the final goal of supporting district heating operators in a proper planning of the heat production and distribution.

The dataset used in [3] concerns the city of Bozen-Bolzano (Italy) and it includes the daily thermal ED of consumers connected to the DH of Bozen-Bolzano and the corresponding daily average of OT and SR as detected by the weather station of S. Maurizio. The period of observation goes from 2014 to 2017 and the analysis is performed only on the data of the heating season (from October 15th to April 15th according to the Italian law). For further information on the collected dataset see Section 3 in [3].

The methodology proposed in [3] consists in three steps and it can be summarised as follows:

1. the analysis of the serial correlation of ED, OT and SR time series taken separately that is performed through seasonal autoregressive integrated moving average (SARIMA hereafter) models;

2. the investigation of the dependence relationship between the three time series of uncorrelated SARIMA residuals using copula models;
3. the analytical derivation of the copula-based conditional probability function of ED given information on OT and SR.

Focusing on Step 2., it can be solved in different ways. [3] follow an approach based on a finite mixture of heterogeneous parametric copulas and specify a mixture of a three-dimensional unstructured Student-t copula $(C^t(\cdot))$ and a three-dimensional flipped Clayton copula $\left(C_{001}^{\text{Clay}}(\cdot)\right)$ for the variable vector $\mathbf{U} = (U_1, U_2, U_3)$ containing the SARIMA residual time series of OT, SR, and ED, respectively:

$$\begin{aligned} C_{\text{mix}}^{t\text{-Clay}}(\mathbf{U}, \boldsymbol{\theta}, \boldsymbol{\pi}) &= \pi_1 C^t(U_1, U_2, U_3) + \pi_2 C_{001}^{\text{Clay}}(U_1, U_2, U_3) \\ &= \pi_1 (t_{3,\nu}(t_\nu^{-1}(U_1), t_\nu^{-1}(U_2), t_\nu^{-1}(U_3); \boldsymbol{\theta}_t)) + \\ &\quad \pi_2 \left(\left(U_1^{-\theta_{\text{Clay}}} + U_2^{-\theta_{\text{Clay}}} - 1 \right)^{-\frac{1}{\theta_{\text{Clay}}}} - \left(U_1^{-\theta_{\text{Clay}}} + \right. \right. \\ &\quad \left. \left. + U_2^{-\theta_{\text{Clay}}} + (1 - U_3)^{-\theta_{\text{Clay}}} - 2 \right)^{-\frac{1}{\theta_{\text{Clay}}}} \right) \end{aligned} \tag{1}$$

where $\boldsymbol{\pi} = (\pi_1, \pi_2)$, with $0 \leq \pi_k \leq 1, \forall k$ and $\sum_{k=1}^{2} \pi_k = 1$, is the vector of weights, $t_{p,\nu}(\cdot)$ is the standard p-variate Student-t distribution with ν degrees of freedom (recall that ν controls the heaviness of the tails) and unstructured correlation matrix $\boldsymbol{\theta}_t$, $t_\nu^{-1}(\cdot)$ denotes the inverse univariate Student-t distribution function, θ_{Clay} is the Clayton dependence parameter, and $\boldsymbol{\theta} = \left(\boldsymbol{\theta}_t, \theta_{\text{Clay}}\right)$ is the unknown dependence parameter vector. The selected model is consistent with the empirical bivariate and multivariate relationships as shown in Fig. 1. The estimated weights in Eq. (1) result $\hat{\pi}_1 = 0.847$ and $\hat{\pi}_2 = 0.153$, and the whole model, which has been selected among a set of models (see, for details, Section 5.2 in [3]) on the basis of the Akaike Information Criterion (AIC hereafter), has AIC equals to -260.98.

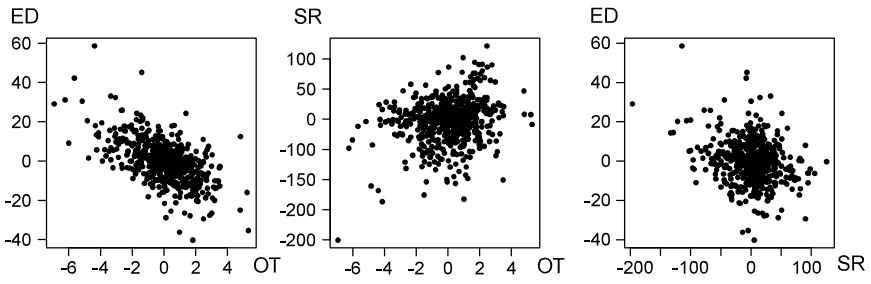

Fig. 1 Scatter plots of the residual time series of outdoor temperature in $^\circ C$ (OT), solar radiation in W/m^2 (SR), and thermal energy demand in MWh (ED).

Since the weight $\hat{\pi}_2$ of the flipped Clayton component in Eq.(1) is small and the selected model is not very parsimonious (7 parameters), we address the three-variate analysis through alternative copula-based approaches. We perform a comparison between different approaches and we stress their advantages and disadvantages.

3 R-vine copula modelling

The simplest way to model the relationships between the residual time series of ED, OT, and SR is to use a single parameter copula model, that is very parsimonious since it expresses the three-variate relationship in only one dependence parameter. This model, however, postulates that all the bivariate marginal models are the same ones, going against the observed bivariate relationships (see Tab. 1) that cannot be reproduced by only one dependence parameter.

Table 1 Estimated Kendall's correlation coefficient $\hat{\rho}_\tau$ of each pair of the residual time series of thermal energy demand (ED), outdoor temperature (OT), and solar radiation (SR), and the p-value of the corresponding test.

	ED and OT	ED and SR	SR and OT
$\hat{\rho}_\tau$	-0.405	-0.135	0.106
p-value	< 0.0001	< 0.0001	0.0002

In light of this consideration, an alternative approach is based on vine copulas [4]. Vines provide the possibility to model multivariate dependencies through a tree of bivariate copulas making it possible to both keep into account all the observed pairwise relationships and define a parsimonious model. We specify a three-dimensional R-vine copula consisting of two trees: the first tree represents the dependence between the residuals of ED and OT, and between the residuals of SR and OT, while the second tree represents the dependence between the residuals of ED and SR conditionally on the residuals of OT. See Fig. 2 for a representation of the described R-vine tree. Based on the AIC, the three bivariate copulas composing the vine model and best fitting the pairwise relationships in our data are: the Student-t copula with $\nu = 9$ and dependence parameter equals to -0.595 for the residual ED and OT, the survival Clayton copula with dependence parameter equals to 0.25 for the residual SR and OT, and the Gumbel copula rotated by 270 degrees with dependence parameter equals to 1.15 for the residual ED and SR, given OT. The selected R-vine copula has the AIC equals to -251.85. Tab. 2 shows the estimation results and Fig. 3 the contour plots of the bivariate densities composing the selected R-vine copula that are in agreement with the patterns observed in the data (see Fig. 1). The analysis of the vine copulas has been carried out using the R package `vinecopula` [6].

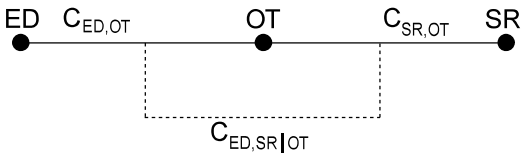

Fig. 2 R-vine copula tree regarding the bivariate copulas ($C_{(\cdot,\cdot)}$) and the conditional copula ($C_{(\cdot,\cdot|\cdot)}$) of the residual time series of ED, OT, and SR according to the model in Tab. 2.

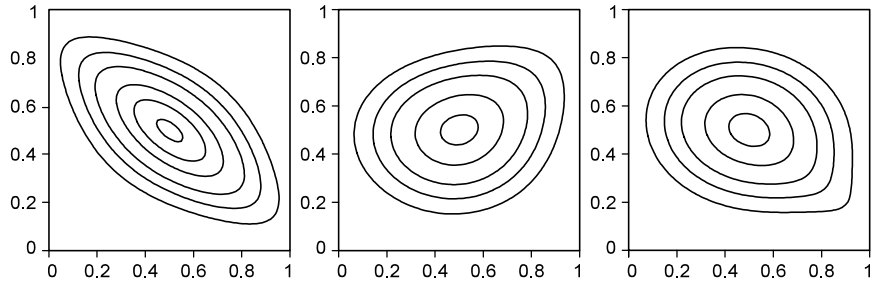

Fig. 3 Bivariate copula density contour plot of the residual time series of ED (x-axis) and OT (y-axis) (left), SR (x-axis) and OT (y-axis) (middle), ED (x-axis) and SR (y-axis) given OT (right) composing the R-vine model in Tab. 2.

Table 2 Three-variate R-vine copula model: estimation results of the bivariate copulas of the residual time series of ED, OT, and SR. Loglik is the value of the maximized log-likelihood of the copula fit.

Tree	Edge	Variables	Copula Model	Rotation	Dependence Parameter	$\hat{\rho}_\tau$	Loglik
1	1	ED,OT	Student-*t*	0	-0.595	-0.406	118.76
1	2	SR,OT	Clayton	180	0.250	0.111	11.77
2	1	ED,SR|OT	Gumbel	270	1.151	-0.130	15.96

4 Conclusion

The mixture copula model is to be preferred to the R-vine copula model on the basis of the AIC that is equal to -260.98 and -251.85, respectively. In addition, the interpretation of the mixture of copulas makes it possible to easily assess the impact of both the meteorological variables on the energy demand, that is the most important goal to support district heating operators in terms of both the production schedule and the storage management of the thermal energy. Hence, even though the R-vine copula model is more parsimonious than the mixture of copulas, we deem that the latter is more advantageous.

CoVaR and backtesting: a comparison between a copula approach and parametric models

Analisi del backtesting del CoVaR: un confronto tra funzioni copula e modelli parametrici

Michele Leonardo Bianchi and Giovanni De Luca and Giorgia Rivieccio

Abstract In this paper, we estimate the backtestable version of the Conditional Value-at-Risk (i.e. CoVaR$^{\leq}$) by fitting different multivariate parametric models that capture four stylized facts about multivariate financial time series of equity returns: heavy tails, negative skew, asymmetric dependence, and volatility clustering. While the volatility clustering effect is got by AR-GJRGARCH dynamics, the other stylized facts are captured through both non-Gaussian multivariate models and copula functions. The CoVaR$^{\leq}$ is computed for four Italian assets on the basis of the multivariate normal, the multivariate normal tempered stable model, the multivariate generalized hyperbolic model and the AIC-based best copula function among a set of Elliptical and Archimedean copulas.

Abstract *Il lavoro contiene una stima della versione del Value-at-Risk condizionato (ovvero CoVaR$^{\leq}$) sottoponibile al backtest. Si considerano diversi modelli parametrici multivariati che catturano quattro fatti stilizzati su serie temporali multivariate di rendimenti finanziari: code pesanti, asimmetria negativa, dipendenza asimmetrica e volatility clustering. Mentre l'effetto del volatility clustering è ottenuto da un modello AR-GJRGARCH, gli altri fatti stilizzati vengono catturati attraverso entrambi i modelli multivariati non gaussiani e funzioni copula. Per quattro asset italiani, il CoVaR$^{\leq}$ viene calcolato considerando il modello normale multivariato, il modello multivariato normale temperato stabile, il modello multivariato generalizzato iperbolico e la migliore funzione copula selezionata secondo il criterio di Akaike (AIC) tra un insieme di copule ellittiche e archimedee.*

Key words: Systemic risk, Value-at-Risk, Conditional Value-at-Risk, copula functions, backtesting.

1 Introduction

Assuming that the Conditional Value-at-Risk (CoVaR$^{\leq}$) is a proper systemic risk measure, we explore to which extent the model assumptions on the univariate financial institution log-returns and on the dependence structure affect the estimation of this risk measure. Additional, we conduct a backtesting analysis to obtain a more robust model comparison.

In [1], the distress of a financial institution is defined as the event $(y^j = VaR^j_\alpha)$, where y^j is the random variable representing the log-returns of the financial institution j and VaR^j_α the corresponding Value-at-Risk (VaR) at tail level α. Here we consider the CoVaR$^{\leq}$ measure, that is the Conditional Value-at-Risk where the conditioning event is the distress of a financial institution represented through $(y^j \leq VaR^j_\alpha)$. This allows us to have a robust systemic risk measure which can be backtested without a great effort (see [14] and [2]).

In this work we assume that the univariate timeseries have AR-GJRGARCH dynamics and then we compare different dependence structures. We consider the multivariate normal (MN) distribution (as a benchmark) and some non-normal multivariate distributions: the multivariate normal tempered stable (MNTS) and the multivariate generalized hyperbolic model (MGH), and the best copula function in terms of AIC among normal, t, BB1 and BB7 copulas, as described in [12] and [13]. Both non-normal multivariate distributions and copula functions are widely known in the financial literature. [9] and [10] analyzed both MNTS e MGH models applied to risk assessment and portfolio optimizations (see also [8] and [7]). [16] developed a model based on the MNTS distribution to estimate the CoVaR.

2 Methodology

For each institution j, the random variable y^j_t represents the log-returns of the market value of equity. Superscript *sys* denotes the entire financial system, i.e. a stock market index or the capitalization-weighted portfolio of all financial institutions in the selected sample.

Given the VaR of financial institution j, with tail level α, for a given tail level β, the $\text{CoVaR}^{\leq j}_{\beta,\alpha,t}$ of the financial system conditional on financial institution j being in distress (i.e. market returns of bank j are less or equal to its VaR_α) is equal to

$$P\left(y^{sys}_t \leq CoVaR^{\leq j}_{\beta,\alpha,t} \,|\, y^j_t \leq VaR^j_{\alpha,t}\right) = \beta \tag{1}$$

The financial institution j contribution to systemic risk is then defined by

$$\Delta CoVaR^{\leq j}_{\beta,\alpha,t} = CoVaR^{\leq j}_{\beta,\alpha,t} - CoVaR^{\leq j}_{\beta,0.5,t}.$$

where a level α equal to 50% denotes a normal, or median, state. $\Delta\text{CoVaR}^{\leq j}_{\beta,t}$ captures the negative externality that financial institution j imposes on the financial system.

The systemic risk measure estimation is divided in three steps. In the first step we estimate a univariate AR-GJRGARCH model to the time-series of log-returns and compute the Value-at-Risk (VaR) at the given tail level α. In the second step we calibrate the bivariate dependence structure by applying different multivariate approaches. In the third step we estimate the systemic risk measure.

Let S_t be the stock price process of a given financial institution and

$$y_t = \log \frac{S_t}{S_{t-1}}$$

be its log-return process for which we assume an AR(m)-GJRGARCH(p,q) model. The most frequent case, the AR(1)-GJRGARCH(1,1) model, is given by

$$\begin{aligned} y_t &= a y_{t-1} + \sigma_t \varepsilon_t + c \\ \sigma_t^2 &= \alpha_0 + \alpha_1 \left(|\sigma_{t-1}\varepsilon_{t-1}| - \gamma(\sigma_{t-1}\varepsilon_{t-1})\right)^2 + \beta_1 \sigma_{t-1}^2 \end{aligned}$$

where the innovation ε_t are independent and identically distributed random variables with zero mean and unit variance. As observed in [15], the follow equality holds

$$-VaR_\alpha(y_{t+1}) = a y_t + \sigma_t(-VaR_\alpha(\varepsilon_{t+1})) + c.$$

It should be noted that a numerical inversion is usually needed to compute these quantiles.

While closed formula for the CoVaR are available under normal distributional assumptions (see [3]), for non-normal models a numerical integration procedure is needed (see [14] and [4]). More in details, equation (1) can be written as

$$P\left(y_t^{sys} \leq CoVaR^{\leq j}_{\beta,\alpha,t}, y_t^i \leq VaR^j_{\alpha,t}\right) = \alpha\beta.$$

In the MNTS and MGH cases, given the density f_t^j of the bivariate random variable defined by y_t^{sys} and y_t^j, the equality

$$\int_{-\infty}^{CoVaR^{\leq j}_{\beta,\alpha,t}} \int_{-\infty}^{VaR^j_{\alpha,t}} f_t^j(y^{sys}, y)dxdy = \alpha\beta$$

can be considered to obtain an estimate of $CoVaR^{\leq}$.

In the copula function cases, as shown in [3]), if one considers the dependence structure between X_t^{sys} and y_t^j, then equation (1) can be rewritten as

$$C\left(F_{y_t^{sys}}(CoVaR^{\leq j}_{\beta,\alpha,t}), F_{y_t^j}(VaR^j_{\alpha,t})\right) = \alpha\beta \tag{2}$$

where C is a given copula function. By following the approach described in [3], it is possible to obtain an estimate of the CoVaR by means of the inversion of the copula function. Equation (2) has been proved under weaker conditions on the copula in [5].

The definition (1) allows one to perform a two-steps backtesting. In both steps it is possible to follow the approach proposed in [11]. First we conduct a preliminary VaR backtest by considering the entire observation window and defining a first hit sequence (1 if the loss of the financial institution on that day was larger than its predicted VaR level, and zero otherwise). Then we define a subset of observations on the basis on the distress of the financial institution j (i.e. $X_t^i \leq VaR_{\alpha,t}^j$). Thus, by looking at this subset, we can backtest the CoVaR. More in details, we compare the CoVaR forecasts with the ex-post losses of the financial system and define a second hit sequence which is 1 if the loss of the financial system on that day is larger than its predicted CoVaR level, and zero otherwise. The accuracy of forecasted VaR and CoVaR is then analyzed performing the unconditional coverage (UC) and the conditional coverage (CC) tests.

3 Data and results

We have analyzed daily dividend-adjusted closing prices from January 2000 through January 2020 for four Italian assets (two banks, Intesa SanPaolo and Unicredit, and two insurance companies, Generali and UnipolSai). Figure 1 shows the behaviour of the log-returns. For the systemic risk we have selected the FTSEMIB index.

One-step-ahead forecasts of VaR and CoVaR are obtained after estimating the time series in the previous five years. The first forecasts are referred to January, 3, 2005, while the rolling samples include 1267 observations.

The results are presented in terms of p-values of the UC and CC tests with $\alpha = \beta = 0.05$.

The backtesting of the VaR is generally satisfactory, except when the MN is applied to UnipolSai.

The backtesting of the CoVaR shows very high p-values. In particular, for Intesa SanPaolo and Unicredit the copula approach shows better results, while for Generali and UnipolSai the p-values provided by the MNTS and MGH cases are slighlty superior. Moreover, it is worthwhile to stress that all the methods appear to be robust in presence of some abnormal values of UnipolSai returns.

Estimating Asymmetric Dependence via Empirical Checkerboard Copulas

Stima della Dipendenza Asimmetrica attraverso le copule checkerboard empiriche

Wolfgang Trutschnig and Florian Griessenberger

Abstract This contribution sketches how empirical checkerboard copulas can be used to construct an asymmetric, scale-free dependence estimator quantifying the information gain of a random variable Y by observing a random variable X (and vice versa) given samples $(x_1,y_1),\ldots,(x_n,y_n)$ from (X,Y). The most important statistical properties of empirical checkerboard estimators (ECBE) are discussed, a quick simulation study using the R-package qad (short for 'quantification of asymmetric dependence') which implements the developed estimator illustrates small sample properties of ECBEs.

Abstract *Questo contributo descrive come la copula checkerboard empirica può essere usata per costruire uno stimatore di dipendenza asimmetrico e invariante per cambiamenti di scala quantificando l'apporto d'informazione di una variabile casuale Y dall'osservazione di una variabile casuale X (e viceversa) dato un campione $(x_1,y_1),\ldots,(x_n,y_n)$ generato da (X,Y). Verranno esaminate le più importanti proprietà statistiche degli stimatori checkerboard empirici (ECBE), verrà presentato un veloce studio di simulazione utilizzando il pacchetto R qad (abbreviazione di 'quantification of asymmetric dependence') che implementa lo stimatore presentato illustrandone le proprietà per piccoli campioni di ECBE.*

1 Introduction

Standard dependence measures like Pearson correlation, Spearman correlation, and Schweizer and Wolff's σ (see [10]) are symmetric, i.e. they assign each pair of random variables (X,Y) the same dependence as they assign the pair (Y,X). Independence of two random variables is a symmetric concept (modelling the situation that knowing X does not change our knowledge about Y and vice versa) - dependence, however, is not. From the authors' point of view, notions 'measuring' dependence should not necessarily be symmetric since in many situations the dependence structure is highly asymmetric - think, for instance, of a sample $(x_1,y_1),\ldots,(x_n,y_n)$ in the shape of the letter V, in which case it is without doubt easier to predict the y-value given the x-value than vice versa.

The copula-based, hence scale-invariant dependence measure ζ_1 introduced in [12] (also see [11]) was developed in order to overcome this problem. ζ_1 detects asymmetries in the dependence structure and clearly separates independence and so-called complete dependence describing the exact opposite - the situation where $Y = f \circ X$ for some measurable $f : \mathbb{R} \to \mathbb{R}$ (i.e. the situation of maximal information gain about/predictability of Y when knowing X).

Considering that ζ_1 is based on conditional distributions (Markov kernels) and that (in the continuous setting) estimating conditional distribution is a difficult endeavor, it is a-priori unclear if good estimators can be derived at all. It is therefore to a certain extend surprising that so-called empirical checkerboard estimators (ECBEs) can be shown to be strongly consistent in the general setting, i.e., without any smoothness assumptions.

The rest of this contribution paper is organized as follows: Section 2 gathers some preliminaries and notations, Section 3 recalls the definition of empirical copulas and checkerboard aggregations as well as the main result saying that ECBEs are strongly consistent if the resolution (used for the aggregation) is chosen suitably. The aforementioned small simulation study concludes the paper.

2 Notation and Preliminaries

Throughout the whole contribution $\mathscr{C}$ will denote the family of all two-dimensional copulas (for background on copulas we refer to [1, 8]). For every copula $A \in \mathscr{C}$ the corresponding doubly stochastic measure will be denoted by μ_A. As usual, $d_\infty(A,B)$ will denote the uniform metric on $\mathscr{C}$, i.e. $d_\infty(A,B) := \max_{(x,y)\in[0,1]^2} |A(x,y) - B(x,y)|$, A^t will denote the transpose of $A \in \mathscr{C}$. For every metric space (Ω,d) the Borel σ-field will be denoted by $\mathscr{B}(\Omega)$, λ will denote the Lebesgue measure on $\mathscr{B}([0,1])$. A mapping $K : \mathbb{R} \times \mathscr{B}(\mathbb{R}) \to [0,1]$ is called a Markov kernel from $\mathbb{R}$ to $\mathscr{B}(\mathbb{R})$ if $x \mapsto K(x,B)$ is measurable for every fixed $B \in \mathscr{B}(\mathbb{R})$ and $B \mapsto K(x,B)$ is a probability measure for every fixed $x \in \mathbb{R}$. Suppose that X,Y are random variables on $(\Omega,\mathscr{A},\mathbb{P})$. Then a Markov kernel $K : \mathbb{R} \times \mathscr{B}(\mathbb{R}) \to [0,1]$ is called regular conditional distribution of Y given X if for every $B \in \mathscr{B}(\mathbb{R})$

$$K(X(\omega),B) = \mathbb{E}(\mathbb{1}_B \circ Y|X)(\omega)$$

holds $\mathbb{P}$-a.s. It is well known that a regular conditional distribution of Y given X exists and is unique $\mathbb{P}^X$-almost sure. For every $A \in \mathscr{C}$ the corresponding regular conditional distribution (i.e. the regular conditional distribution of Y given X in the case that $(X,Y) \sim A$) will be denoted by $K_A(\cdot,\cdot)$ and considered as function from $[0,1] \times \mathscr{B}([0,1])$ to $[0,1]$. Note that for every $A \in \mathscr{C}$ and Borel sets $E,F \in \mathscr{B}([0,1])$ we have

$$\int_E K_A(x,F)d\lambda(x) = \mu_A(E \times F).$$

For more details and properties of conditional expectations and regular conditional distributions see [5, 6].

In the current paper we will mainly work with the metrics D_1 and D_∞ introduced in [12]. These metrics are defined by

$$D_1(A,B) := \int_{[0,1]} \underbrace{\int_{[0,1]} |K_A(x,[0,y]) - K_B(x,[0,y])|\, d\lambda(x)}_{=:\Phi_{A,B}(y)}\, d\lambda(y) \tag{1}$$

$$D_\infty(A,B) := \sup_{y\in[0,1]} \Phi_{A,B}(y) \tag{2}$$

respectively. It can be shown that both metrics generate the same topology (without being equivalent), that the metric space $(\mathscr{C},D_1)$ is complete and separable. Furthermore, firstly, $D_1(A,\Pi)$ attains only values in $[0,\frac{1}{3}]$ and that, secondly, $D_1(A,\Pi)$ is maximal if and only if A is completely dependent, i.e. if a λ-preserving transformation $h : [0,1] \to [0,1]$ exists such that $K_A(x,\{h(x)\}) = 1$ for λ-a.e. $x \in [0,1]$. In the sequel we will let $\mathscr{C}_d$ denote the family of all completely dependent copulas, and write A_h and $K_h(\cdot,\cdot)$ for the completely dependent copula and the Markov kernel of the completely dependent copula induced by the λ-preserving transformation h respectively. For equivalent definitions and properties of completely dependent copulas we refer to [12] and the references therein.

Letting (X,Y) denote a pair of continuous random variables with joint distribution function H and copula A the dependence measure ζ_1 is defined by (see [12])

$$\zeta_1(X,Y) = \zeta_1(A) := 3D_1(A,\Pi). \tag{3}$$

As a direct consequence of the properties of D_1 it follows that for all continuous random variables X,Y we have $\zeta_1(X,Y) \in [0,1]$, that $\zeta_1(X,Y) = 0$ if and only if X and Y are independent, and that $\zeta_1(X,Y) = 1$ if and only if the copula A of (X,Y) is completely dependent.

3 Empirical checkerboard estimators

Let (X,Y) be a random vector with joint distribution H, margin distributions F,G and copula $A \in \mathscr{C}$. Given a sample $(x_1,y_1),\ldots,(x_n,y_n)$ of (X,Y) we want to estimate

$\zeta_1(X,Y) = \zeta_1(A)$. The natural idea of simply calculating the empirical copula $\hat{E}_n$ (see, e.g. [2, 3]) and considering $\zeta_1(\hat{E}_n)$ does not yield a reasonable estimator. In fact, it is straightforward to show that for every copula A we have

$$\lim_{n\to\infty} \zeta_1(\hat{E}_n) = 1$$

with probability one (the reason being that empirical copulas are 'close' to complete dependence since the conditional distributions have an interval of length $\frac{1}{n}$ as support).

A natural and simple way to overcome this problem is to smooth or aggregate the empirical copula. Aggregation leads to so-called checkerboard copulas with which we are going to work in the sequel. To simplify notation, for every $N \in \mathbb{N}$ and $i,j \in \{1,\ldots,N\}$ define the square R_{ij}^N by $R_{ij}^N = \left[\frac{i-1}{N}, \frac{i}{N}\right] \times \left[\frac{j-1}{N}, \frac{j}{N}\right]$.

Definition 1. Suppose that $N \in \mathbb{N}$. A copula $A \in \mathscr{C}$ is called N-checkerboard copula if A is absolutely continuous and (a version of) its density k_A is constant on the interior of each square R_{ij}^N. We call N the resolution of A.

Letting $\mathfrak{CB}_N(A)$ denote the so-called N checkerboard approximation of A, i.e.,

$$\mathfrak{CB}_N(A)(x,y) := \int_0^x \int_0^y N^2 \sum_{i,j=1}^{N} \mu_A(R_{ij}^N) \mathbb{1}_{R_{ij}^N}(s,t)\, d\lambda(t) d\lambda(s)$$

then according to [7] (also see [12]) for every copula $A \in \mathscr{C}$ it can be shown that

$$\lim_{N\to\infty} D_1(\mathfrak{CB}_N(A), A) = 0 = \lim_{N\to\infty} D_1(\mathfrak{CB}_N(A)^t, A^t).$$

Having this we can use the fact that, according to [3], for continuous random variables with underlying copula A

$$d_\infty(\hat{E}_n, A) = O\left(\sqrt{\frac{\log(\log(n))}{n}}\right) \tag{4}$$

holds with probability one, and choose the resolution N adequately as a function of the sample size n to prove the following consistency result (for a proof based on several lemmata linking d_∞, D_1 and D_∞ we refer to [4]).

Theorem 1. *Suppose that $(X_1,Y_1),(X_2,Y_2),\ldots$ is a random sample from (X,Y) and assume that (X,Y) has continuous joint distribution function H and copula A. Furthermore suppose that $s \in (0,\frac{1}{2})$ and set $N(n) := \lfloor n^s \rfloor$ for every $n \in \mathbb{N}$. Then:*

$$\lim_{n\to\infty} \zeta_1(\mathfrak{CB}_{N(n)}(\hat{E}_n)) = \zeta_1(A) \ [\mathbb{P}]. \tag{5}$$

In what follows we will refer to $\zeta_1(\mathfrak{CB}_{N(n)}(\hat{E}_n))$ as empirical checkerboard estimator (ECBE) for $\zeta_1(A)$. Summing up, our chosen procedure for estimating

$\zeta_1(X,Y) = \zeta_1(A)$ based on a sample $(x_1,y_1),\ldots,(x_n,y_n)$ of (X,Y) with underlying copula A is as follows:

1. Calculate the empirical copula $\hat{E}_n$.
2. Select the resolution $N = N(n)$ and calculate the empirical N-checkerboard $\mathfrak{CB}_N(\hat{E}_n)$.
3. Estimate $\zeta_1(A)$ by $\zeta_1(\mathfrak{CB}_N(\hat{E}_n))$.

Remark 1. Notice that Theorem 1 holds without any smoothness assumptions about the copula A, not even continuous first order partial derivatives (essential in the context of the empirical copula process, see [9]) are required. Numerous simulations insinuate that $\mathfrak{CB}_{N(n)}(\hat{E}_n)$ might also be a strongly consistent estimator for more flexible choices of $N(n)$, particularly for the case $N(n) := \lfloor n^s \rfloor$ and some $s \geq \frac{1}{2}$ - a clarification of this question is future work, in the R-package 'qad' $s = \frac{1}{2}$ was considered.

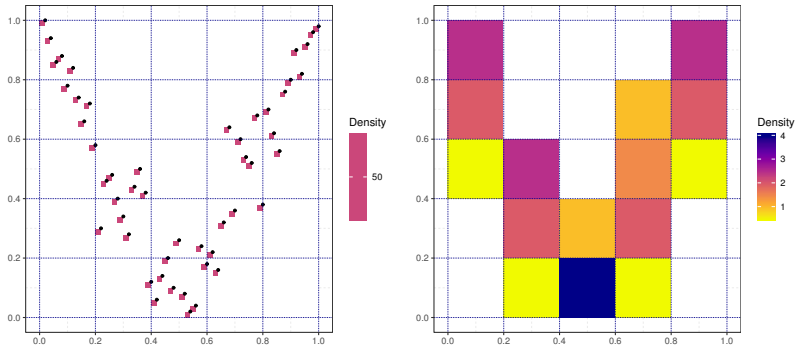

Fig. 1 Left panel: Pseudoobservations of the original sample of size $n = 50$ (black points) and density of the empirical copula $\hat{E}_n$ (magenta squares), Right panel: Density of the empirical checkerboard copula $\mathfrak{CB}_5(\hat{E}_n)$.

4 Simulations

In order to illustrate the performance of the estimator $\zeta_1(\mathfrak{CB}_{N(n)}(\hat{E}_n))$ we consider the Marshall-Olkin copula $M_{0.3,1}$ and the completely dependent copula A_h, where h is given by $h(x) = 5x\,(mod 1)$. Figure 2 and Figure 3 (left panel) depict a sample of size $n = 5000$ of these two copulas. According to Theorem 1 in both cases the empirical checkerboard estimator converges with probability one to $\zeta_1(M_{0.3,1})$ and $\zeta_1(A_h)$, respectively, the theorem does, however, not provide information on the speed of convergence. Generating samples of sizes $n \in \{10,50,100,500,1000,5000,10000\}$ a total of 1000 times yields the results depicted in Figure 2 and Figure 3, respectively.

Strong Convergence of Multivariate Maxima
Convergenza Forte Di Massimi Multivariati

Michael Falk and Simone A. Padoan and Stefano Rizzelli

Abstract It is well known and readily seen that the maximum of n independent and uniformly on $[0,1]$ distributed random variables, suitably standardised, converges in total variation distance, as n increases, to the standard negative exponential distribution. We extend this result to higher dimensions by considering copulas. We show that the strong convergence result holds for copulas that are in a differential neighbourhood of a multivariate generalized Pareto copula. Sklar's theorem then implies convergence in variational distance of the maximum of n independent and identically distributed random vectors with arbitrary common distribution function.
Abstract *È noto come il massimo di n variabili casuali indipendenti e uniformemente distribuite su* $[0,1]$*, opportunamente standardizzate, converga all'aumentare di n alla distribuzione esponenziale negativa standard, secondo la distanza totale di variazione. Estendiamo questo risultato in dimensioni maggiori di uno utilizzando la teoria delle copule. Mostriamo che il risultato di convergenza forte vale per le copule multivariate che sono differenziabili e si trovano in un intorno della famiglia Pareto multivariata generalizzata. Quindi, utilizzando il teorema di Sklar, mostriamo la convergenza rispetto alla distanza totale di variazione del vettori di massimi (per componente) di n vettori casuali indipendenti e distribuiti secondo una comune distribuzione arbitraria.*

1 Introduction

Let U be a random variable (rv), which follows the uniform distribution on $[0,1]$, say $V(u)$, $u \in [0,1]$. Let $U^{(1)}, U^{(2)}, \ldots$ be independent and identically distributed (iid) copies of U. Then, clearly, we have for $x \leq 0$ and large $n \in \mathbb{N}$ (natural set),

$$P\left(n\left(\max_{1\leq i\leq n} U^{(i)} - 1\right) \leq x\right) \to_{n\to\infty} G(x), \tag{1}$$

where $G(x)$ is the standard negative exponential distribution function (df). Thus, we have established convergence in distribution of the suitably normalised sample maixmum, i.e.

$$n\left(M^{(n)} - 1\right) \to_D \eta, \tag{2}$$

where $M^{(n)} := \max_{1\leq i\leq n} U^{(i)}$, $n \in \mathbb{N}$, the arrow "$\to_D$" denotes convergence in distribution, and the rv η has df G. Note that, with $v(x) := V'(x) = 1$, if $x \in [0,1]$, and zero elsewhere, we have

$$\begin{aligned} v_n(x) &:= \frac{\partial}{\partial x}\left(V^n\left(1+\frac{x}{n}\right)\right) = V^{n-1}\left(1+\frac{x}{n}\right) v\left(1+\frac{x}{n}\right) \\ &\to_{n\to\infty} g(x) := G'(x) = \begin{cases} \exp(x), & x \leq 0 \\ 0, & x > 0 \end{cases}, \end{aligned}$$

i.e., we have pointwise convergence of the sequence of densities of normalised maximum $n\left(M^{(n)} - 1\right)$, $n \in \mathbb{N}$, to that of η. Scheffé's lemma, see e.g. [4, Lemma 3.3.3], now implies convergence in total variation:

$$\sup_{A\in\mathbb{B}} \left| P\left(n\left(M^{(n)} - 1\right) \in A\right) - P(\eta \in A)\right| \to_{n\to\infty} 0, \tag{3}$$

where $\mathbb{B}$ denotes the Borel-σ-field in $\mathbb{R}$.

Let now X be a rv with *arbitrary* df F and $F^{-1}(q) := \{t \in \mathbb{R} : F(t) \geq q\}$ with $q \in (0,1)$ be the usual *quantile function* or *generalized inverse* of F. Then, we can assume the representation $X = F^{-1}(U)$. Let $X^{(1)}, X^{(2)}, \ldots$ be independent copies of X. Again we can consider the representation $X^{(i)} = F^{-1}(U^{(i)})$, $i = 1, 2, \ldots$. The fact that each quantile function is a nondecreasing function yields

$$\begin{aligned} \max_{1\leq i\leq n} X^{(i)} &= \max_{1\leq i\leq n} F^{-1}\left(U^{(i)}\right) = F^{-1}\left(\max_{1\leq i\leq n} U^{(i)}\right) \\ &= F^{-1}\left(1 + \frac{1}{n}\left(n\left(\max_{1\leq i\leq n} U^{(i)} - 1\right)\right)\right). \end{aligned}$$

The strong convergence in equation (3) now implies the following convergence in total variation:

$$\sup_{A\in\mathbb{B}}\left|P\left(\max_{1\le i\le n}X^{(i)}\in A\right)-P\left(F^{-1}\left(1+\frac{1}{n}\eta\right)\in A\right)\right|\to_{n\to\infty}0. \tag{4}$$

Finally, assume that F is a continuous df with density $f=F'$. We denote the right endpoint of F by $x_0:=\sup\{x\in\mathbb{R}:F(x)<1\}$. Assume also that $F\in\mathscr{D}(G^*_\gamma)$, i.e. F belongs to the domain of attraction of a generalised extreme-value df G^*_γ [3, p. 21]. This means, for $n\in\mathbb{N}$, there are norming constants $a_n>0$ and $b_n\in\mathbb{R}$ such that

$$F^n(a_nx+b_n)\to_{n\to\infty}\exp\left(-(1+\gamma x)_+^{-1/\gamma}\right)=:G^*_\gamma(x), \tag{5}$$

for all $x\in\mathbb{R}$, where $(x)_+=\max(0,x)$ and $\gamma\in\mathbb{R}$ is the so-called *tail index*. Such a coefficient describes the heaviness of the upper tail of the probability density function corresponding to G^*_γ see [3] for details. Furthermore, in this general case, we also have the pointwise convergence at the density level, i.e.

$$f^{(n)}(x):=\frac{\partial}{\partial x}F^n(a_nx+b_n)\to_{n\to\infty}\frac{\partial}{\partial x}G^*_\gamma(x)=:g^*_\gamma(x) \tag{6}$$

for all $x\in\mathbb{R}$, see e.g. Proposition 2.5 in [5]. In particular, if (6) holds true, Scheffé's lemma entails that

$$\sup_{A\in\mathbb{B}}\left|P\left(a_n^{-1}\left(\max_{1\le i\le n}X^{(i)}-b_n\right)\in A\right)-P(Y\in A)\right|\to_{n\to\infty}0, \tag{7}$$

where Y is a rv with distribution G^*_γ and $X^{(i)}$, $i=1,\ldots,n$ are independent copies of a rv X with distribution F, with $F\in\mathscr{D}(G^*_\gamma)$ see [2] for all the details.

In the recent paper [2], we have extended the results in (3), (4) and (7) to higher dimensions. In Theorem 2, we demonstrate that the strong convergence result holds for copulas that are in a differential neighbourhood of a multivariate generalized Pareto copula. As a result of this, we also establish strong convergence of the copula of the maximum of n iid random vectors with arbitrary common df to the limiting extreme-value copula (Corollary 1). These results are discussed in Section 2. The proofs of Theorems 1, 2 and Corollary 1 are available in [2]. Sklar's theorem is then used in the paper [2] to derive convergence in variational distance of the maximum of n iid random vectors with arbitrary common df and of its normalised versions. We do not report this last result here for brevity. All the results developed in [2] address some still open problems in the literature on multivariate extremes.

2 Strong Results for Copulas

Suppose that the random vector (rv) $\boldsymbol{U}=(U_1,\ldots,U_d)$ follows a *copula*, say C, on $\mathbb{R}^d$, i.e., each component U_j has a uniform df V_j. Let $\boldsymbol{U}^{(1)},\boldsymbol{U}^{(2)},\ldots$ be independent copies of $\boldsymbol{U}$ and put for $n\in\mathbb{N}$

$$\boldsymbol{M}^{(n)} := \left(M_1^{(n)},\dots,M_d^{(n)}\right) := \left(\max_{1\le i\le n} U_1^{(i)},\dots,\max_{1\le i\le n} U_d^{(i)}\right). \tag{8}$$

In the sequel the operations involving vectors are meant componentwise, furthermore, we set $\mathbf{0}=(0,\dots,0)$, $\mathbf{1}=(1\dots,1)$ and $\boldsymbol{\infty}=(\infty,\dots,\infty)$. Finally, hereafter, we denote the copula of the random vector in (8) by $C^n(\boldsymbol{u})$, $\boldsymbol{u}\in[0,1]^d$. Suppose there exists a nondegenerate df G on $\mathbb{R}^d$ such that for $\boldsymbol{x}=(x_1,\dots,x_d)\le\mathbf{0}\in\mathbb{R}^d$

$$\begin{aligned} P\left(n\left(\boldsymbol{M}^{(n)}-\mathbf{1}\right)\le\boldsymbol{x}\right) &= P\left(n\left(M_1^{(n)}-1\right)\le x_1,\dots,n\left(M_d^{(n)}-1\right)\le x_d\right)\\ &\to_{n\to\infty} G(\boldsymbol{x}). \end{aligned} \tag{9}$$

Then, G is necessarily a *multivariate max-stable* or *multivariate extreme-value df*, with *extreme-value copula* C_G and standard negative exponential margins G_j, $j=1,\dots,d$ [2, see the reference therein]. In the sequel we refer to the df G in (9) as *standard* multivariate max-stable df. Precisely, the form of G is

$$G(\boldsymbol{x}) = C_G(G_1(x_1),\dots,G_d(x_d)),$$

where the copula C_G can be expressed in terms of $\|\cdot\|_D$, a *D-norm* on $\mathbb{R}^d$, via

$$C_G(\boldsymbol{u}) = \exp\left(-\|\log u_1,\dots,\log u_d\|_D\right), \quad \boldsymbol{u}\in[0,1]^d, \tag{10}$$

while the margins G_j, $j=1,\dots,d$, are exponentially distributed, see e.g. [1]. Therefore, the distribution in (9) has the representation

$$G(\boldsymbol{x}) = \exp\left(-\|\boldsymbol{x}\|_D\right), \qquad \boldsymbol{x}\le\mathbf{0}\in\mathbb{R}^d. \tag{11}$$

The convergence result in (9) implies that $C^{(n)}(\boldsymbol{u}) := C^n(\boldsymbol{u}^{1/n}) \to_{n\to\infty} C_G(\boldsymbol{u})$, for all $\boldsymbol{u}\in[0,1]^d$ x. For brevity, with a little abuse of notation we also denote this latter fact by $C\in\mathscr{D}(C_G)$. The convergence result in (9) is also equivalent to the expansion

$$C(\boldsymbol{u}) = 1-\|\mathbf{1}-\boldsymbol{u}\|_D + o(\|\mathbf{1}-\boldsymbol{u}\|) \tag{12}$$

as $\boldsymbol{u}\to\mathbf{1}\in\mathbb{R}^d$, uniformly for $\boldsymbol{u}\in[0,1]^d$, see Proposition 3.1.5 in [1]. In a first step we drop the term $o(\|\mathbf{1}-\boldsymbol{u}\|)$ in expansion (12) and require that there exists $\boldsymbol{u}_0\in(0,1)^d$, such that

$$C(\boldsymbol{u}) = 1-\|\mathbf{1}-\boldsymbol{u}\|_D, \qquad \boldsymbol{u}\in[\boldsymbol{u}_0,\mathbf{1}]\subset\mathbb{R}^d. \tag{13}$$

A copula, which satisfies the above expansion is a *generalized Pareto copula* (GPC). The df of $n\left(\boldsymbol{M}^{(n)}-\mathbf{1}\right)$ is, for $\boldsymbol{x}<\mathbf{0}\in\mathbb{R}^d$ and n large so that $\mathbf{1}+\boldsymbol{x}/n\ge\boldsymbol{u}_0$,

$$P\left(n\left(\boldsymbol{M}^{(n)}-\mathbf{1}\right)\le\boldsymbol{x}\right) = \left(1-\frac{1}{n}\|\boldsymbol{x}\|_D\right)^n =: F^{(n)}(\boldsymbol{x}).$$

Suppose that the norm $\|\cdot\|_D$ has partial derivatives of order d. Then the df $F^{(n)}(\boldsymbol{x})$ has for $\mathbf{1}+\boldsymbol{x}/n \geq \boldsymbol{u}_0$ the density

$$f^{(n)}(\boldsymbol{x}) := \frac{\partial^d}{\partial x_1 \ldots \partial x_d} F^{(n)}(\boldsymbol{x}) = \frac{\partial^d}{\partial x_1 \ldots \partial x_d} \left(1 - \frac{1}{n}\|\boldsymbol{x}\|_D\right)^n. \tag{14}$$

As for the standard multivariate max-stable df G in (11), its density exists and is given by

$$g(\boldsymbol{x}) := \frac{\partial^d}{\partial x_1 \ldots \partial x_d} G(\boldsymbol{x}) = \frac{\partial^d}{\partial x_1 \ldots \partial x_d} \exp\left(-\|\boldsymbol{x}\|_D\right), \qquad \boldsymbol{x} \leq \mathbf{0} \in \mathbb{R}^d. \tag{15}$$

We are now ready to state our first multivariate extension of the convergence in total variation in equation (3). For brevity, we occasionally denote with the same letter a Borel measure and its distribution function.

Theorem 1. *Suppose the rv $\boldsymbol{U}$ follows a GPC C with corresponding D-norm $\|\cdot\|_D$, which has partial derivatives of order $d \geq 2$. Then*

$$\sup_{A \in \mathbb{B}^d} \left| P\left(n\left(\boldsymbol{M}^{(n)} - \mathbf{1}\right) \in A\right) - G(A) \right| \to_{n\to\infty} 0,$$

where $\mathbb{B}^d$ denotes the Borel-σ-field in $\mathbb{R}^d$.

Next we extend Theorem 1 to a copula C, which is in a *differentiable neighborhood* of a GPC, defined next. Suppose that C satisfies expansion (12), where the D-norm $\|\cdot\|_D$ on $\mathbb{R}^d$ has partial derivatives of order d. Assume also that C is such that for each nonempty block of indices $B = (i_1, \ldots, i_k)$ of $\{1, \ldots, d\}$,

$$\frac{\partial^k}{\partial x_{i_1}, \ldots, \partial x_{i_k}} n\left(C\left(\mathbf{1} + \frac{\boldsymbol{x}}{n}\right) - 1\right) \to_{n\to\infty} \frac{\partial^k}{\partial x_{i_1}, \ldots, \partial x_{i_k}} \phi(\boldsymbol{x}), \tag{16}$$

holds true for all $\boldsymbol{x} < \mathbf{0} \in \mathbb{R}^d$, where $\phi(\boldsymbol{x}) = -\|\boldsymbol{x}\|_D$.

Theorem 2. *Suppose the copula C satisfies conditions* (12) *and* (16)*. Then we obtain*

$$\sup_{A \in \mathbb{B}^d} \left| P\left(n\left(\boldsymbol{M}^{(n)} - \mathbf{1}\right) \in A\right) - G(A) \right| \to_{n\to\infty} 0,$$

where G is the standard max-stable distribution with corresponding D-norm $\|\cdot\|_D$, i.e., it has df $G(\boldsymbol{x}) = \exp(-\|\boldsymbol{x}\|_D)$, $\boldsymbol{x} \leq \mathbf{0} \in \mathbb{R}^d$.

Example 1. Consider, the *Gumbel-Hougaard family* $\{C_p : p \geq 1\}$ of Archimedean copulas, with generator function $\varphi_p(u) := (-\log(u))^p$, $p \geq 1$. This is an extreme-value family of copulas. In particular, we have

$$C_p(\boldsymbol{u}) = \exp\left(-\left(\sum_{j=1}^d (-\log(u_j))^p\right)^{1/p}\right) = 1 - \|\mathbf{1} - \boldsymbol{u}\|_p + o(\|1 - \boldsymbol{u}\|),$$

as $\boldsymbol{u} \in (0,1]^d$ converges to $\mathbf{1} \in \mathbb{R}^d$, i.e., condition (12) is satisfied, where the D-norm is the logistic norm $\|\cdot\|_p$ and the limiting distribution is $G(\boldsymbol{x}) = \exp(-\|\boldsymbol{x}\|_p)$. The copula C_p also satisfies conditions (16). For the proof see [2].

Example 2. Consider the copula

$$C(\boldsymbol{u}) = 1 - d + \sum_{j=1}^{d} u_j + \sum_{2 \le i \le d} \left((-1)^i \sum_{\substack{B \subseteq \{1,\ldots,d\} \\ |B|=i}} \left(\sum_{j \in B} \frac{1}{1-u_j} - d + 1 \right)^{-1} \right). \quad (17)$$

This provides the d-dimensional version (with $d \ge 2$) of the 2-dimensional copula associated to the df discussed in [5, Example 5.14]. It can be checked that $C \in \mathscr{D}(C_G)$, where C_G is, for all $\boldsymbol{u} \in [0,1]^d$, the extreme-value copula

$$C_G(\boldsymbol{u}) = \exp\left(\sum_{j=1}^{d} \log u_j + \sum_{2 \le i \le d} \left((-1)^{i+1} \sum_{\substack{B \subseteq \{1,\ldots,d\} \\ |B|=i}} \left(\sum_{j \in B} \frac{1}{\log u_j} - d + 1 \right)^{-1} \right) \right).$$

Then, by Proposition 3.1.5 and Corollary 3.1.12 in [1], the copula in (17) satisfies condition (12). See [2] for the details.

Let C be a copula and C^n be the copula of the corresponding componentiwise maxima, see (8). We recall that $C^{(n)}(\boldsymbol{u}) := C^n(\boldsymbol{u}^{1/n})$, $\boldsymbol{u} \in [0,1]^d$. Assume that $C \in \mathscr{D}(C_G)$, where C_G is an extreme-value copula. A readily demonstrable result implied by Theorem 2 is the convergence of $C^{(n)}$ to C_G in variational distance.

Corollary 1. *Assume C satisfies conditions* (12) *and* (16)*, with continuous partial derivatives of order up to d on $(0,1)^d$, then*

$$\sup_{A \in \mathbb{B}^d \cap [0,1]^d} |C^{(n)}(A) - C_G(A)| \to_{n \to \infty} 0.$$

Bayesian stochastic modelling of the temporal evolution of seismicity

Modellazione stocastica Bayesiana dell'evoluzione temporale della sismicità

Elisa Varini and Renata Rotondi

Abstract Seismic hazard assessment is based on the research achievements developed in a lively multidisciplinary context involving seismologists, geologists, and geophysicists as well as computer scientists, mathematicians, statisticians, and other scientists. The statistical approach to seismological issues mainly contributes to deal with uncertainty, including of course data uncertainty. Another important source of uncertainty comes from the lack of a physical model capable of satisfactorily describing the earthquakes process. In this paper we present our most recent research which focuses on stochastic modelling of temporal seismic sequences and earthquakes forecasting at long-middle time scale. In particular we favour the Bayesian approach for data analysis as it is especially suitable for the treatment of uncertainties.

Abstract *La valutazione del pericolosità sismica è frutto di risultati di ricerca sviluppati in un vivace contesto multidisciplinare che coinvolge sismologi, geologi e geofisici, nonché informatici, matematici, statistici e altri studiosi. Il principale contributo dell'approccio statistico alla risoluzione di problematiche sismologiche consiste nella gestione dell'incertezza. Oltre all'incertezza dei dati, un'importante fonte di incertezza deriva dalla mancanza di un modello fisico in grado di descrivere in modo soddisfacente il processo dei terremoti. In questo lavoro presentiamo la nostra ricerca più recente sulla modellazione stocastica di sequenze sismiche temporali e la previsione dei terremoti a medio-lungo termine. In particolare, adottiamo l'approccio bayesiano per l'analisi dei dati in quanto è particolarmente adatto per il trattamento delle incertezze.*

Key words: Point processes, Failure models, Bayesian inference, Seismic hazard assessment

1 Introduction

A long debate on the intrinsic unpredictability of earthquakes is ongoing, but a scientifically convincing outcome has not yet been achieved based on the limited current knowledge of seismic phenomena. To date the standard approach for assessing seismic hazard and forecasting earthquakes has been necessarily probabilistic in order to properly deal with uncertainty; from this perspective, the stochastic modelling of seismic data should be appropriate to incorporate as much geological and geophysical information as possible.

Historical and instrumental seismic catalogs are definitely important sources of information on earthquakes. What emerges from seismic catalogs all over the world is that the earthquakes process broadly evolves at different spatio-temporal scales, i.e. long-term scale for background seismicity and short-term scale for earthquake clusters (e.g. sequences of aftershocks due to strong earthquakes, seismic swarms). The most part of the stochastic models for earthquake occurrences in the literature targets one of these spatio-temporal scales, in particular self-correcting point processes are used for long-term modelling and self-exciting point processes for short-term modelling. However, a better description of seismicity is certainly expected from stochastic models that overcome the duality introduced by considering separately seismic phenomena at different scales and, for example, are able to model the clustering effects observed at both long and short space-time scales.

In Section 2 we first focus on long-term modelling of earthquake sequences emphasizing the contribution provided by the available geophysical and tectonic knowledge in the stochastic modelling, then in Section 3 we propose a new stochastic model that can operate at different time scales, specifically at long-middle time scale. Applications of both models to the Italian historical seismicity are briefly illustrated.

2 Long-term stochastic modelling of the Italian seismicity

We consider the stress release model (SRM), a well-known self-correcting point process based on the Reid's elastic rebound theory and suitable for long-term seismic hazard assessment ([3] and references therein). According to Reid's theory, some tectonic stress X slowly accumulates in a seismic region until it exceeds the strenght of the medium; then it drops sharply causing an earthquake. In the SRM, stress is assumed to increase linearly with time at a constant loading rate ρ:

$$X(t) = X_0 + \rho t - S(t) \tag{1}$$

where X_0 denotes an initial unknown level of stress and $S(t) = \sum_{t_i<t} X_i$ is the stress release due to all previously occurred earthquakes. SRM is completely defined by its conditional intensity function $\lambda(t \mid \mathscr{H}_t) = exp\{\nu + \beta X(t)\}$, where $\mathscr{H}_t$ is the seismic history up to time t.

The stress release X due to an earthquake is not directly measurable so far; however it can be approximated by several empirical relations involving earthquake magnitude M, which is a measure of the strength of the earthquake based on its effects, e.g. some characteristics of the seismic wave and damages.

In [2] we explored four possible proxy measures of stress release X among those that are evaluable for historical events. The first proxy measure is the Benioff strain $X_B \propto 10^{0.75M}$, which was proposed in the original version of the SRM [4]; it is an approximation of the square root of the energy release. The remaining three proxy measures consider different features of the energy release, such as heat loss, coseismic slip, and damaging potential of the seismic wave. They are: the seismic moment $M_0 \propto 10^{1.5M_w}$, the seismic energy $E \propto X_M^{1.5}/\sqrt{A}$, and the scaled energy $E_S \propto E/M_0$, where A is the area of the fault surface that ruptures during an earthquake. Rupture area A is approximated by using the regressions of Wells and Coppersmith [5].

We proposed four versions of the SRM, where X is respectively defined by the Benioff strain, the seismic moment, the seismic energy, and the scaled energy; each of them was then fitted to the historical earthquakes occurred in the eight Italian macro-regions (MRs) depicted in Fig. 1a (large polygons). Each MR has a tectonically homogeneous behaviour according to the Database of Individual Seismogenic Sources (DISS, version 3.0.2), a large repository of geological, tectonic and active

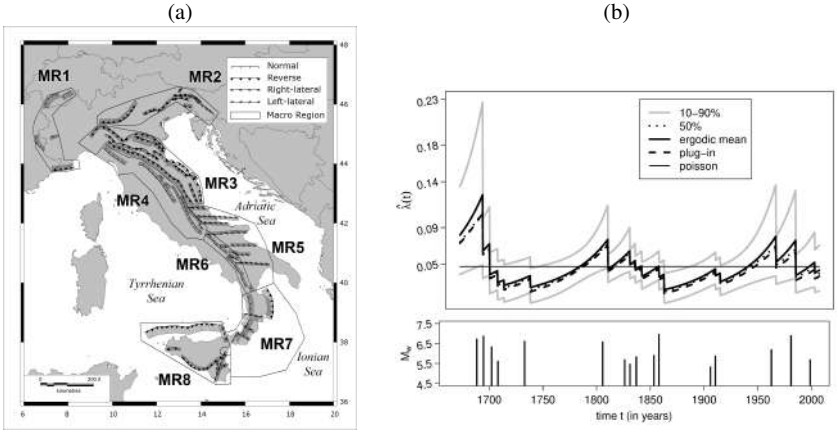

Fig. 1 (a) Map of the Composite Seismogenic Sources from DISS database, version 3.0.2, classified according to the faulting mechanism. Shaded area: vertical projection of the fault plane to the ground surface. The outlined polygons are the identified macro-regions (MRs). (b) Estimated conditional intensity function of the SRM based on scaled energy as for MR4. Ergodic mean (solid line), plug-in (dashed line), and median (dotted line) are practically indistinguishable from each other; 10% and 90% quantiles (gray line). The Poisson rate is shown for comparison (horizontal solid line). The bottom panel shows the magnitude versus the occurrence time of the data.

Italian fault data. In particular, the Composite Seismogenic Sources (CSS) from DISS database were very helpful in delineating the eight MRs, because each CSS identifies an active fault system capable of releasing destructive earthquakes for Italy and their predominant faulting mechanism (small dark polygons in Fig. 1a). Each MR was then associated with a dataset of historical strong earthquakes ($M \geq 5.3$) drawn from the Parametric Catalog of the Italian Earthquakes (CPTI04).

The four versions of the SRM were fitted to each dataset by following the Bayesian paradigm so as to obtain the corresponding posterior distribution of the model parameters [3, 2]; Fig. 1(b) shows the estimated conditional intensity function of the SRM based on the scaled energy as for MR4.

Moreover, we found that the distribution of the waiting time of the next event from any time t follows a Gompertz distribution, in which the shape parameter is history dependent or, in other words, dependent on the current level of stress in the region [3]; this enabled us to perform both retrospective and prospective forecasting tests. According to both Bayes factor and forecasting performance, the best model turns out to be the SRM based on scaled energy.

3 A new multi-scale compound model

We proposed a new stochastic model for earthquake occurrences, hereinafter named compound model, which combines knowledge gained at the different space-time levels [1]. The model assumes the existence of two categories of events, the mainshocks and the subordinate events. The mainshocks are identified among the strongest events occurred in a region and are assumed to follow the SRM based on scaled energy. The subordinate events are especially expected to cluster in the space-time neighborhood of the mainshocks, so as to represent possible premonitory events (foreshocks) and aftershocks; this suggests a bathtub-shaped hazard function for their occurrence times between two consecutive strong earthquakes. Since the hazard functions of some generalized Weibull distributions admit a great variety of

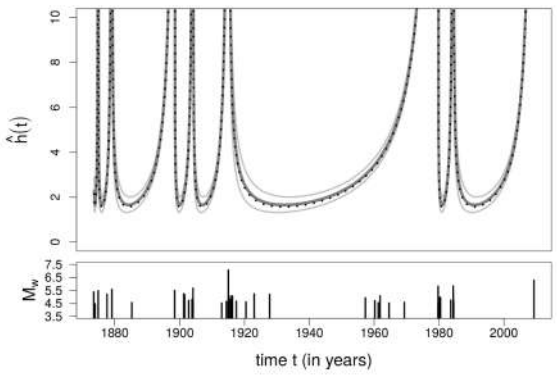

Fig. 2 Compound model: estimated hazard function of the modified Weibull distribution, as ergodic mean (red line), plug-in (dotted line) estimate, and median (black line). These are practically indistinguishable from each other. Also shown: 10% and 90% quantiles (gray line). Magnitude versus occurrence time of the data.

shapes including the bathtub one, we considered two options from this large family: the modified Weibull model and the additive Weibull model.

The compound model was applied to CSS 25 of DISS database, which is part of MR4 in Central Italy (Fig.1a). CSS 25 was associated with a dataset of 58 earthquakes with $M \geq 4.45$ drawn from the CPTI15 catalog; the 9 strongest events of $M \geq 5.3$ were identified as mainshocks through some clustering analysis. Bayesian analysis of the data was performed showing that the best fit is obtained from the compound model based on the modified Weibull distribution, of which the estimated hazard function is illustrated in Fig. 2.

4 Conclusions and remarks

We analysed four different versions of the SRM, based on the Reid's elastic rebound theory and including the contribution of the tectonic information. Under the hypothesis underlying the SRM, the four models differ from one to the other in the definition of a quantity, i.e. the stress, that drives the mechanism of earthquakes occurrence. We found that scaled energy is the best option in SRM. Moreover, we derived the exact distribution of the waiting times to the next event conditioned on the past history of the SRM; it is a Gompertz distribution whose shape parameter is history dependent. Finally, we proposed a new compound model for earthquake occurrences that captures both long- and short-time features of seismic activity by combining in a hierarchical structure the SRM based on scaled energy and a generalized Weibull model that admit bathtub shaped hazard functions.

Cluster Analysis for the Characterization of Residential Personal Exposure to ELF Magnetic Field

Analisi Cluster per la Valutazione dell'Esposizione ai Campi Magnetici ELF nei Bambini

Gabriella Tognola, Silvia Gallucci, Marta Bonato, Emma Chiaramello, Isabelle Magne, Martine Souques, Serena Fiocchi, Marta Parazzini and Paolo Ravazzani

Abstract Cluster analysis was applied to characterize indoor personal exposure to Extremely Low Frequency magnetic field (ELF MF) in children with respect to the type and distance of electric networks near the child home. An association effect analysis was then applied to investigate the possible impact of environmental variables, such as heating type, age and size of the home, and family size on the exposure patterns identified with cluster analysis. Cluster analysis identified three different patterns of exposure: the first one was of children with the highest exposure living near overhead lines of high (63-150 kV), extra-high (225 kV) and ultra-high voltage (400 kV); the second one was of children with mid exposures living near underground networks of low (400V) to mid voltage (20 kV) and substations; the last one was of children with lowest level of exposure living far from electric networks. Electric heating, or living in big buildings or in larger families led to higher levels of exposures.

Abstract *L'analisi Cluster è stata utilizzata per l'identificazione dei pattern di esposizione residenziale ai campi magnetici a bassissima frequenza (ELF MF) nei bambini considerando come variabili di interesse il tipo e la distanza delle linee elettriche dalle abitazioni. Successivamente, è stata fatta anche un'analisi di associazione tra i cluster identificati precedentemente e una serie di variabili di tipo ambientale, quali la tipologia di riscaldamento usata nell'abitazione, l'età e la dimensione dell'abitazione e la dimensione del nucleo famigliare. L'analisi cluster ha identificato 3 diversi pattern di esposizione: il primo è caratterizzato da alti*

livelli di esposizione ed è costituito da bambini che abitano nelle vicinanze di linee elettriche aeree ad alta (63-150 kV), extra-alta (225 kV) e ultra-alta potenza (400 kV); il secondo cluster è caratterizzato da livelli di esposizione media ed è costituito da bambini che vivono vicino a linee elettriche interrate di bassa (400 V) e media potenza (20 kV) e alle stazioni di trasformazione elettrica; l'ultimo cluster ha i livelli più bassi di esposizione ed è costituito dai bambini che vivono più lontani dalle linee elettriche. Per quanto riguarda l'effetto delle variabili ambientali, i bambini che vivono in edifici con un elevato numero di unità abitative, oppure in abitazioni ove si fa uso di dispositivi di riscaldamento di tipo elettrico ed infine in famiglie numerose sono tendenzialmente esposti ad un livello di campi magnetici maggiore che negli altri casi.

Key words: Cluster Analysis, residential magnetic field exposure, children, environmental variables

1 Introduction

Studies in the first decade of year 2000 (see e.g., Kheifets et al., (2010)) showed that the risk of childhood leukemia increased for a daily average of Extremely Low Frequency Magnetic Fields (ELF MF, 50/60 Hz) exposure greater than 0.4 μT, without evidencing a causal relationship. Since then, several studies and measurement campaigns have been implemented to characterize ELF MF exposure in children in everyday contexts (Bedja et al., (2010); Magne et al., (2017); Schüz et al., (2016)).

In the present study, we aimed to identify recurrent patterns of indoor ELF MF exposure in children with respect to the presence of electric lines near the child home and then assess with an association effect analysis if other 'secondary' variables, such as the use of electric heating appliances, the age and type of the residence, and family size have an impact on the exposure patterns identified with cluster analysis.

2 Materials and Methods

2.1 Materials

The analyzed dataset consisted of 24h indoor measurements of ELF MF (magnetic flux density B) from 884 children living in France. Measurements were performed

with a personal exposimeter (EMDEX II, Enertech, Campbell, CA, USA; sensitivity: 0.01-300 μT; sampling rate 3 s).

The dataset comes from the EXPERS study (Bedja et al., (2010); Magne et al., (2017)): for each child, it reported the number of electric lines near home for 400 V underground cables within 40 m (UNDlow), 20 kV underground cables within 40 m (UNDmid), 63-150 kV underground cables within 20 m (UNDhigh), 225 kV underground cables within 20 m (UNDextra), 400 V overhead lines within 40 m (OVHDlow), 20 kV overhead lines within 40 m (OVHDmid), 150 or 90 or 63 kV overhead lines within 100 m (for 150 kV lines) or 70 m (for 63 and 90 kV lines) (OVHDhigh), 225 kV overhead lines within 120 m (OVHDextra), 400 kV overhead lines within 200 m (OVHDultra), and 20 kV/400 V substations inside the building within 40 m (Substation). The dataset also reported the type of heating appliances used in the child home, the age and type of the residence, and the family size.

2.2 Methods

Data were clustered with the *K*-means algorithm (Matlab, ver. R2018a, MatWorks Inc., Natick MA, USA) (Kaufman and Rousseeuw, (1990)). More details on the procedure we used to perform clustering can be found in (Tognola, Bonato et al., (2019); Tognola, Chiaramello et al., (2019)). The similarity between the observations in a cluster was measured by the squared Euclidean distance. As clustering variables we considered the geometric mean (GM) of the 50 Hz component of B and the number of electric networks close to the child home, according to the classes of electric networks defined above, i.e., for the variables from 'UNDlow' to 'substation'.

We then applied an association test on a number of 'secondary' variables that did not contribute to differentiate the clusters but might have a potential effect on the clusters previously identified. Specifically, we applied the Chi-square (χ^2) test on the categorical variables house heating, residence age, and residence type and the Kruskal-Wallis test on the numerical variable family size. For all tests, we set the significance level at $p<0.05$. The variable "heating type" was discretized into three categories, namely: non-electric, mixed, and electric heating. The variable "residence type" was discretized into 4 categories, namely: individual home, terraced home, apartment in small building (with two to nine residential units), and apartment in big building (with 10 or more residential units). Finally, the variable "residence age" was discretized into four categories, namely: house built before 1950, from 1950 to 1969, from 1970 to1989, and after 1989.

3 Results

The median GM over the whole dataset was 0.010 μT (1st quartile Q1: 0.003 μT; 3rd quartile Q3: 0.028 μT). For only four children, the exposure level (GM value) was >0.4 μT.

The optimal clustering solution was found by partitioning the data with $K = 3$ clusters; this solution had a silhouette score greater than 0.60 (indicative of a cluster solution of good quality). The results of clustering are displayed in Figure 1, which shows the normalized values of the centroids of the three clusters. The centroid is the 'representative' of the observations belonging to a given cluster and it is calculated as the mean of the observations assigned to that cluster for each variable used in clustering.

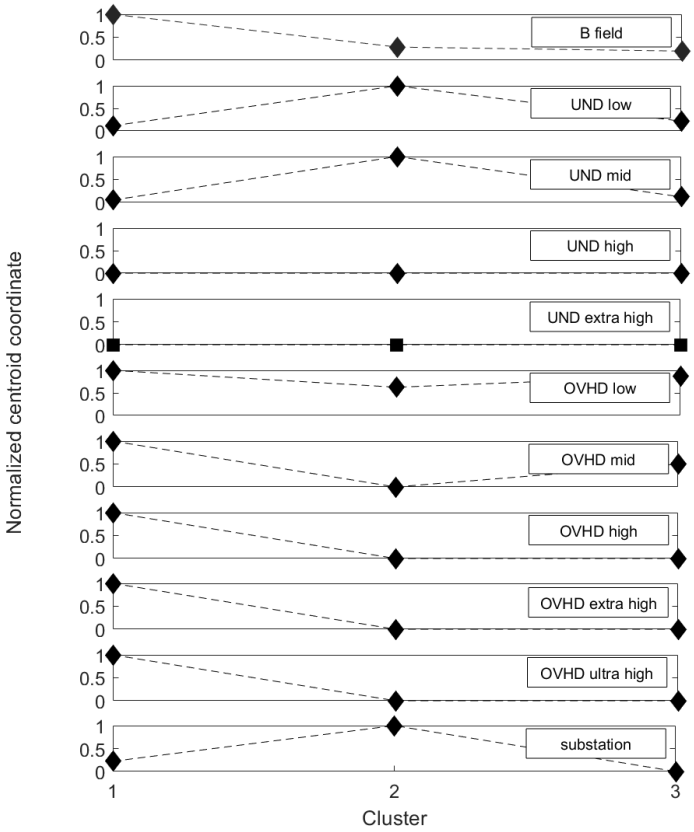

Figure 1: Normalized values of the centroids of the three clusters.

In our analysis each centroid has 11 dimensions, i.e., one for each variable we used to perform the clustering. The centroids in Figure 1 were normalized to the maximum of each of the 11 analyzed variables. The normalization of the centroids allows to better identify which variables were most important in discriminating the clusters. As a matter of fact, it is noted from Figure 1 that the B field, UNDlow,

UNDmid, OVHDmid to OVHD ultra and 'substation' were the variables whose centroids changed more across the clusters, meaning that these latter variables were most important in discriminating cluster characteristics.

As to the clusters, observations were partitioned in three groups: Cluster 1 consisted of children with the highest exposure (average GM: 0.126 μT) living near overhead lines of high (63-150 kV), extra-high (225 kV) and ultra-high voltage (400 kV); Cluster 2 consisted of children with mid exposures (average GM: 0.036 μT) living near underground networks of low (400V) and mid voltage (20 kV) and substations (20kV/400V); Cluster 3 consisted of children with the lowest level of exposure (average GM: 0.025 μT) living far from electric networks.

For what concerns the association effect, we found no statistical significant association of the residence age with the clusters; instead, the type of heating (χ^2: 17.58, p=0.002), the type of residence (χ^2: 138.49 p=2.09x10^{-27}) and the family size (η^2 = 8.63, p<0.02) had a statistical significant association with clusters. For what concerns heating, we found that Cluster 2 (which corresponded to mid levels of indoor exposure) was mainly characterized by children living in homes with electric heating appliances; vice versa, children in Cluster 3 (lowest level of exposure) mainly lived in homes with mixed electric and non-electric heating. As to the residence size, we found that Cluster 3 was characterized by children living in individual and terraced houses, whereas Cluster 2 was mainly characterized by children living in big buildings with more than 10 residential units. Finally, we found that the family size differed significantly across the clusters; in particular, we found that Cluster 2 was characterized by children living in families of bigger size than those in Cluster 3 (Dunn's post-hoc test, p<0.005), whereas no statistically significant differences were found between Cluster 1 and Cluster 2 or 3.

4 Discussion and Conclusions

The current study evidenced how cluster analysis could be helpful in identifying recurrent patterns in personal exposure to indoor ELF MF that were characterized by the type of electric networks close to the child home.

Moreover, this study revealed that secondary environmental variables had an impact on the pattern of ELF MF exposure but of a lesser extent than electric lines. In particular, we found that the use of electric heating appliances or living in big flats or in larger families was generally associated to higher level of personal indoor exposure. This would suggest that to fully characterize ELF MF residential exposure it is important not only to take into account the type and position of electric lines but also the environmental variables such as heating, residence type, family size.

Statistical Assessment and Validation of Ship Response in High Sea State by Computational Fluid Dynamics

Analisi e Validazione Statistica della Risposta di Navi in Mare Grosso Ottenuta Mediante Fluidodinamica Computazionale

Andrea Serani, Matteo Diez and Frederick Stern

Abstract The study presents the statistical assessment and validation of ship response in heavy weather using the moving block bootstrap method. Computational fluid dynamic results are validated versus experimental fluid dynamics data. The test case is a free-running model of a naval destroyer in heavy weather, namely the 5415M model in irregular stern-quartering waves in sea state 7.

Abstract *Lo studio presenta l'analisi e la validazione statistica della risposta di navi in mare grosso, ottenuta mediante fluidodinamica computazionale. L'approccio per l'analisi e validazione usa un metodo di tipo* moving block bootstrap*. I risultati computazionali sono validati attraverso il confronto con dati sperimentali. Il caso di studio è un modello di cacciatorpediniere, nello specifico il modello 5415M in stato di mare 7.*

analysis and optimization in real-world environmental and operating conditions. The validation of stochastic computational responses versus experimental data is an important issue to ensure accurate analysis and informed decision making. In ship hydrodynamics, statistical validation procedures for ship responses were proposed in [2] and applied to computational fluid dynamics (CFD) simulations in irregular waves.

The objective of the current study is to present the extension to high sea states of the statistical validation of stochastic CFD simulations versus experimental fluid dynamics (EFD) data. Namely, free-running CFD simulations of a naval destroyer in heavy-weather conditions are presented. The 5415M model is assessed for course keeping in irregular stern-quartering waves in sea state 7.

The validation is achieved by statistical assessment of EFD data and CFD results for both input waves and ship response time series. Statistical estimators of interest are the expected value, standard deviation, and in general the probability density function. To define validation values and confidence intervals for the statistical estimators a moving block bootstrap (MBB) approach [4] is applied.

The results are part of the activity of the NATO Science and Technology Organization Task Group AVT-280 “Evaluation of prediction methods for ship performance in heavy weather” and have been presented in [7].

2 Test Case Description

The 5415M model is a geosim replica of the DTMB 5415 model with different appendages designed by the Maritime Research Institute of Netherlands (MARIN). EFD data are provided by MARIN and available in [8]. The free-running tests were performed with propeller rate of revolutions fixed to the self-propulsion point of the

model for the envisaged speed. A proportional-derivative controller for the rudder is used taking into account yaw and sway motions.

The selected test case includes seven runs at fixed revolutions per minute RPM = 950 (in model scale), stern-quartering sea (heading of 300 deg) using the JONSWAP spectrum with nominal significant wave height equal to 6 m (full scale), modal period equal to 9.2 s, and 2000 wave components. A total of 130 encounter waves have been recorded, with an average of 20 encounter waves per run. The average run length per run is close to 300 s (in full scale). The model scale data rate is equal to 198.8 Hz.

3 Computational Fluid Dynamics Method and Setup

The unsteady Reynolds-averaged Navier-Stokes equation code CFDShip-Iowa V4.5 [3] is used for CFD computations. Details of equations, numerical implementations, and validation of the numerical solver can be found in [3]. For the current study, absolute inertial earth-fixed coordinates are employed with Menters blended $k-\omega/k-\varepsilon$-BKW) with shear stress transport (SST) using no wall function. The 6 degrees of freedom rigid body equations of motion are solved to calculate linear and angular motions of the ship.

The irregular wave is based on a linear superposition of 80 (regular wave) components. The wave angular frequency values for the wave components are selected evenly distributed within 0.41 and 1.47 rad/s as in the EFD campaign. The phase for each component is randomly selected. Free-running CFD simulations are conducted at Froude number $\mathrm{Fr} = 0.33$ and Reynolds number $\mathrm{Re} = 6.62E+06$ (model scale), with constant propeller RPM. Details on the computational grid and setup can be in found in [7].

4 Analysis and Validation Method

Statistical assessment and validation are studied for time series values of wave elevation, ship motions, rudder angle, ship x- and y-velocities, and immersion probes.

Statistical estimators of interest are the expected value (EV), standard deviation (SD), and in general the probability density function (PDF). EV and SD are evaluated using a sample of M items from time series, $J_i = J(t_i)$, $i = 1,\ldots,M$, as

$$\mathrm{EV}(J) = \frac{1}{M}\sum_{i=1}^{M} J_i \qquad \mathrm{SD}(J) = \sqrt{\frac{1}{M-1}\sum_{i=1}^{M}\left[J_i - \mathrm{EV}(J)\right]^2} \tag{1}$$

The PDF is evaluated via kernel density estimation [5] as

$$\mathrm{PDF}(J,y) = \frac{1}{Mh}\sum_{i=1}^{M}\frac{1}{\sqrt{2\pi}}\exp\left[-\frac{(y-J_i)^2}{2h^2}\right] \tag{2}$$

where $h = \mathrm{SD}(J)M^{-1/5}$ [6].

To define the validation values and confidence intervals for the statistical estimators of Eqs. 1 and 2 the MBB method [4] is applied to time series, using a number $C = M - l + 1$ moving blocks, each formed by J_i, $i = j,\ldots,j+l-1$, where j is the block index and $l = (2\phi/c)^{2/3}M^{1/3}$ is an optimal block length with

$$\phi = \frac{M\sum_{i=1}^{M-1}\left[J_{i+1}-\mathrm{EV}(J)\right]\left[J_i-\mathrm{EV}(J)\right]}{(M-1)\sum_{i=1}^{M}\left[J_i-\mathrm{EV}(J)\right]^2} \tag{3}$$

and $c = (1-\phi)(1+\phi)$ [1]. From the original set of C blocks, a number of $C' = M/l$ blocks are drawn at random with replacement and concatenated in the order they are picked, forming a new bootstrapped series of size M. $B = 100$ bootstrapped series are used. The validation value for EV and its 95% confidence lower and upper bounds are evaluated as

$$\mathrm{EV} = \mathrm{Median}(\mathrm{EV}_b) = \mathrm{EV}_{\lceil 0.5B\rceil} \quad \mathrm{EV}_l = \mathrm{EV}_{\lceil 0.025B\rceil} \quad \mathrm{EV}_u = \mathrm{EV}_{\lceil 0.975B\rceil} \tag{4}$$

where EV_b represents the EV value of the b-th bootstrapped series, ordered such as $\mathrm{EV}_{b-1} \le \mathrm{EV}_b \le \mathrm{EV}_{b+1}$. Finally, the uncertainty of the estimate is $U_{\mathrm{EV}} = 0.5(\mathrm{EV}_u - \mathrm{EV}_l)$. The validation values and confidence interval for SD are evaluated similarly.

The validation error for EV is evaluated as $E = \mathrm{EV}^{(\mathrm{CFD})} - \mathrm{EV}^{(\mathrm{EFD})}$ and the associated validation uncertainty is defined as

$$U_v = \sqrt{\left[U_{\mathrm{EV}}^{(\mathrm{CFD})}\right]^2 + \left[U_{\mathrm{EV}}^{(\mathrm{EFD})}\right]^2}. \tag{5}$$

Validation is achieved if $|E| \le U_v$. SD validation error and uncertainty are assessed similarly.

5 Results

The statistical validation results are presented for the input wave elevation, ship motions, rudder angle, x- and y-velocities, and two immersion probes. Errors and uncertainties for the statistical estimators provided by the MBB method are normalized with 2SD.

Table 1 shows the input wave validation. EFD and CFD uncertainties of the estimators are close to 4.4 and 9%, respectively. A reduction of the uncertainty would require both EFD and CFD to run longer. Nevertheless, validation is achieved for wave elevation SD (about 5.2% error). Finally, Figure 2a shows the PDF of wave

Table 1 Validation of time series statistics by MBB.

Note: E and U are %2SD.

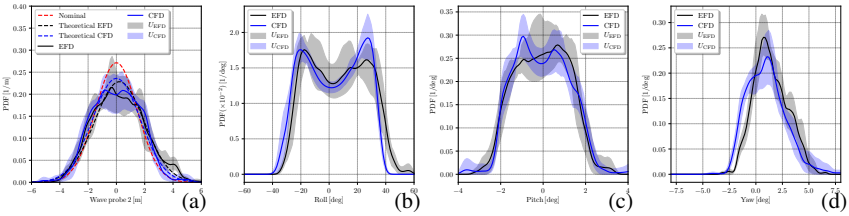

Fig. 2 Comparison of EFD and CFD probability density functions for selected variables.

elevation, using MBB. Both EFD and CFD values are shown along with nominal and theoretical distribution, revealing a good agreement.

Results for ship motions are shown in Fig. 2 and Tab. 1. Specifically, Figs. 2 compare EFD and CFD PDFs of significant ship-motion variables. The results are in good agreement. Ship motions SD is validated on average with an error of 8.3% and an associated uncertainty of 14.3%. Ship velocity EV is validated with an error equal to 6.2% and an uncertainty equal to 11.3%. Rudder angle SD is also validated with error and uncertainty equal to 4.1 and 12.3% respectively. Immersion probes EV and SD show an average error close to 12% with an associated uncertainty close to 9%, likely due to the use of the level set method (in CFD) in combination with rough waves and extreme motions. Variables are validated with an average error of 9.6% and 8.8% for EV and SD, respectively, and the corresponding uncertainties are equal to 11.1% and 11.5%. It is worth noting hot EFD distribution for the roll angle shows an evident bi-modal shape, which is very well captured by CFD.

6 Conclusions

A statistical validation has been presented and assessed for the 5415M model in (sea state 7) irregular stern-quartering waves by free-running CFD simulations. Stochastic input wave and ship response validation has been investigated by statistical assessment of EFD data and CFD results via MBB analysis of time series. On average, validation has been achieved with 9.3 and 8.5% validation errors, along with 10.4 and 11.3% validation uncertainties, for time series EV and SD, respectively. A reduction of the validation uncertainty is desired and require both EFD and CFD to run longer. Current results show that CFD is in a very good agreement with EFD.

Uncertainty Quantification for PDEs with random data using the Multi-Index Stochastic Collocation method

Quantificazione dell'Incertezza per EDP con dati aleatori tramite il metodo "Multi-Index Stochastic Collocation"

Lorenzo Tamellini and Joakim Beck

Abstract In many real-life applications, one needs to solve partial differential equations (PDEs) to predict the behavior of a system, most often by numerical methods. This goal is often hampered by the fact that the parameters of the equations might be not known exactly, and modeled as random variables; one therefore would like to assess how this uncertainty propagates to the solution of the PDE. To this end, we discuss in this contribution the Multi-Index Stochastic Collocation method, and show its effectiveness with a few numerical tests.

Abstract *In molti contesti applicativi, è necessario risolvere delle equazioni alle derivate parziali (PDE) per ottenere una predizione del comportamento di un sistema, il più delle volte tramite tecniche numeriche. Questo obiettivo è spesso reso difficoltoso dal fatto che i parametri dell'equazione potrebbero non essere noti con esattezza, e descritti comoe variabili aleatorie; di conseguenza, è interessante stimare come questa incertezza si propaga alla soluzione della PDE. A questo scopo, in questo contributo discutiamo il metodo "Multi-Index Stochastic Collocation", e mostriamo la sua efficacia tramite alcuni esempi numerici.*

1 Introduction

In many applications, scientists and engineers need to solve ordinary / partial differential equations (ODEs / PDEs respectively) to predict the behavior of a system, either analytically or more commonly by computer simulations (in the remainder of this contribution we focus only on PDEs). While the mathematical structure of these PDEs is often well-understood (at least for classical applications, such as solid mechanics, fluid dynamics, heat exchange, electromagnetism, etc) and numerous well-studied numerical methods exist to approximate their solutions, the predictive power of these simulations is often hampered by the fact that the parameters of the equations might be not known exactly, and they might be considered e.g. as random variables (or random fields). "Parameters" here is used in a broad sense, and includes physical/chemical coefficients (e.g., density, viscosity, thermal conductivity, permeability), shape of the domain, initial conditions, boundary conditions, which can be thoughts as the "inputs" or "data" of the PDE, as opposed to the solution of the PDE, which can be thought as the "output" of the PDE. This uncertainty can be due to multiple reasons, such as limited experimental measurements, or intrinsic randomness of the quantity (e.g. rainfall, earthquakes).

It is therefore crucial to assess how the uncertainty on the data/inputs of the ODEs/PDEs propagates to the outputs of these equations, i.e., to compute mean, variance and higher moments of the solution, and ideally its probability density function. This is the goal of the so-called forward Uncertainty Quantification (UQ) analyses. Other related tasks are inverse UQ and Optimization Under Uncertainty): they can be tackled with similar approaches, but we do not discuss them here. In this context, it is useful to think of the solution of the PDE as a random function, that associates to each realization of the random parameters the corresponding solution of the PDE. In the following, assuming that the PDE depends on N random parameters: we denote by $\boldsymbol{y} \in \mathbb{R}^N$ the vector containing the realizations of the random parameters, by $\Gamma \subset \mathbb{R}^N$ the set in which $\boldsymbol{y}$ can take values (the so-called "parameter space"), and by $u(\boldsymbol{x}, \boldsymbol{y})$ the solution of the PDE, where we have also highlighted the dependence of u on the space/time variables $\boldsymbol{x}$.

Most methods for forward UQ rely on solving the PDE for multiple realizations of the random parameters (i.e., sampling $u(\boldsymbol{y})$ over Γ) and then post-processing the corresponding solutions to obtain the desidered statistical information on the solution. The most trivial of these methods is of course the Monte Carlo method, whereby the statistical information for the solution is obtained by simply averaging the samples of $u(\boldsymbol{y})$ obtained. It is of course possible to replace Monte-Carlo with more effective sampling methods, such as Quasi Monte Carlo or Latin Hypercube Sampling, see e.g. [7]. These methods however do not take full advantage of the possible smoothness of the function to be sampled, i.e. the fact that the map $\boldsymbol{y} \to u(\boldsymbol{x}, \boldsymbol{y})$ could be not only a continuous function but actually a function whose derivatives up to a certain degree might be continuous or square-integrable – even an analytic function at times. These properties derive from the structure of the PDE at hand. This fact can instead been exploited by methods that are more traditional of the numerical analysis background, i.e., numerical quadrature and interpolation methods

(stemming from the fact that computing an expected value / higher moment is nothing but a weighted integral over the parameter space Γ). On the other hand, classical numerical quadrature/interpolation methods scale poorly with the dimension N of the parameter space – in the worst case, the number of required samples grows exponentially with N ("curse of dimensionality"). In addition to this, the function $u(\boldsymbol{y})$ to be sampled is typically expensive to evaluate (since it requires solving numerically a PDE), so that naive approaches become unbearably expensive. A very popular and quite effective approach to reduce the "curse of dimensionality" effect are the so-called "sparse-grids" schemes, i.e., quadrature/interpolation schemes carefully designed to deal with high-dimensional, possibly smooth functions, see e.g. [9, 10].

Another very popular approach to reduce the computational complexity is the so-called multi-level approach, first proposed in the context of numerical finance and then applied to engineering applications [3, 2]. In this approach, a first sampling of the parameters space is performed by solving the required PDEs with a coarse computational mesh (hence, with a cheap method); then, a refinement of the mesh is introduced and a few additional PDEs are solved, to correct the previous estimate. The procedure can be iterated on a hierarchy of increasingly refined meshes where at each level less and less PDEs are solved. In this way, the computational cost of the procedure is substantially reduced without compromising the accuracy of the prediction. In this version (and in the several improvements proposed in literature, see e.g. [5, 8]) the sampling strategy at each level is still a Monte-Carlo / Quasi-Monte-Carlo strategy, i.e., strategies that again do not fully exploit the regularity of the solution u. This can be reached instead combining the multi-level strategy with the sparse-grids schemes mentioned above, [11, 4, 1]. In this contribution we focus on one specific example of such method, the Multi-Index Stochastic Collocation method. In particular, our exposition follows closely [1].

2 Multi-index Stochastic Collocation (MISC)

To fix the ideas, let's consider a specific PDE with random coefficients for which we want to perform a forward UQ analysis. For instance, let's consider the heat equation to compute the pointwise temperature of a metal bar being heated, whose heat-conduction coefficient is uncertain. In this scenario, the parameter $\boldsymbol{y}$ represents the heat conduction coefficient: one parameter $N = 1$ is enough if the bar is homogeneous, while if the bar is composite with pieces with different material, then we will need $N > 1$. Each $y_n, n = 1, \dots N$ can be thought as a uniform random variable over a certain range $y_n \sim \mathscr{U}(a_n, b_n)$, and we can assume y_n to be independent. The parameter space Γ is the hypercube obtained by taking Cartesian products of each $[a_n, b_n]$, and the probability density function of $\boldsymbol{y}$ is simply $\rho(\boldsymbol{y}) = \prod_{n=1}^{N} \frac{1}{b_n - a_n}$. The solution u of the PDE is the pointwise temperature in the bar, and is a function of the spatial coordinate $\boldsymbol{x}$ as well as of the random heat-conductivities $\boldsymbol{y}$, i.e. $u = u(\boldsymbol{x}, \boldsymbol{y})$.

Let us now consider an exahedral mesh to approximate u for a given value of the heat coefficient, by solving the PDE. For simplicity, let us assume that all the

elements have the same size and are allowed to be non-cubic, i.e., their edges have size $h_1 = c_1 2^{-\alpha_1}$, $h_2 = c_2 2^{-\alpha_2}$, $h_3 = c_3 2^{-\alpha_3}$, for some constants c_1, c_2, c_3 and user-defined integer values $\alpha_1, \alpha_2, \alpha_3$. We collect the three values of α_i in a multi-index $\boldsymbol{\alpha} = [\alpha_1, \alpha_2, \alpha_3]$; prescribing the multi-index $\boldsymbol{\alpha}$ thus prescribes the computational mesh to be generated. If this flexibility is not allowed by the mesh-generator (or by the problem itself), one can set $\alpha_1 = \alpha_2 = \alpha_3 = \alpha$, i.e., controlling the mesh-generation by a single integer value α. Let us denote by $G_{\boldsymbol{\alpha}}$ the quantity of interest of our UQ analysis computed over the mesh specified by $\boldsymbol{\alpha}$; this could be for instance the value of the temperature in a specific point of the bar being heated. Thus, the final goal of the UQ analysis is to compute an approximation of e.g. $\mathbb{E}[G_{\boldsymbol{\alpha}}]$, i.e., of the expected value of $G_{\boldsymbol{\alpha}}$.

The MISC method can be used for this goal. It is based on selecting the values $\boldsymbol{y}_j$ as points of a Cartesian grid obtained by tensorization of univariate quadrature rules (which should be chosen according to $\rho(\boldsymbol{y})$ for computational efficiency). In this work, we use as univariate quadrature rule the Clenshaw–Curtis (CC) univariate quadrature, which is optimal when $y_1, y_2, \ldots, y_N$ are uniform and independent random variables as in our case. Then, for a multi-index $\boldsymbol{\beta} \in \mathbb{N}^N$ and given the function $m(i)$ with $m(0) = 0$, $m(1) = 1$, $m(i) = 2^{i-1} + 1$ for $i \geq 2$, $m(\beta_1)$ CC values are generated for y_1, $m(\beta_2)$ CC values for y_2 etc, and then consider the grid obtained by taking the Cartesian product of the N sets of points thus generated. The quadrature weight of each point of the Cartesian grid is immediately obtained by taking the product of the corresponding univariate weights. The approximation of $\mathbb{E}[G_{\boldsymbol{\alpha}}]$ computed over this grid is denoted as $\mathscr{Q}_{\boldsymbol{\alpha},\boldsymbol{\beta}}$. Clearly, one would like to have both multi-indices $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ with large components, say $\boldsymbol{\alpha} = \boldsymbol{\alpha}^\star$ and $\boldsymbol{\beta} = \boldsymbol{\beta}^\star$, i.e., to average the values of many PDE solutions over a refined computational mesh. However, as we already mentioned this is typically unfeasible due to computational costs.

Instead, the idea of MISC resorts to the previously mentioned multi-level approach, i.e. the single, highly refined approximation $\mathscr{Q}_{\boldsymbol{\alpha}^\star,\boldsymbol{\beta}^\star}$ is replaced by a linear combination of many coarser $\mathscr{Q}_{\boldsymbol{\alpha},\boldsymbol{\beta}}$, where whenever one refines the spatial discretization $\boldsymbol{\alpha}$, the quadrature level $\boldsymbol{\beta}$ is kept to a minimum and vice versa (of course, the combined cost of computing the set of coarse discretizations should be smaller than the cost of the highly refined one). In formula,

$$\mathbb{E}[G_{\boldsymbol{\alpha}^\star}] \approx \mathscr{Q}_{\boldsymbol{\alpha}^\star,\boldsymbol{\beta}^\star} \approx \sum_{[\boldsymbol{\alpha},\boldsymbol{\beta}] \in \mathscr{I}} c_{[\boldsymbol{\alpha},\boldsymbol{\beta}]} \mathscr{Q}_{\boldsymbol{\alpha},\boldsymbol{\beta}} \tag{1}$$

where $c_{[\boldsymbol{\alpha},\boldsymbol{\beta}]}$ is a real number and $\mathscr{I}$ is a collection of feasible discretizations, designed with the purpose just explained. For instance,

$$\mathscr{I} = \{\boldsymbol{\alpha} \in \mathbb{R}^3, \boldsymbol{\beta} \in \mathbb{R}^N : |\boldsymbol{\alpha}| + |\boldsymbol{\beta}| \leq L\}$$

for some integer value L. A suitable set $\mathscr{I}$ can be designed can either be designed a-priori, by a careful analysis of the PDE at hand, see e.g. [1], or on-the-run by adaptive algorithms, see e.g. [6]; in this contribution the focus is on the former option.

3 Numerical results

To show the effectiveness of MISC, we briefly comment in this section on a set of results originally reported in [1], to which we refer the interested reader for details. The metal bar is shown in Figure 1 top-left. The pointwise heat-conductivity is modeled as a random field, parametrizes with $N = 3$ i.i.d. uniform random variables, $y_i \sim \mathscr{U}(-1,1)$, i.e., $\Gamma = [-1,1]^3$; one possible realization of this random field is shown in Figure 1 top-right. The quantity of interest (the quantity $G_{\boldsymbol{\alpha}}$) is the integral of the temperature over the metal bar, and we aim at computing its expected value, $\mathbb{E}[G_{\boldsymbol{\alpha}}]$.

Figure 1 bottom-left reports the growth of the computational time required to approximate $\mathbb{E}[G_{\boldsymbol{\alpha}}]$ as we require a smaller and smaller tolerance. The methods considered are MISC, the standard Multi-Level Monte-Carlo method (MLMC) and a certain variant of MLMC, called Multi-Index Monte Carlo (MIMC). We can immediately see that the computational time required by MISC grows significantly slower than for MLMC and MIMC, especially for small tolerances. We also report in dotted lines the theoretical growth of the computational times for all these methods (as well as standard Monte-Carlo), which show good agreement between the theory and the actual computational times.

Finally, Figure 1 bottom-right shows for the number of PDEs solved on each mesh, for some of the tolerances required to obtain the tolerance-vs-time plot. The horizontal axis reports the "total mesh refinement", i.e. the sum $\alpha_1 + \alpha_2 + \alpha_3$: the larger this sum, the more refined the computational mesh, and the more expensive solving the PDE over it. Tolerances are named $TOL_1, TOL_2, \ldots, TOL_5$, with TOL_1 being the largest and TOL_5 the smallest. As expected, if a large tolerance is required, only a few PDE solves are needed, on a few meshes, none of them very refined. As the required tolerance gets smaller, the number of meshes required increases, and more refined meshes are introduced; at the same time, more and more PDEs are being solved on each mesh. Crucially, however, the number of PDEs that need to be solved on the refined meshes is always significantly smaller than those to be solved on coarse meshes: e.g., for TOL_5 we are solving a few thousand PDEs on meshes with total refinement 3 and slightly more than a hundred on the meshes with total refinement 8, which makes MISC a quite effective method for forward UQ purposes.

Emerging challenges in official statistics: new data sources and methods

Small area poverty indicators adjusted using local spatial price indices

Indicatori di povertà per piccole aree corretti con indici spaziali dei prezzi a livello locale

Stefano Marchetti, Luigi Biggeri, Caterina Giusti and Monica Pratesi

Abstract In this work we focus on estimating monetary poverty indicators at provincial level in Italy taking into account the different price levels within the country. Indeed, the historical Italian North-South divide also correspond to a strong differential in price levels, which can affect the poverty threshold. The local price levels are accounted using two sub-regional spatial price indices: 1. the indices based on retail volumes (units) and prices for food and grocery, and 2. the indices based on housing costs collected through the Household Budget Survey. Sub-regional poverty estimates are then computed using area level small area models, which link direct unreliable estimates to aggregated auxiliary information.

Abstract *In questo lavoro si propone un metodo per ottenere stime di povertà relativa in Italia a livello provinciale, considerando il diverso livello dei prezzi presente tra il nord ed il sud del paese. La linea di povertà nazionale viene opportunamente corretta utilizzando due indici dei prezzi: 1. indice spaziale dei prezzi per alimenti, calcolato utilizzando big data delle vendite al dettaglio nelle catene della grande distribuzione e 2. indice spaziale dei prezzi per l'affitto calcolato utilizzando i dati l'indagine sulle spese delle famiglie. Per la stima della povertà relativa a livello provinciale si utilizzano metodi di stima per piccole aree in quanto le stime tradizionali ("dirette") non risultano affidabili.*

Key words: poverty mapping, retail scanner data, small area estimation.

1 Introduction

Local poverty indicators are essentials for a data driven welfare policy. Among the possible measures, we focus on monetary poverty indicators, and in particular on the Head Count Ratio (HCR), which is the proportion of poor households in a given area or domain.

In Italy, Istat, the National Statistical Office, publishes HCRs estimated from the Household Budget Survey (HBS), which provides good estimates at the national and regional level However, sub-regional estimates, such as provincial estimates, can help the decision makers to plan and implement local welfare policies. Usually, such local estimates are unreliable because of the small sample size of the HBS at local level. For example, for the HBS 2017 the national sample was composed by 16496 households, with provincial sample sizes ranging from 20 to 1036, with a median value of 125. Small area estimation methods (Rao and Molina, 2015) can allow for reliable estimates at local level.

When the focus of the HCR are regions, provinces or municipalities, the national (monetary) poverty threshold can be misleading because the price levels within the country are not equal, as noted by Biggeri et al. (2018). In this work we propose to adjust the relative national poverty line (NPL) at the province level taking into account the spatial distribution of two indexes: the Spatial Food Price Index (SFPI), limited to the prices of food and grocery items as collected by the retail trade scanner data on prices processed by Istat, and the Spatial Housing Cost Index (SHCI), limited to the housing rents as collected by the Italian Household Budget Survey.

To obtain estimates of HCRs at provincial level adjusted taking into account different price levels, we first compute spatial price indexes that are used together to adjust the national poverty line at provincial level, and we finally estimate the provincial HCRs using area-level model-based estimators.

2 Estimation of Spatial Food Price Indexes (SFPI)

The data set used is a selection of price quotations of 73,000 different products (barcodes or GTINs – Global Trade Item Numbers) in food and beverages categories, excluding fresh food, classified in 55 ECOICOP-5-digits, and turning out into about 1,300,000 annual quotations in 2017. In the following they are indicated as the scanner data of grocery products[1].

Retail scanner data on prices are the result of an agreement started in 2013 between ISTAT and the associations of modern distribution, retail trade chains (RTCs) and Nielsen. In 2017 the price scanner data used by Istat were limited to the quotations of a sample of outlets selected by a probability sampling design. Scanner data for 1,781

[1] Retail scanner data were provided by Istat under an agreement with the Centre ASESD "Camilo Dagum" for the research in the framework of the H2020 MAKSWELL project www.makswell.eu

of the main 16 retail trade chains (RTCs) covering the entire national territory were monthly collected by ISTAT on a weekly basis at item code level. Outlets have been stratified according to provinces (107), chains (16) and outlet-types (hypermarket, supermarket) for a total of 867 strata. Probabilities of selection were assigned to each outlet based on the corresponding turnover value. Concerning the selection of the sample of items, a cut off sample of barcodes (GTINs) has been selected within each outlet/aggregate of products (covering 40% of turnover but selecting no more than the first 30 GTINs in terms of turnover). For each GTIN, prices were calculated taking into account turnover and quantities: weekly price is equal to the weekly turnover divided by weekly quantities. Monthly and annual prices are calculated by the arithmetic mean of weekly prices weighted with quantities.
The spatial food price indexes (SFPI) have been computed by using the scanner data and applying the Country Product Dummy (CPD) model according to Laureti and Rao (2018). The CPD is essentially a hedonic regression model where the observed price is related to the country of origin and the characteristics of the product are represented by the commodity itself.

The CPD model can be seen as a simple fixed effects model where country-effects provide estimates of the spatial price index and commodity-specific effects provide estimates of between areas prices. In our work we specified the CPD as follows:

$$\ln p_{jr} = \alpha_0 + \sum_{r=1}^{R} \gamma_r D_r + \sum_{j=1}^{J} \eta_j A_j + \epsilon_{jr} \qquad (1)$$

where p_{jr} is the price of the commodity j in area (province) r, D_r is the same as in equation (1), γ_r is the area r price coefficient, A_js are commodity dummy variables, η_j account for the quality of commodity j and ϵ_{jr} is a normal distributed error with constant variance. As usual, by imposing the constraint $\gamma_1 = 0$, then γ_r is the difference of (fixed) effects connected with the area r compared with the base area 1. To use as a reference Italy instead of area 1, the coefficient γ_r has been adjusted following Suits (1984). In this way, γ_r represent the fixed effect of area r compared to Italy. Thus, the quantity $\exp(\gamma_r)$ represents the spatial price index for food in area r ($SFPI_r$) with respect to Italy, and it is also called purchasing power parity of area r (PPP_r). The SFPI at provincial level are summarized in Table 1 grouped by geographic repartition (North, Centre, South).

Table 1: Distribution of province SFPI grouped by geographical repartition

Repart.	***Min***	***1st Q.***	***Median***	***Mean***	***3rd Q.***	***Max***
North	0.9116	1.0027	1.0365	1.0358	1.0799	1.1216
Centre	0.9339	0.9845	1.0039	1.0025	1.0178	1.0888
South	0.7925	0.9057	0.9423	0.9554	1.0002	1.1350

From Table 1 we can see that food prices in the retail trade chains are higher in the northern and central provinces with respect to the southern ones, as expected (Italy is again the reference).

3 Estimation of Spatial Housing Price Indexes (SHPI)

To estimate the Spatial Housing Price Indexes (SHPI) we used the data coming from the HBS conducted yearly by Istat. Data are collected on the basis of a two-stage sample design where the first stage are the municipalities and the second stage are the households. The regions are the finest geographical level for which direct estimates of the target indicators are usually reliable. The survey collects information on the rent payed by the occupants and on the main characteristics of each house, as well the characteristics of the area where the house is located.

Taking into account the data available, we use a hedonic price method to estimate the SHPI at provincial level. The hedonic price method is basically a regression of the price of the house (rent) against known relevant determinants (characteristics of the unit) that indirectly affect the price. A classical hedonic equation is as follows:

$$\ln p_{ir} = \alpha_0 + \sum_{r=1}^{R} \alpha_r D_r + \sum_{k=1}^{K} \sum_{h=1}^{H} \beta_{kh} C_{kh} + \epsilon_{ir}, \qquad (2)$$

where p_{ir} is the rent cost per square meter of house i in province r, D_r is a vector equal 1 if house i is in area r and 0 otherwise, α_r is the area r price, C_{kh} is the characteristic k and classification h of the house i with β_{kh} its regression coefficient, also called characteristic shadow price and ϵ_{ir} is the error term for house i in area r, which should satisfy the standard assumptions of the multiple linear regression model. As for model (1), α_r represent the fixed effect of area r compared to Italy. Once the α_r are estimated, the SHPI of area r is obtained as $\exp(\alpha_r)$.

To control for the characteristics and classification of the house, we use the following variables: municipality type, kitchen included in the leaving room, presence of: small kitchen, heating, building age, satellite TV, garden, dish-washer, broadband; rent type, number of rooms, surface. Parameters have been estimated using weighted least squares to account for the presence of heteroscedasticity. The estimated SHPIs are summarized in Table 2, where provinces are grouped by geographic repartitions (North, Centre, South).

Table 2: Distribution of province SHPI grouped by geographical repartition

Repart.	*Min*	*1st Q.*	*Median*	*Mean*	*3rd Q.*	*Max*
North	0.7047	1.0436	1.1444	1.1675	1.2818	1.9378
Centre	0.6807	1.0032	1.0595	1.1494	1.3234	1.7712
South	0.5042	0.6390	0.8025	0.8292	0.9919	1.2651

From Table 2 we can see that the distribution of SHPI among provinces of north and central Italy are very similar, even though SHPI in the northern provinces are a little higher than those in the centre. The SHPI values in southern provinces are smaller, with almost 75% of the provinces with an index below 1, the SHPI value of Italy. It can be noted that the values of the SFPI show a reduced geographically dispersion than those of the SHPI (see Table 1), but the two indexes are coherent as they both indicated a higher level of the prices in the south.

4 Adjusting the NPL

The NPL for a household of two components is set by Istat as the mean per-capita consumption expenditure. For different household sizes this threshold is adjusted according to the Carbonaro equivalence scale, which takes the following values: 0.6 for households with one component, 1.33 with three, 1.63 with four, 1.90 with five, 2.16 with six and 2.40 for households with seven or more components. In 2017 the NPL for two components is estimated equal to 1102.52 euros.
We decided to adjust the NPL for each province using both the SFPI and the SHPI values opportunely weighted (extending the idea in Renwick et al. (2014)):

$$NPL_r^* = NPL \times (\phi_r SFPI_r + \lambda_r SHPI_r + 1 - \lambda_r - \phi_r),$$

where NPL_r^* is the adjusted poverty line for province *r*, ϕ_r is the estimated share of expenditure for food and beverages and λ_r is the estimated share of expenditure for the house in province *r*. The quantities ϕ_rs and λ_rs are estimated from the HBS and summarized in table 3.

Table 3: Distribution of province share of expenditure for house and food grouped by geographical repartition

Repart.	*Min*	*1st Q.*	*Median*	*Mean*	*3rd Q.*	*Max*
Estimated share of house expenditure (%)						
North	15.66	17.97	19.37	19.55	20.92	24.57
Centre	14.34	18.84	20.53	20.21	21.77	25.13
South	13.68	17.34	18.71	18.98	20.63	25.48
Estimated share of food expenditure (%)						
North	12.89	16.36	17.74	18.04	18.94	26.83
Centre	13.87	18.05	19.11	19.38	20.29	25.47
South	18.96	21.34	23.71	23.34	25.27	27.74

Results from Table 3 show a similar distribution among provinces in the north, center and south of Italy of the share of expenditure for house rent, while the distribution of the share of expenditure for food is higher in the southern provinces than in the central and northern provinces.
For each province we use the adjusted NPL to estimate the HCR. Direct estimates of HCR have been obtained using Horwitz-Thompson like estimators – where design weights have been adjusted for the population size at provincial level. Direct estimates prove to be unreliable showing high level of coefficient of variation. Therefore, we use small area estimation methods to improve the precision of the estimates. Given the availability of provincial auxiliary data and the absence of spatial correlation in the conditional distribution of the target variable given the auxiliary variables, we used the basic Fay-Herriot area-level model (Fay and Herriot, 1979). As province level auxiliary variables, we used the ratio between number of taxed persons over the population, and the ratios between the number of persons with *i.* income coming from salary, *ii*. income coming from pensions and *iii*. income lower than 10,000 euros per

year, over the number of taxed persons. These data come from the Italian tax agency database. The Fay-Herriot model assumptions are reasonable and model fit is good.

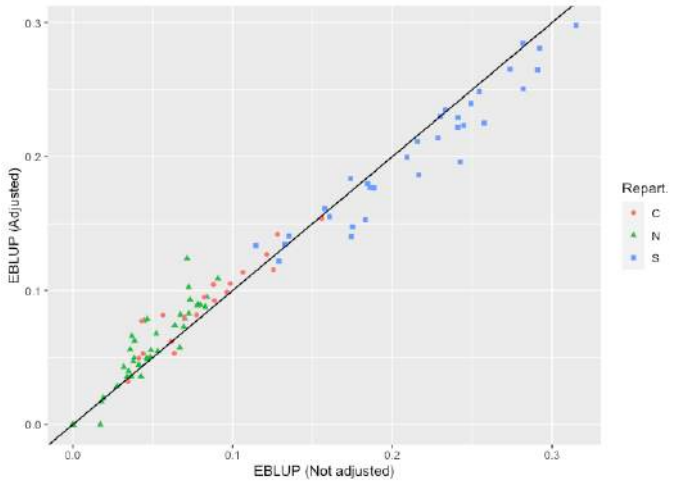

Figure 1: EBLUP estimates of HCR for Italian provinces, Not adjusted poverty line (NPL) and Adjusted poverty line (NPL_r).

From Figure 1 we can see that the HCR of southern provinces estimated using the adjusted poverty line is lower than the HCR obtained using the NPL, while for central and northern provinces is the contrary, as we expected given the perception that in the south of Italy food goods and house rents are cheaper.

Smart solutions for trusted smart statistics: the European big data hackathon experience

Soluzioni smart per "trusted smart statistics": l'esperienza del "European big data hackathon"

Francesco Amato, Mauro Bruno, Tania Cappadozzi, Fabrizio De Fausti, Manuela Michelini[1]

Abstract The European Statistical System Committee (ESSC) is promoting innovation in social statistics, recognizing the importance of social statistics to support evidence-based policymaking. Within this context Eurostat promoted the European big data hackathon, with the aim to stimulate research on the use of new data sources for diary-based Time Use survey (TUS) and test new methodologies to improve the quality of statistical outputs. This paper focuses on the characteristics of TUS diary and the challenges for its innovation. In the second part of the paper, we describe SMart Use of TIme Survey (SMUTIS), implemented by Istat during the hackathon. SMUTIS offers a set of innovative functionalities for data processing, such as machine-learning techniques.

Abstract *Lo European Statistical System Committee (ESSC) è impegnato nella promozione dell'innovazione nelle statistiche sociali, riconoscendone l'importanza a supporto della formulazione di politiche sociali. In questo contesto Eurostat ha promosso lo European big data hackathon, con l'obiettivo di stimolare la ricerca nell'uso di nuove fonti di dati per migliorare la qualità dell'indagine Uso del Tempo. Questo articolo si concentra sulle sfide metodologiche per l'innovazione del diario di Uso del Tempo. In particolare, viene descritto il sistema SMart Use of TIme Survey (SMUTIS), realizzato dall'Istat allo European big data hackathon. SMUTIS, offre diverse funzionalità innovative di analisi, come ad esempio tecniche di machine-learning per il processamento di nuove fonti di dati.*

Key words: Time Use survey**,** trusted smart statistics, European big data hackathon, machine learning

1 Introduction

The European Statistical System Committee (ESSC) has been committed to promoting innovation in social statistics for over a decade, recognizing the importance of social statistics to support evidence-based policymaking, in times of resource constraints. Indeed, the high costs of some social surveys[1] often hamper their development in EU Member States [1]. In particular, the collection method based on the traditional paper-and-pencil self-completed diary and the expensive post-coding process are objective obstacles to their introduction as compulsory surveys into the Integrated European Social Statistics (IESS) Regulation. The ESSC states the need for better information on time use and household budgets in terms of coverage and comparability. To this aim, the ESSC promotes the implementation of new capabilities that improve the responsiveness of users, the linkage of TUS or HBS data with other data sources and the design and implementation of new methods and tools.

Eurostat started several projects enabling Member States to develop innovative solutions for diary-based surveys. In particular the Task Force on Innovative Tools and Sources for HBS and TUS [2], in continue cooperation with the Big Data project[2], highlighted how specific mobile applications could be used in the TUS and HBS domains to collect data. In particular the use of smartphones (motion tracker, camera, microphone, etc.), smart watches and activity trackers (e.g. speech recognition for activity labelling, record the time of activity, record location where activity took place, etc.) for collecting TUS data.

Another initiative promoted by Eurostat, for modernizing diary-based social surveys, is the European Big Data Hackathon. The aim of the challenge is to stimulate research on the use of data collected by smartphones and their possible integration with data collected through the respondent by filling in an online prototypal time use diary. The focus of this paper is to briefly describe the characteristics of the TUS diary, the challenge for its innovation and the main outcome achieved by Istat during the hackathon.

1.1 Challenges for the diary-based Time Use survey

In the paper-and-pencil self-completed time use diary, respondents report in free text the activities carried out during a reference day, in a time schedule with minimum slots of 10 minutes [3]. For each daily activity, respondents report the starting and finishing time as well as important contextual information like the place of occurrence and the possible presence of others. This tool allows collecting very detailed and useful information for the formulation of policies related to lifetimes and gender equality. However, the survey is very time and cost consuming for the

[1] Time Use Surveys (TUS) and Household Budgets Surveys (HBS)

[2] More information on the Big Data project is available on CROS portal https://ec.europa.eu/eurostat/cros/content/essnet-big-data_en

NIS and with high burden for the respondents. Therefore, the challenges for this survey to be achieved with the use of new technologies are manifold:

- *reduce respondent's burden*: pre-filling part of the diary using big data collected automatically by smartphone (i.e. travel time using GPS data, the ICT use);
- *improve the diary quality*: introducing immediate consistency checks at the end of the diary;
- *reduce time and costs*: using smart solutions eliminates the registration and coding phases of paper diaries;
- *provide feedback to respondent*: at the end of the diary day, respondents can receive an immediate feedback on their time use compared to the average, as an incentive strategy for participation.

In this challenging context, participation in the Big Data hackathon represented the first concrete attempt to find solutions, albeit experimental, to these innovation needs.

2 The Big Data hackathon experience

The European Big Data Hackathon is an event organised by the European Commission (Eurostat) which gathers teams from all over Europe to compete for the best data product combining official statistics and big data to improve quality of official statistics products. The European Big Data Hackathon has five objectives[1].

1. Solve statistical problems by leveraging algorithms and available data, by engaging with data scientist across Europe to build relevant algorithms and by exposing relevant data sets to participants to come up with ideas.
2. Identify first-class data scientists, by targeting local developers' and data scientists' communities to attend the events, by connecting with the best participants during the events for possible future collaboration.
3. Promote and accelerate big data for statistics initiatives in Europe, by developing prototypes that European countries will be able to integrate, and by generating buzz about big data within communities of scientists' entrepreneurs.
4. Promote partnerships with the research community and the private sector, by raising awareness about big data initiatives in Official Statistics in Europe, by starting partnerships with the private sector and Universities.
5. To produce innovative products and tools, to stimulate the use of open data and public use files and to engage with new audiences.

The teams compete for the best application of big data providing an answer to the following challenge:

"*How can innovative solutions for data collection reduce response burden and enrich or replace the statistical information/data provided by the time use survey?*"

[1] More information on the hackathon is available on CROS portal https://ec.europa.eu/eurostat/cros/EU-BD-Hackathon_en

2.1 The implemented solution

To achieve the hackathon goals and provide an accurate answer to the challenge, Istat team implemented the application SMUTIS (SMart Use of TIme Survey)[1]. The guiding principles in the design and implementation of SMUTIS were the following:

1. *Use of new data sources to enrich traditional output*. The input data provided to the teams combined the collection of data captured by sensors available in smart phones with data entered by the users (e.g. activities performed).
2. *Increase of quality of statistical output by analysing sensor data*. Sensor data provided by the mobile applications included location data and recorded signals from accelerometer, barometer, proximity sensor, etc.
3. *Test the use of machine learning techniques to produce new statistical outputs*. The mobile application used for the hackathon collected pictures of meal and food advertisement. A key goal of the hackathon was to analyse food images as a proxy of nutritional facts and health indicators.
4. *Compliance with official statistics standards.* Implementation of a tool compliant with CSPA principles [4], i.e. software components should be modular, shareable and use standard metadata. Design of a metadata repository according to GSIM [5] information model and classification of metadata according to the GSBPM phases [6].

The hackathon imposed further constraints to the teams, each team had to establish links between the heterogeneous data sets provided and identify and use other data sources beyond those currently at hand. The implemented tools had to integrate or at least had to consider the aspect of data quality for the analysis and visualization.

Given the abovementioned objectives and constraints, SMUTIS architecture fulfills the following requirements:

- *Access and analyse heterogeneous data sources*. SMUTIS needs to access data generated by mobile applications (i-Log and BigO) and the results of the Harmonised European Time Use Survey (HETUS), available on Eurostat website.
- *Analyse and integrate sensor data in a GIS framework*. SMUTIS provides functionalities to process sensor data to derive statistical information on travel/commute activities. The functionality should display data on GIS maps.
- *Use of machine learning algorithms to process food images*. SMUTIS integrates machine-learning algorithms to process food images and produce health indicators, based on nutrition facts. This component is the most challenging and innovative; more details on the deep neural network implemented are provided in the next paragraph.
- *The tool should provide a set of standard services for data processing and analysis.* SMUTIS follows the service-oriented architecture (SOA) design pattern. The server component will provide loose-coupled services with a well-defined interface, e.g. “Sensor data processing service”, “Machine leaning

[1] SMUTIS is an open source project, released under the EUPL 1.1 public license. The source code is available at: https://github.com/mecdcme/smutis

service". The client component should invoke the services and display the outputs on a graphical user interface, accessible via web browser. The main components of SMUTIS architecture are displayed in Figure 1.

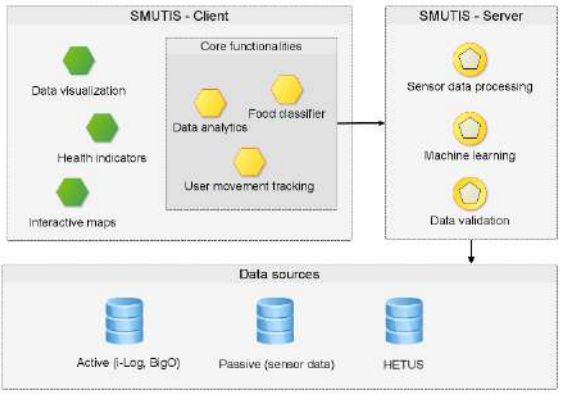

Figure 1: SMUTIS components

SMUTIS, conceived as a proof-of-concept, has confirmed that new data sources and machine learning techniques can be combined to improve traditional output and produce new indicators.

2.2 Machine learning for food classification

With respect to the policy question of the hackathon, we focused on "enrich or replace the statistical information/data provided by the time use survey". We tested the opportunity of creating a new wellness indicator based on the activities of daily life, linking physical activity and healthy eating.

Among the data collected via smart devices, we took advantage of the photos taken at meals through the BigO mobile application[1]. BigO was initially designed to collect and analyze big data on behavior and living environments, to allow public health authorities to plan and execute effective programs to reduce the prevalence of childhood obesity. Further, we created the food classification algorithm with the aim of recognizing the meal eaten by the user and associating the value of the typical average macronutrients for the meal. To implement the food classification algorithm, we used very powerful and versatile machine learning tools such as CNN convolutional neural networks [7], the state of the art in image recognition. For power and relative simplicity, we have chosen to implement the architecture called Incepitonv3 [8]. To train the network we used the Food101 dataset [9], a dataset that collects about one hundred classes of international foods with a cardinality of one thousand images per class. The images collected for the hackathon were classified

[1] More details concerning the "Big data against childhood Obesity" (BigO) project are available at: https://bigoprogram.eu/

for each user according to the Food101 classification and contextually linked to the corresponding typical macronutrients, such as carbohydrates, fats and proteins.

Using the food recognizer as a backend micro service, the SMUTIS application offers the possibility of recognizing in real time the meals eaten and provides information on the ratios of the macronutrients consumed by the user.

3 Conclusion

The European big data hackathon experience proved that new data sources and methodologies could be exploited to achieve challenges related to diary-based surveys. Although such results are experimental, they point the way for both methodological and technological innovation in social surveys.

Indeed Eurostat launched at the beginning of 2020 a new ESSNet project on "Trusted Smart Statistics", with the aim to define the specifications for a European Platform supporting the use of shared smart survey solutions and furthermore to assess the usage of applications for European social surveys, such as the Time Use Survey (TUS) or the Household Budget Survey (HBS).

The ESSnet Project Smart Surveys: new data sources and tools for Surveys of Official Statistics

Il progetto ESSnet Smart Surveys: nuove fonti di dati e strumenti per le indagini della Statistica Ufficiale

Claudia De Vitiis[1], Francesca Inglese[2]

Abstract Trusted Smart Statistics represent the step forward taken by official statistics as evolution of the Big Data framework and can be seen as the future extended role of official statistics in a world impregnated with smart technologies and new data sources. New data sources represent a unique opportunity to produce new and improve existing statistics within a collective collaborative framework. The ESSnet Smart surveys, in this context, has the objective to conceive a methodological and conceptual framework, define the specifications for a European Platform supporting the use of shared smart survey solutions and, moreover, to assess the usage of smart applications for the European social surveys, implementing privacy by design approaches.

Abstract *Nel contesto europeo delle Trusted Smart Statistics, che costituiscono l'evoluzone del paradigma Big Data per la statistica ufficiale, il paper presenta il progetto ESSNet Smart Surveys, finanziato da Eurostat. Il progetto si propone di testare e implementare soluzioni basate sull'uso di smart devices per la produzione statistica e in particolare per indagini sociali che risultano molto pesanti per il risponente. L'obiettivo principale è definire il framework concettuale per lo sviluppo di una piattaforma europea per la conduzione di smart surveys, insieme alla sperimentazione di strategie e tool già sviluppati da altri progetti Eurostat.*

Key words: Official statistics, Trusted Smart Statistics, Trusted Smart Surveys

1 Introduction

The last decades have seen important changes in data collection and in their dissemination and use in all sectors of society. This *big data revolution* phenomenon is mainly due to the increased ability to collect and store information automatically through very different sources such as sensors of various kinds, satellites, mobile devises, internet, drones and many others. Big data represented a great opportunity for official statistics in a hyper-connected world dominated by the IoT (Internet of things), but must be used in order to build a reliable information set: they pose new challenges for Statistics, a science that realizes knowledge of reality on empirical-observational data (Arbia, 2019).

The big data revolution, from digitalization to datafication (Ricciato *et al*, 2019), determined for official statistics a totally new situation, together with the massive use of administrative data sources. This state stimulated in recent years the definition of a *new paradigm* for the official statistics: the production of statistics becomes a process in which data from various sources converge, establishing the need not only of methods and techniques to structure and elaborate data coming from each source, but also new reliable methodologies and algorithms to integrate them in order to obtain statistics compliant with the international quality standards (Citro, 2014). In the most recent years a further step forward derived from the transition from the notion of Big data in Official Statistics to the concept of *Trusted Smart Statistics*. This caused a *shift from data sources to data systems*, towards a systemic paradigm change (Ricciato et al 2019).

The paradigm shift requires methodologies, but also an effort to conceptualize, measure, and communicate new sources of error and the statistical accuracy of integrated data. This paradigm needs to be built on new methodological frameworks fit for new data sources (e.g. sensor data), and such frameworks must be designed to enable methodological agility, cooperative development and continuous evolution. Common concepts, as meta-data, data lifecycle, data lineage and provenance, need to be extended from data to methods or equivalently analytics, algorithms, software etc.. New methods and their implementations will not be static or quasi-static but rather dynamic objects (Ricciato et al 2019).

The development of Smart Surveys - surveys in which respondents are asked to employ smart devices (e.g. smartphones, tablets, activity trackers) to collect survey data through active and passive data collection - and Trusted Smart Surveys (TSS) - surveys in which respondents are asked to share existing data collected by trusted third parties, like government authorities and larger, stable enterprises willing to establish data delivery agreements - offers new challenges to improve the quality of social surveys in the NSIs.

The ESSnet on Smart Surveys, which started its activities at the beginning of 2020, fits into this context and represents the focus of this work. The aim of this paper is to present the objectives of the project Smart Surveys and outline the main activities that the ESSnet will undertake to pursue these goals. The paper is organized as follows: in section 2 the background on big data and TSS is outlined, section 3 describes the main

objectives of the ESSnet Smart Surveys and section 4 reports the first ideas regarding the methodological framework for the Smart Survey Platform.

2 Background on Trusted Smart Statistics in the ESS

The European Statistical System Committee (ESSC) adopted in 2013 the Scheveningen Memorandum on Big Data and Official Statistics (European Commision, 2013) and in 2014 an ESS action plan and roadmap (Big Data Action plan and Roadmap - BDAR2). The Bucharest memorandum in 2018 (European Commission, 2018), followed by the Trusted Smart Statistics Action plan and Roadmap, establishes the need for integrating new data sources and data collection methods in the production of official statistics. In particular, the ESS has established privacy-by-design approaches, including the resolution of the legal aspects and putting in place the necessary technical requirements at national and European level.

The definition of TSS will be the eventual result of a process for developing the concept and the respective statistics. Tentatively, we can define TSS as automated, algorithm-based production of official statistics that is trusted by design: it adheres to widely agreed principles and standards of algorithmic transparency, auditability, reproducibility and privacy preservation. The term "Smart Statistics" is inspired by the notion of "smart systems" as systems that are capable of autonomously sensing, processing and interactively analysing information across network infrastructures. Trust is a cornerstone of the current system of official statistics. "Trusted Smart Statistics" from smart systems requires a new coherent set of technical, organisations and legal means respected by all involved stakeholders.

Trusted smart statistics is therefore conceptually integrated in national strategies across the ESS. Its implementation includes prototyping and developing: (i) national and trans-national trusted smart surveys, based on advanced interaction models through smart devices combined with advanced privacy-by design technologies; (ii) use of citizen science data and open data sources; (iii) methodological and quality frameworks integrating the use of multiple data sources (multi-source statistics and multipurpose sources) in the production of official statistics.

Different smart survey solutions were developed within the Eurostat Grants for "Innovative Tools and Sources" for two specific surveys: the Harmonised European Time Use Survey (HTUS) and the Household Budget Survey (HBS)..

In this context, the ESS lauched in 2019 an ESSnet on Smart Surveys which started its activities in 2020. This project will contribute towards many important achievements that are foreseen within the TSSAR: (i) testing and developing (trusted) smart surveys within the ESSnet, (ii) the conceptualisation, development and implementation of a new reference architecture for trusted smart statistics as well as the evolvement of new skills within the ESS. In the ESSnet, the existing solutions for smart surveys will be tested in other European countries and the applicability to other domains will be evaluated. Furthermore, the ESSnet will deliver preparatory work to create a Europeanwide platform to share und re-use smart survey solutions and components.

3 The ESSnet Smart surveys: objectives and planned activities

Mobile devices have become standard tools for communication within the time span of just a decade and have a high population coverage worldwide. Because of their high population coverage and daily life use and because of the availability of sensors, mobile devices have become tools that may supplement surveys with automated data from sensors. Some of these sensor data may also replace survey data (Eurostat Grant Mimod, 2019).

The term *smart surveys* refers to surveys that use smart personal devices, equipped with sensors and mobile applications. The concept of smart surveys goes well beyond the mere use of web-based (online) data collection that essentially transform the paper questionnaire into an electronic version. Smart surveys involve dynamic and continuous interaction with the respondent and with her/his personal device(s). They combine data collection modes based on input from the data subjects with data collected passively by the device sensors (e.g. accelerometer, GPS, microphone, camera, etc.), involving relevant consent issues.

Using "trusted smart surveys" we refer to an augmentation of smart surveys by technological solutions that collectively increase their degree of trustworthiness and hence acceptance by the citizens. Constituent elements of a trusted smart survey are the strong protection of personal data based on privacy-preserving computation solutions, full transparency and auditability of processing algorithms.

The overall goal of the ESSnet Smart Surveys is to define the specifications for a European Platform supporting the use of shared smart survey solutions and furthermore to assess the usage of applications for European social surveys, such as the Time Use Survey (TUS) or the Household Budget Survey (HBS). Both surveys are considered, in fact, to be very burdensome to respondents and to be prone to low recall as well as underreporting errors. Modernization of these surveys and similar ones is therefore urgently needed. In the context of five ESS grants on "Innovative tools and sources for diary-based surveys, the Household Budget Survey and/or the Time Use Survey", members of the ESS are currently developing and testing apps and new data collection methods for these surveys. In the ESSnet Smart Surveys, these solutions will be tested and transferred to other countries and domains.

On the whole the ESSnet Smart Surveys has two main goals: (i) Evaluate existing tools for smart surveys in particular domains, with particular focus on those where tools have already been developed (Time Use Survey, HETUS, and Household Budget Suervey, HBS), with the goal of identifying points for improvement; (ii) Developing technological and methodological solutions for processing the input personal data in a privacy-preserving fashion (e.g., by leveraging Secure Multi-Party Computation), with no need to centralize the data at a single entity (concentration risk) and in a way that provides solid guarantees in terms of privacy protection, full auditability and complete transparency of the processing methods applied over the data.

A conceptual framework will be developed that serves as the basis for a future European platform for trusted smart surveys. This ESSnet is intended to take a first step towards the future development of the platform and will cover the pre-

development stage: collection of requirements, identification of design principles, architecture design and formulation of concrete specifications. The outcome of this ESSnet is intended to serve as a direct input to the future development of such a platform in other follow-up project(s).

The platform will be flexible and implementing a set of common (horizontal) functions and configurable services that can be used to build particular instances of trusted smart surveys for specific application domains and/or target areas. Such a platform should be modular, evolvable, extensible and agnostic to particular application domains. It should provide ready-to-use solutions for horizontal functions. It should allow each platform user (i.e., any ESS member) to instantiate a specific trusted smart survey by selecting and configuring different modules. The platform should include support for secure private computing to avoid data concentration (e.g., secure multiparty computation), full transparency and public auditability.

The activities planned for the ESSnet are structured in three work-packages, the first devoted to coordination and management. The WP2 will carry on the pilot projects using available tools, through the following steps: identification and collection of the functional and technical characteristics of the solutions developed for the HETUS and HBS; establishment and execution of a solutions evaluation protocol for existing data collection applications; developing pilot projects demonstrating the use of scalable secure private computing solutions (e.g. Secure Multiparty Computation) to process individual citizen data without concentrating personal data at a single entity, in combination with appropriate technological solutions to provide full auditability. Test and pilot project will be conducted during 2020-21.

The WP3 will work on the TSS platform through two main tasks: (i) conceptualization and development of a general platform for trusted smart surveys for collecting data for official statistics, following a top-down design approach from abstract framework through architecture down to detailed technical specifications. (ii) development of proofs-of-concept in the form of modular prototype elements for essential aspects of the architecture. A strict connection with the activities of the WP2 will guarantee the coherence and the consistency between the theoretical framework and the feedbacks that will come from the tests and pilots on the existing smart tools.

4 The methodological and conceptual framework for the Smart Surveys: first steps

The first step in the direction of defining a conceptual framework in vision of the platform for the trusted smart survey, is the identification and description of the specificities of the statistical process for a smart survey.

Going through GSBPM, the sub-processes involved/affected especially by the use of smart devices for the data collection will be identified. A methodological scheme of the overall process of a smart survey will be defined, considered as a mixed mode

survey and a multiple data source survey, in which data deriving from different data collection mode are integrated. In particular the points will be highlighted where: (i) smart data are integrated with traditionally collected data; (ii) the impact on the estimates of the use of smart data can be assessed, together with the effect on data quality in terms of selectivity of device usage, nonresponse bias and measurement error (Herzing, 2019).

The specification of methods for data collection and treatment of sensor data through smart devices will be established starting from the Inventory of tools (linking with the WP2 and the Task Force "Innovative Tools and Sources"), together with the identification of the requirements for the APPs for data collection in social surveys.

Relevant steps will be: the review of sensor data sources (starting from the work done in the Eurostat Grant "The use of mixed-mode data collection in social surveys", MIMOD, 2019); the definition of methods for representation and structuring of sensor data to obtain statistical information; the construction of a metadata system that describes the data in terms of concepts, techniques, processes and origins; the definition of new and advanced methodological concepts to link different data sources and to validate data; the definition of technology to obtain secure data access, in conjunction with the appropriate methodology and algorithms to guarantee privacy and confidentiality. These steps are necessary to define a data model that contemplates on the one hand the process of methodological development and the statistics production on the other.

Factorial and dimensional reduction methods for the construction of indicators for evaluation (SVQS-SIS)

A comparison of MBC with CLV and PCovR methods for dimensional reduction of the soccer players' performance attributes

Un confronto di MBC con i metodi CLV e PCovR per la riduzione dimensionale degli attributi di performance dei calciatori

Maurizio Carpita, Enrico Ciavolino and Paola Pasca

Abstract This work extends the research on soccer performance attributes classification given by EA Sports esperts and available on Kaggle in the KES dataset. Although a first clustering-based inquiry through the Clustering around Latent Variables (CLV) as well as the Principal Covariates Regression (PCovR) produced more detailed and meaningful groupings, no consistent improvement in the predictive performance of match results was observed. Moreover, as the new composite indicators are produced, these dimensional reduction methods does not account for the data uncertainty. In order to overcome this limit, a Model-Based Clustering (MBC) method is considered and tested on players' performance variables.

Abstract *Questo lavoro estende e approfondisce alcuni studi per classificare con metodi statistici gli attributi di performance dei calciatori forniti dagli esperti di EA Sports presente nel dataset KES su Kaggle, piattaforma dedicata alla Data Science. Sebbene l'uso di metodi quali Clustering around Latent Variables (CLV) e Principal Covariates Regression (PCovR) produca classificazioni più interessanti, non si è rilevato un miglioramento nella capacità predittiva dei risultati delle partite. Inoltre, le precedenti modalità di clustering non incorporano l'incertezza dei dati. Per risolvere tale limite, si propone il clustering basato su modelli di mistura (MBC), applicato agli indicatori di performance.*

1 Introduction

The latest benefits and developments in sports research, specifically that on soccer, come from a "data-scientific" approach. Players' performance on the soccer field has been extensively measured and described by soccer experts: particularly known and detailed are the attribute classification provided by the experts from Electronic Arts (EA)[1]. In their opinion, players' performance can be thought of as a multidimensional construct made up of 7 performance composite indicators (e.g. *defending*), each of which consists of several, more specific skills (e.g. *marking, standing tackle* and *sliding tackle* as elements of the above mentioned *defending* dimension).

Thanks to world's widespread Data Science platforms such as Kaggle, this wide variety of players' performance attributes can be joined to data about real soccer matches and, most of all, is now accessible to everyone [1]. These data lend themselves to both predictive modeling [3], but also to test the soundness of experts' classification of players' performance. A statistical inquiry of experts' performance areas showed strong correlations between variables belonging to different dimensions, thus indicating that experts' theorization might not be statistically supported. If so, a clustering approach might provide an increase in both theoretical and predictive power of players' performance variables.

2 Performance composite indicators of soccer players: a review

Literature about modeling soccer matches is rich and a vivid debate is still going on (see, among the others [11, 12, 2]). In such predictive models, experts' ratings of players are used as predictors to feed machine learning algorithms. To this end, the Kaggle European Soccer (KES) database represents one of the biggest available datasets in the European framework [10]. A more recent version [5] covers a timespan of 7 seasons (from 2009-2010 to 2015-2016) in 10 different countries (Belgium, England, France, Germany, Italy, Netherlands, Portugal, Scotland, Spain and Switzerland) and melts information from two different sources: 20,973 *matches*, which include home and away team goals, as well as players' position on the pitch, and 33 *performance attributes* (variables) reflecting *players' abilities* measured at regular intervals (twice a year until 2013, then just once a month). For what concerns attributes' description, experts of Electronic Arts (EA) Sports state that players' performance can be summarized into 7 *performance composite indicators* made up, in their turn, of specific skills to be mastered by players.

Such procedure, although reflecting experts' opinion, needs a statistical assessment. Indeed, from a statistical point of view, performance indicators aim at measuring the abilities of players that can be considered as latent traits. Moreover, different indicators measure the same latent trait and can be summarized into a composite

[1] EA Sports, a division of Electronic Arts, develops and publishes sports video games, such as the FIFA series. A link to the website: https://www.easports.com/

indicator. [3] created 7 role-based players' composite indicators and used them to predict match outcomes. An alternative method to create composite indicators is based on multivariate data inspection and dimensionality reduction technique such as Principal Components Analysis (PCA) and Cluster Analysis (CA), as proposed in [15] and [8]. In [6] and [4] respectively, performance indicators were clustered via two different methods:

– *Clustering around Latent Variables* (CLV) [13, 14], a method that simultaneously catches variables that occur together (K clusters) and characterizes K latent traits.
– *Principal Covariates Regression* (PCovR) [7], a method that allows to flexibly tune on predictors reconstruction rather than on the predictive power of a regression model and vice versa.

However, such methods do not account for the uncertainty in the data, and in this paper we propose a *Model-Based Clustering* (MBC) method that relies on the definition of a mixture distribution for the players' performance attributes with a random number of mixture components.

2.1 The proposed Model-Based Clustering (MBC) method

As specified in the previous section, in the paper [6] performance indicators are first clustered via Clustering of Variables around Latent Variables (CLV) approach. This procedure simultaneously finds out K clusters of variables as well as K latent components (dimensions) such that variables in each cluster are strongly correlated with the corresponding latent component. Variables that belong to the same cluster show strong association among them and lower association with variables belonging to other cluster. This goal is achieved by decomposing the variance-covariance matrix between variables. In this work, we adopt a different approach, a Model-Based Clustering (MBC) based on a mixture model. Mixture models, widely known in literature [9], can be used to classify variables according to unobserved latent ones. More formally, we say that a distribution f is a mixture of K component distributions $f_1, f_2, ..., f_k$ if:

$$f(x;\pi,\theta) = \sum_{k=1}^{K} \pi_k f_k(x;\theta_k)$$

with the π_k being the mixing weights or marginal probabilities of mixture components ($\pi_k > 0$ and $\sum_{k=1}^{K} \pi_k = 1$) and θ_k are the parameters characterizing these mixture components. We consider a Gaussian mixture model, so that:

$$f_k(x;\theta_k) = \phi(x;\mu_k,\sigma_k^2) = \frac{1}{\sqrt{2\pi\sigma_k^2}} \cdot exp\left(-\frac{(x-\mu_k)^2}{2\sigma_k^2}\right).$$

Let X_{pi} be the p-th performance attribute ($p = 1, ..., P$) for the i-th role ($i = 1, .., 4$; attack, defense, mild-player and goal keeper). Following the motivations in [6], we

do not consider the goal keepers, and therefore $P = 28$ and $i = 1,2,3$.
With the MBC method we assume that performance attributes are modeled as a K-component Gaussian mixture model with parameters μ_k and σ_k^2 ($k = 1,...,K$):

$$X_{pi} \sim \sum_{k=1}^{K} \pi_k N(\mu_k, \sigma_k^2). \tag{1}$$

The mixture in Equation (1) is a convex combination, or weighted average, of Gaussian distributions. According to the mixture in Equation (1), for each performance indicator we can compute the probability to belong to a mixture component whose mean μ_k defines the latent trait the performance indicator aims at measuring. Indeed, performance indicators measuring the same unobserved latent trait belong to the same mixture component and are thus clustered together.
In order to write the likelihood of the model with a more compact notation, we introduce the variable Z_{pim} that will be equal to k when the corresponding statistical unit belongs to the k-th mixture component. Considering the attributes x_{pim} *observed before* the m-th match ($m = 1,...,20973$), the likelihood of the model is the following:

$$L(X,Z|K,\mu,\sigma^2) = \prod_{m=1}^{20973} \prod_{p=1}^{28} \prod_{i=1}^{3} \sum_{k=1}^{K} \pi_k^{I(Z_{pim}=k)} \phi(x_{pim};\mu_k,\sigma_k^2)^{I(Z_{pim}=k)}. \tag{2}$$

Note that attribute values are *observed before the matches*, so that we may use the obtained performance composite indicators to predict match results. As expected, no closed-form expression can be derived for the model parameters but they are estimated numerically. Notice that the number K of mixture components of the MBC method, interpreted in this context as the number of latent traits the performance indicators aim at modelling, is a model parameter and it is jointly estimated as all the other model components assuming a multinomial distribution. Optimization for MBC is done according to information criteria; as practice in this context, EM algorithm is involved for model estimation. In estimating the model we rely on the package Mclust implemented in R: such a function specifies a mixture distribution with complete variance-covariance matrix whose structure is simplified optimizing the number of mixture component and the BIC criterion. In our case, the best selected model corresponds to VII (spherical, unequal variance structure).

3 Results and Discussion

Preliminary results in Table 1 showed that MBC identifies 5 mixture components with different parameters. $Cluster\_1$ is the largest cluster (the estimate of π_1 is 0.32), with estimated mean 57.4 and variance 13.8, whereas $Cluster\_4$ is the smallest cluster (the estimate of π_1 is 0.11), with lower estimated mean 51 and variance 8.9.

Table 2 showed the 28 performance attributes (variables and long names; the three player roles are considered together), the $sofifa$, CLV and PCovR classifi-

Table 1 Parameter estimate for the clusters obtained with the MBC method

Cluster	μ	σ^2	π
Cluster_1	57.359	13.767	0.321
Cluster_2	67.781	9.817	0.250
Cluster_3	50.641	7.769	0.143
Cluster_4	50.975	8.868	0.107
Cluster_5	64.316	5.820	0.179

cations, and the classification obtained using the MBC method (in this case, each attribute is assigned to the cluster with max π_k).

Table 2 The 28 performance attributes with the *sofifa* and MBC, CLV, PCovR classifications

Attributes			**Dimension classifications with:**		
(variables)	**Long Names**	*sofifa* (LABEL)	MBC	CLV	PCovR
x_1	shot power	power (POW1)	Cluster_1	Group_2	Comp_1
x_2	jumping	power (POW2)	Cluster_2	Group_3	Comp_4
x_3	stamina	power (POW3)	Cluster_5	Group_1	Comp_3
x_4	strength	power (POW4)	Cluster_2	Group_3	Comp_4
x_5	long shots	power (POW5)	Cluster_3	Group_2	Comp_1
x_6	aggression	mentality (MEN1)	Cluster_1	Group_4	Comp_4
x_7	interceptions	mentality (MEN2)	Cluster_4	Group_4	Comp_2
x_8	positioning	mentality (MEN3)	Cluster_4	Group_2	Comp_1

x_{12}	curve	skill (SKI2)	Cluster_1	Group_2	Comp_1
x_{13}	free kick	skill (SKI3)	Cluster_1	Group_2	Comp_1
x_{14}	long passing	skill (SKI4)	Cluster_1	Group_1	Comp_1
x_{15}	ball control	skill (SKI5)	Cluster_2	Group_2	Comp_1
x_{16}	acceleration	movement (MOV1)	Cluster_5	Group_5	Comp_2
x_{17}	sprint speed	movement (MOV2)	Cluster_5	Group_5	Comp_2
x_{18}	agility	movement (MOV3)	Cluster_5	Group_5	Comp_2
x_{19}	reactions	movement (MOV4)	Cluster_2	Group_2	Comp_3
x_{20}	balance	movement (MOV5)	Cluster_5	Group_5	Comp_3
x_{21}	crossing	attacking (ATT1)	Cluster_1	Group_1	Comp_3
x_{22}	finishing	attacking (ATT2)	Cluster_1	Group_2	Comp_1
x_{23}	heading	attacking (ATT3)	Cluster_2	Group_3	Comp_3
x_{24}	short passing	attacking (ATT4)	Cluster_2	Group_1	Comp_1
x_{25}	volleys	attacking (ATT5)	Cluster_1	Group_2	Comp_1
x_{26}	marking	defending (DEF1)	Cluster_3	Group_4	Comp_4
x_{27}	standing tackle	defending (DEF2)	Cluster_3	Group_4	Comp_1
x_{28}	sliding tackle	defending (DEF3)	Cluster_3	Group_4	Comp_1

Classification obtained with the three methods are not the same. The clusters of the MBC solution are a little more balanced than those of the CLV and PCovR solutions: $Cluster\_1$ of MBC incorporates 9 out of the 28 attributes, $Group\_2$ of CLV incorporates 11 attributes and $Comp\_1$ of PCovR incorporates 15 attributes, resulting into lower discrimination of these last two methods. MBC reflect better the players' roles: for example, $Cluster\_1$ are related to attacking capabilities, while

these attributes belong to various groups and components for CLV and PCovR respectively.

For the MBC method, *movement* and *defending* attributes (except MOV4) are in two clusters as for $sofifa$, but this is not the case for CLV and PCovR solutions.

In summary, the MBC clusters result to be good candidates to contruct performance composite indicators to potentially enhance prediction of match results: we will use these and those of the CLV and PCovR into the Skellam model to predict the goal-differences of matches in the KES database.

A framework of cumulated chi-squared type statistics for ordered correspondence analysis. New tools and properties.

Uno schema di statistiche di tipo chi-quadrato cumulato per l'analisi della corrispondenze ordinali. Nuovi strumenti e proprietà.

Antonello D'Ambra, Pietro Amenta and Luigi D'Ambra

Abstract Aim of this contribution is twofold: 1) to show the links between the Cramer-von Mises and the Taguchi statistics with other indices in a single framework, and 2) to suggest a family of correspondence analyses coping with ordinal variables and based on these statistics, providing the basic rationale for an easier single software implementation of all of them.
Abstract *Obiettivo di questo lavoro di mostrare i collegamenti tra la famiglia delle statistiche di Cramer-von Mises e quello di Taguchi con altri indici e, al contempo, di suggerire un framework di analisi della corrispondenze in presenza di variabili ordinali e basate su queste statistiche.*

Key words: Ordinal data, Cramer-von Mises statistics, Taguchi's statistic, Correspondence analysis of cumulative frequencies.

1 Introduction and notation

The Cramer-von Mises family of goodness-of-fit statistics is a well-known group of statistics used to test fit to a continuous distribution. For a single sample of grouped data, this family has been extended to provide tests for discrete distribution when cell probabilities are known [5]. They are based on the empirical distribution func-

tion of the sample, likewise the Kolmogorov-Smirnov statistic [4]. These statistics have been extended to the case where parameters must be estimated from the sample. Extensions of these statistics to test that I samples have the same distribution for grouped data have been also introduced [11]. The Taguchi's statistic [16] is instead a cumulative-sum statistic obtained by assigning a weight to each term that is inversely proportional to its conditional expectation under the null hypothesis of independence. See [6] for its main properties. It has been suggested as a simple alternative to Pearson's statistic for ordered contingency tables. Indeed, the Pearson's statistic can perform poorly when dealing with ordinal structures because it does not have a good power against ordered alternatives [1]. We point out that an interesting difference between the Cramer-von Mises statistics and the Pearson's statistic X^2 is that the formers, as well as the Taguchi's statistic, depend on the order of the cells.

The aim of this paper is twofold: On the one hand, the links between the Cramer-von Mises and the Taguchi statistics with other indices are shown in a single framework and, on the other hand, to suggest a family of correspondence analyses (CA) coping with ordinal variables and based on these statistics. These frameworks can aid the user to better understand the methodological differences between these approaches providing the basic rationale for an easier single software implementation.

Consider a two-way contingency table $\mathbf{N}$ that cross-classifies n statistical units according to I row categories and J ordered column categories of two variables X and Y. Let n_{ij} be the number of observations for the i-th row ($i = 1,\ldots,I$) and the j-th category ($j = 1\ldots,J$). Let $n_{i\bullet} = \sum_{j=1}^{J} n_{ij}$ be the number of observations of the i-th row (sample) of $\mathbf{N}$. We denote by p_{ij} the proportion of observations that fall in the i-th row and j-th column of the table and the generic element of matrix $\mathbf{P}$. Therefore, denote $\mathbf{D}_I$ and $\mathbf{D}_J$ to be the diagonal matrices of the row and column marginal proportions $p_{i\bullet}$ and $p_{\bullet j}$, respectively, where $p_{i\bullet} = \sum_{j=1}^{J} p_{ij}$, $p_{\bullet j} = \sum_{i=1}^{I} p_{ij}$ and p_j is the probability that an original observation falls into cell j. $p_{\bullet s} = \sum_{j=1}^{s} p_{\bullet j}$ is then the cumulative total of Y evaluated in s ($s = 1,\ldots,J-1$). We consider the null hypothesis (H_0) that p_j is the same for all the I samples or, equivalently, these samples have the same parent population. Under H_0, define $T_{is} = n_{i\bullet} p_{\bullet s}$ and let $Z_{is} = \sum_{j=1}^{s} n_{ij}$ and $Z_{\bullet s} = \sum_{j=1}^{s} n_{\bullet j}$ to be the cumulative count and the cumulative column total up to the s-th column category, respectively. Finally, for a given sample, p_j and $p_{\bullet s}$ can be estimated by using $\hat{p}_j = n_{\bullet j}/n$ and $d_s = Z_{\bullet s}/n$, respectively.

2 A framework of Correspondence Analyses based on a class of weighted cumulative chi squared type statistics

2.1 A class of weighted cumulative chi squared type statistics

Let consider the Kolmogorov-Smirnov (KS) statistic $KS = \sup_x |F_n(x) - F(x)|$ for a given cumulative distribution function $F(x)$ with $F_n(x)$ cumulative empirical distribution function for n i.i.d. ordered observations X_i. It is well known that it can be

modified to serve as a goodness of fit statistic. In a *KS* perspective [4], consider then the following statistic

$$T_{CCS}^{KS} = \sum_{s=1}^{J-1} w_s \sum_{i=1}^{I} \frac{1}{n_{i\bullet}} S_{is}^2 \tag{1}$$

where $S_{is} = Z_{is} - T_{is}$ is the difference between the empirical distribution function of the observations Z_{is} and the cumulative distribution function T_{is} of Y, both evaluated in s. It is possible to show that T_{CCS}^{KS} subsumes several indices according to suitable values of w_s. Indeed, under the hypothesis $H_0 : S_{1s} = \ldots = S_{Is}$ and since $n_{i\bullet}^{-1} S_{is}^2 = n_{i\bullet} (Z_{is}/n_{i\bullet} - d_s)^2$ then we get from T_{CCS}^{KS} the following statistics

w_s	Statistic	Author
$1/J$	$T_N = \sum_{i=1}^{I} n_{i\bullet} \sum_{s=1}^{J-1} (Z_{is}/n_{i\bullet} - d_s)^2/J$	Nair [13]
$1/[d_s(1-d_s)]$	$T = \sum_{i=1}^{I} n_{i\bullet} \sum_{s=1}^{J-1} (Z_{is}/n_{i\bullet} - d_s)^2/[d_s(1-d_s)]$	Taguchi [16]
$\hat{p}_s/[d_s(1-d_s)]$	$A_I^2 = \sum_{i=1}^{I} n_{i\bullet}^{-1} \sum_{s=1}^{J-1} S_{is}^2 \hat{p}_s/[d_s(1-d_s)]$	Anderson-Darling [15]
$\hat{p}_s$	$W_I^2 = \sum_{i=1}^{I} \sum_{s=1}^{J-1} n_{i\bullet} S_{is}^2 \hat{p}_s$	Cramér-von Mises [11]

We point out that the Anderson Darling statistic A_I^2 and the discrete I sample Cramér-Von Mises statistic amount also to $A_I^2 = \sum_{i=1}^{I} n_{i\bullet} \sum_{s=1}^{J-1} (Z_{is}/n_{i\bullet} - d_s)^2 \hat{p}_s/[d_s(1-d_s)]$ and $W_I^2 = \sum_{i=1}^{I} n_{i\bullet} \sum_{s=1}^{J-1} (Z_{is}/n_{i\bullet} - d_s)^2 \hat{p}_s$, respectively. See [15] for further info on the statistic A_I^2.

Let us introduce the new statistic $\tilde{T} = \sum_{s=1}^{J-1} [w_s d_s (1-d_s)] X_s^2$ where X_s^2 is the Pearson's chi-squared statistic for the $I \times 2$ contingency sub-tables $\mathbf{N}_s$ obtained by aggregating the first s column categories ($y_{(1:s)}$) and the remaining categories ($s+1$) to J ($y_{(s+1:J)}$) of table $\mathbf{N}$, respectively. It is possible show that if $w_s = [d_s(1-d_s)]^{-1}$ then $\tilde{T}$ amounts to the Taguchi's statistic T. Nair [13] refers to T as the *cumulative chi-squared statistic* (CCS) because $T = \sum_{s=1}^{J-1} X_s^2$ and introduces then the class of CCS-type tests $T_{CCS} = \sum_{s=1}^{J-1} w_s \sum_{i=1}^{I} n_{i\bullet} (Z_{is}/n_{i\bullet} - d_s)^2$. Since it is possible to show that $X_s^2 = \sum_{i=1}^{I} n_{i\bullet} (Z_{is}/n_{i\bullet} - d_s)^2/[d_s(1-d_s)] = \sum_{i=1}^{I} n_{i\bullet}^{-1} S_{is}^2/[d_s(1-d_s)]$, then statistic $\tilde{T} = \sum_{s=1}^{J-1} [w_s d_s (1-d_s)] X_s^2$ amounts to (1) and so T_{CCS}^{KS} can be also considered as a class of CCS-type statistics (likewise T_{CCS}) because it is a weighted cumulative chi-squared statistics subsuming T, T_N, A_I^2 and W_I^2.

We point out that we can replace the X_s^2 statistics in T_{CCS}^{KS} by likelihood ratio statistics G_s^2 obtaining $T_{CCS}^{KS} \approx \sum_{s=1}^{J-1} [w_s d_s (1-d_s)] G_s^2$. This formulation allows then to achieve approximations of statistics W_I^2, A_I^2 and T_N based on G_s^2. Indeed, Taguchi's statistic can be viewed as a approximate sum of likelihood ratios (with $w_s = 1/[d_s(1-d_s)]$) within the regression model for binary dependent variables following a scaled binomial distribution [6].

We introduce now an alternative interpretation of (1). Indeed, we can rewrite it as $T_{CCS}^{KS} = \frac{n}{n-1} \sum_{s=1}^{J-1} [w_s d_s (1-d_s)] \times C_s$ where C_s is the statistic $C = [(n-1)(J-1)/(n - n^{-1} \sum_{j=1}^{i} n_{\bullet j}^2)] \tau$ [10] computed on the s-th $(I \times 2)$ contingency table obtained by aggregating the first s column categories and the remaining $(s+1)$ to J of $\mathbf{N}$, and $\tau = [\sum_{i=1}^{I} \sum_{j=1}^{J} p_{i\bullet} (p_{ij}/p_{i\bullet} - p_{\bullet j})^2]/(1 - \sum_{j=1}^{J} p_{\bullet j}^2)$ is the Goodman-Kruskal

index [8], which is identical to Light and Margolin's R^2 index [10], and so it has a proportion of explained variation interpretation. Under the zero predictability hypothesis (i.e. $H_0 : p_{ij}/p_{i\bullet} = p_{\bullet j}$) the C-statistic is asymptotically chi-squared distribution with $(I-1)(J-1)$ degree of freedom [10]. This new formulation of T_{CCS}^{KS} highlights that it reflects also a unidirectional association between the categorical variables. Moreover, the numerator of τ index (N_τ) is at hearth of a Non Symmetrical extension of Correspondence Analysis (NSCA) [7]. Also note that $T_{CCS}^{KS} = n\sum_{s=1}^{J-1}[w_s d_s(1-d_s)]\tau_s$.

Let now consider the weighted Leti's index $\bar{D}/2 = \sum_{s=1}^{J-1} w_s p_{\bullet\underline{s}}(1-p_{\bullet s})$ [6] which subsumes the τ denominator with $w_s = 1$. We can decompose $\bar{D}/2$ according to the well-known principle of Between- and Within-group variance decomposition (noted D_B and D_W) of a quantitative variable such that

$$\frac{\bar{D}}{2} = \overbrace{\sum_{i=1}^{I} p_{i\bullet} \sum_{s=1}^{J-1} w_s \frac{p_{is}}{p_{i\bullet}} \left(1 - \frac{p_{is}}{p_{i\bullet}}\right)}^{=D_W} + \overbrace{\underbrace{\sum_{s=1}^{J-1} w_s \sum_{i=1}^{I} \frac{1}{n_{i\bullet}} S_{is}}_{=T_{CCS}^{KS}}}^{=D_B}.$$

T_{CCS}^{KS} then turns out to be a part of the $\bar{D}/2$ index. This result allows to obtain also W_I^2, A_I^2, T and T_N as parts of $\bar{D}/2$ by setting suitable values for w_s (Fig. 1). Moreover, a normalized dependence index for ordinal variables can then be easily defined: $\delta = 2T_{CCS}^{KS}/\bar{D}$. It can be considered as an extension of the τ index for ordinal categorical variables which subsumes several other indices according to suitable w_s values. Its main properties will be highlighted in the extended version of this paper.

According to Nair [12, 13] and under the multinomial law hypothesis for the rows, it is possible to find the asymptotic distribution of T_{CCS}^{KS} that takes into account the highlighted alternative interpretation of (1) based on the statistic C. It is based on a matrix decomposition of T_{CCS}^{KS} into orthogonal components. Let $\mathbf{A} = \mathbf{M} - (\mathbf{d}_{J-1} \times \mathbf{1}^T)$ be a matrix of order $((J-1)\times J)$ where $\mathbf{M}$ is a $((J-1)\times J)$ lower unitriangular matrix and $\mathbf{d}_{J-1} = [d_1, \ldots, d_{J-1}]^T$. The T_{CCS}^{KS} statistic can be also written as $T_{CCS}^{KS} = n \times \mathrm{tr}(\mathbf{D}_I^{1/2}\mathbf{H}\mathbf{A}^T\mathbf{W}\mathbf{A}\mathbf{H}^T\mathbf{D}_I^{1/2})$ where $\mathbf{W}$ is the $((J-1)\times(J-1))$ diagonal matrix of weights w_s and $\mathbf{H} = \boldsymbol{\Xi}_{\mathbf{1}/\mathbf{D}_I}^{\perp}\mathbf{D}_I^{-1}\mathbf{P}$ with $\boldsymbol{\Xi}_{\mathbf{1}/\mathbf{D}_I}^{\perp} = \mathbf{I}_I - \boldsymbol{\Xi}_{\mathbf{1}/\mathbf{D}_I} = \mathbf{I}_I - \mathbf{1}(\mathbf{1}^T\mathbf{D}_I\mathbf{1})^{-1}\mathbf{1}^T\mathbf{D}_I$ that eliminates the row marginal effects from the entire relationship between rows and columns, and $\mathbf{I}_I$ identity matrix of order I. Let $\boldsymbol{\Gamma}$ be the $(J-1)\times(J-1)$ diagonal matrix of the nonzero eigenvalues γ of $\mathbf{A}^T\mathbf{W}\mathbf{A}$ and $\tilde{\mathbf{Q}}$ be the $J\times(J-1)$ matrix of the associated eigenvectors such that $\tilde{\mathbf{Q}}^T\tilde{\mathbf{Q}} = \mathbf{I}$ with $\mathrm{SVD}(\mathbf{A}^T\mathbf{W}^{\frac{1}{2}}) \Rightarrow \mathbf{A}^T\mathbf{W}^{\frac{1}{2}} = \tilde{\mathbf{Q}}\boldsymbol{\Lambda}\tilde{\mathbf{S}}^T$ and $\tilde{\mathbf{S}}^T\tilde{\mathbf{S}} = \mathbf{I}$. Using the Satterthwaite's two-moment approximation [14], it is possible to show that the asymptotic distribution of the statistic $\tilde{T}_{CCS}^{KS} = (k/n)T_{CCS}^{KS}$, with $k = [(n-1)(J-1)/(n-n^{-1}\sum_{j=1}^{i} n_{\bullet j}^2)]$, can be approximated by $d(I-1)\times\chi_{(\nu)}^2$ with $\nu = d^{-1}\sum_{s=1}^{J-1}\gamma_s$ degrees of freedom and $d = (I-1)^{-1}\sum_{s=1}^{J-1}\gamma_s^{\,2}/\sum_{s=1}^{J-1}\gamma_s$.

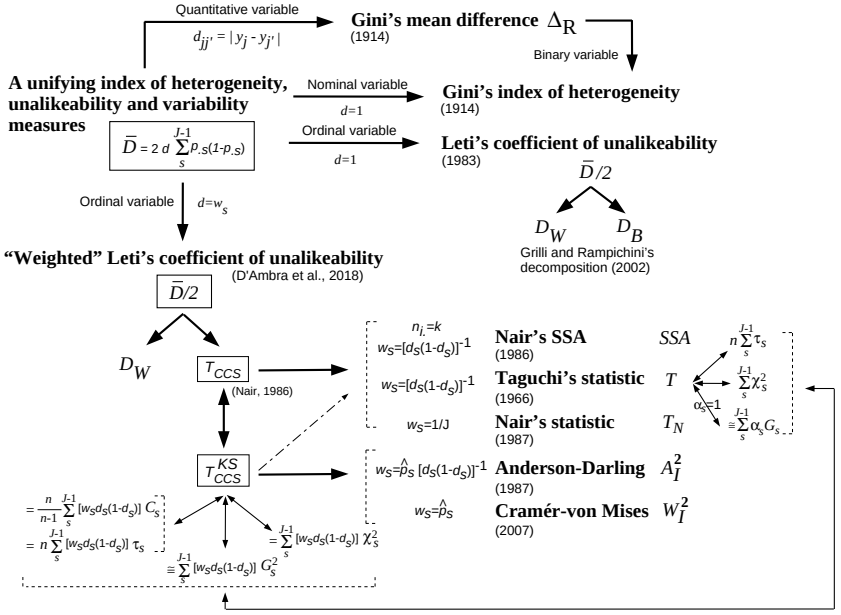

Fig. 1 A recapitulative scheme.

2.2 A family of cumulative correspondence analyses

It is possible to introduce a unified framework of correspondence analyses (CA) coping with ordinal variables and based on the T_{CCS}^{KS} decomposition. Their main goals will be to show how similar cumulative categories are with respect to nominal ones from a graphical point of view, according to a preselected association index.

Let $\tilde{\mathbf{I}}$ be an identity matrix without the last row of order $((J-1)\times J)$. Consider the SVD of matrix $\mathbf{F}=\mathbf{D}_I^{-\frac{1}{2}}(\mathbf{P}-\mathbf{D}_I\mathbf{1}\mathbf{1}^T\mathbf{D}_J)\mathbf{D}_J^{-\frac{1}{2}}\mathbf{R}^T\mathbf{W}^{\frac{1}{2}}$ such that $\mathbf{F}=\mathbf{U}\boldsymbol{\Lambda}\mathbf{V}^T$ with $\mathbf{U}^T\mathbf{U}=\mathbf{I}$, $\mathbf{V}^T\mathbf{V}=\mathbf{I}$, $\boldsymbol{\Lambda}=\mathrm{diag}(\lambda_1,\ldots,\lambda_{min(I,J-1)})$ where λ_i are the singular values of $\mathbf{F}$ arranged in descending order. It is possible to show that $T_{CCS}^{KS}/n=\sum_{i=1}^{min(I,J-1)}\lambda_i$. If the generic element of $\mathbf{W}$ is given by $w_s=1/[d_s(1-d_s)]$, then we achieve a decomposition of the Taguchi's statistic which is at heart of a cumulative extension of correspondence analysis (TA) [2]. Then we can easily get the decomposition of other indices according to figure 1. Table 1 shows the suitable choices of the elements of matrices $\mathbf{W},\mathbf{R}$ and $\mathbf{A}_J$ in order to obtain a CA of cumulative frequencies using a decomposition of a specific statistic: W-CA for W_I^2, A-CA for A_I^2, TA for T and TN-CA for T_N, respectively. Non cumulative methods CA and NSCA are also shown in Table 1 where "Nom" and "Ord" stand for Nominal and Ordinal variable, respectively.

Table 1 A unified framework of CAs coping with ordinal data.

$\text{SVD}[\mathbf{D}_I^{-1/2}(\mathbf{P}-\mathbf{D}_I\mathbf{1}_I\mathbf{1}_J^T\mathbf{D}_J)\mathbf{A}_J^{-1/2}\mathbf{R}^T\mathbf{W}^{\frac{1}{2}}] = \mathbf{U}\boldsymbol{\Lambda}\mathbf{V}^T$

Exploring drug consumption via an ultrametric correlation matrix

Una analisi del consumo di droghe mediante una matrice di correlazione ultrametrica

Giorgia Zaccaria and Maurizio Vichi

Abstract In many real applications, the existence of a general concept (a multidimensional phenomenon) composed of nested specific ones is often theorised. In the specialised literature, different sequential methodologies have been proposed to identify a hierarchy of latent dimensions. In this paper, we investigate drug consumption via an ultrametric correlation matrix which allows to detect different, nonoverlapping groups of drugs and their hierarchical relationships, starting from the correlation matrix of the observed data. Since its social and economic relevance, a model-based approach to drug consumption can provide an in-depth understanding of this challenging phenomenon, which turns out to be fundamental to address policies aimed at reducing it.

Abstract *In molte applicazioni l'ipotesi dell'esistenza di un concetto generale (un fenomeno multidimensionale), definito mediante concetti più specifici, è spesso avvalorata. In letteratura, molteplici metodologie di tipo sequenziale sono state proposte con lo scopo di identificare una gerarchica di dimensioni latenti. In questo articolo indaghiamo il fenomeno del consumo di droghe mediante una matrice di correlazione ultrametrica, che permette di individuare diversi, disgiunti gruppi di droghe e le loro relazioni gerarchiche, a partire dalla matrice di correlazione dei dati osservati. Data la sua rilevanza sociale ed economica, un approccio basato su modello per lo studio del consumo di droghe può fornire una conoscenza più approfondita di tale fenomeno, che a sua volta può risultare fondamentale nella definizione di politiche volte alla sua riduzione.*

Key words: Hierarchical structures, drug consumption, ultrametric correlation matrix, dimensionality reduction

1 Introduction

The identification of a hierarchy of nested latent concepts is a considerable aspect in the study of phenomena composed of different facets. Manifold methodologies as higher-order factor models [1, 10] and hierarchical factor models [9, 11] deal with the problem of the construction of a general latent concept via a hierarchy of more specific ones. In order to detect consistent groups of variables and their hierarchical factorial structure, [2] propose a novel exploratory, parsimonious and simultaneous model which is based upon the estimation of an ultrametric correlation matrix to reconstruct the relationships between the observed variables, i.e., within groups of variables and between them.

In many fields as the psychometric and marketing ones, the detection of latent dimensions with different relationship intensities is a crucial need for a correct and all-around understanding of the phenomenon under study, along with the dimensionality reduction of the variable space. In this paper, we demonstrate the large-scale applicability of the model proposed by [2] with its application to the phenomenon of drug consumption. The latter is one of the most challenging problems in the modern societies. Indeed, drug consumption contributes to rise the risk of poor health, crimes, social harm, environmental damage and it has become a social problem over years - especially among young people - governments have to face with. Many studies have been developed to analyse drug consumption, its individual and community effects, e.g., [8]. Therefore, an in-depth analysis of this phenomenon through the aforementioned model - which identifies groups of drugs highly correlated and their (hierarchical) relationships - can contribute to its better understanding and to consequently implement policies aimed at reducing it.

The paper is organised as follows. In Section 2 the methodology used to investigate the phenomenon under study is presented and in Section 3 it is applied on the Drug Consumption data set to stress its usefulness. Finally, in Section 4 some conclusions end the paper.

2 Methodology

The exploratory, parsimonious and simultaneous model, called *Ultrametric Correlation Model* (UCM) and proposed by [2], introduces a novel approach to the identification of hierarchical structures of latent variables (concepts). Indeed, starting from a nonnegative correlation matrix, the UCM estimates highly correlated, nonoverlapping groups of variables and different levels of relationships among them in a least-squares framework. The model is mathematically represented by an ultrametric correlation matrix, whose definition gives rise to a hierarchical structure of variable groups as detailed below. Let us consider the following correlation matrix of order J which is composed of 3 variable groups such that $J_1 + J_2 + J_3 = J$, where J_q, $q = 1,2,3$, is the number of variables in the q^{th} group (g_q).

$$\mathbf{R} = \begin{bmatrix} \begin{matrix} 1 & & \\ & 1 & r_{g_1}^{\text{Within}} \\ & & \ddots \\ & & 1 \end{matrix} & r_{g_1,g_2}^{\text{Between}} & r_{g_1,g_3}^{\text{Between}} \\ & \begin{matrix} 1 & & \\ & 1 & r_{g_2}^{\text{Within}} \\ & & \ddots \\ & & 1 \end{matrix} & r_{g_2,g_3}^{\text{Between}} \\ & & \begin{matrix} 1 & & \\ & 1 & r_{g_3}^{\text{Within}} \\ & & \ddots \\ & & 1 \end{matrix} \end{bmatrix}$$

Within each block of the matrix $\mathbf{R}$, the correlation between variables assumes the same value: $r_{g_q}^{\text{Within}}$, $q = 1,2,3$ represents the correlation within the q^{th} group, whereas $r_{g_q,g_p}^{\text{Between}}$, $q,p = 1,2,3\,(p \neq q)$, represents the correlation between the q^{th} and the p^{th} group. $\mathbf{R}$ is an ultrametric correlation matrix if it satisfies the following conditions[1]:

(i) $r_{g_q,g_p}^{\text{rel}} = r_{g_p,g_q}^{\text{rel}}$ for rel $\in \{\text{Within, Between}\}$, $p,q = 1,2,3$ (symmetry);

(ii) $r_{g_q}^{\text{Within}} \geq \max\{r_{g_q,g_p}^{\text{rel}} : q = 1,2,3\}$ for all $p = 1,2,3$, where rel = Within if $q = p$, rel = Between, otherwise (column pointwise diagonal dominance);

(iii) $r_{g_q,g_p}^{\text{rel}} \geq \min\{r_{g_q,g_h}^{\text{rel}}, r_{g_p,g_h}^{\text{rel}}\}$, for all $q,p,h = 1,2,3$ and rel $\in \{\text{Within, Between}\}$ (ultrametric inequality).

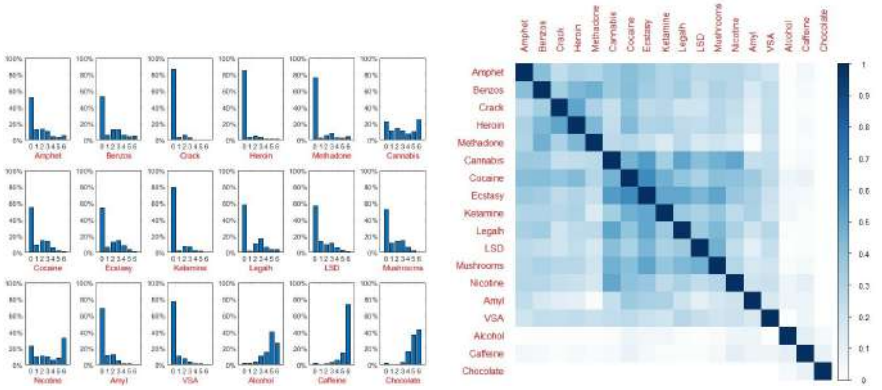
Thus, the ultrametric correlation matrix $\mathbf{R}$ of the UCM model identifies higher correlations within groups of variables and lower (and hierarchically ordered) correlations between those groups by giving rise to a hierarchy of nested latent concepts, each one associated with a variable group. The aforementioned conditions can be easily generalised to Q groups of variables.

3 Drug consumption: evaluation of the hierarchical relationships between groups of drugs

The data set analysed in the paper herein[2] [6] contains information on 1885 respondents, mainly coming from UK (55.58%), USA (29.55%), Canada (4.62%) and Australia (2.86%) and aged from 18 years old, on their drug consumption. Specifically, the use of 18 legal (alcohol, caffeine, chocolate, nicotine) and illegal (am-

[1] The definition of the ultrametric correlation matrix provided herein is based upon [5, pp.58-59].

[2] Drug consumption (quantified) data set available at: `https://archive.ics.uci.edu/ml/datasets/Drug+consumption+\%28quantified\%29`.



(a) Bar chart of the 18 ordinal variables

(b) Correlation matrix of the quantified data via the CatPCA

Fig. 1: Drug consumption data set.

phetamines, amyl nitrite, benzodiazepine, cannabis, cocaine, crack, ecstasy, heroin, ketamine, legal highs, LSD, methadone, mushrooms, Volatile Substance Abuse) drugs is investigated in terms of ordinal variables. The response classes are the following: *Never Used, Used over a Decade Ago, Used in Last Decade, Used in Last Year, Used in Last Month, Used in Last Week* and *Used in Last Day*.

In order to apply the methodology described in Section 2 to investigate the correlation structure among drugs, the ordinal variables - each one representing consumption of a specific drug - have to be quantified. This quantification is implemented via the Categorical Principal Component Analysis (CatPCA) [7] and the correlation matrix of the corresponding quantitative variables is computed. Six correlation coefficients assume negative values (not lower than[3] -0.05) which turn out to be statistically nonsignificant; whereas, the variable *Chocolate* has negative correlations with all the other drugs (Figure 1a) - except for *Alcohol* and *Caffeine* - which are not lower than -0.09 and considered nonsignificant in literature [6]. For this reason, in both cases the negative correlations are set to zero such that the non-negativity condition necessary for the UCM holds (Figure 1b). Furthermore, the number of the variable groups necessary to implement the exploratory, parsimonious model described in Section 2 is set according to the scree plot and it is equal to five. It is worthy of remark that hierarchical clustering methods could be implemented to study the correlation between usage of different drugs, but they would not guarantee the correct identification of the underlying hierarchical structure [3].

The application of the model described in Section 2 to the aforementioned data set provides a representation of drug consumption through the identification of different groups of drugs mostly correlated (Figure 1b), and broader ones defined by merging the initial five groups (Figure 2). In this framework, a model-based ap-

[3] In this case, the term *not lower than* refers to small negative correlation coefficients close to zero.

Table 1: Initial five groups identified by the Ultrametric Correlation Model.

Group	Group Name	Variables
Group 1	Depressant and Artificial Drugs	Ampeth, Benzodiazepine, Crack, Heroine, Methadone
Group 2	Stimulant Drugs and Hallucinogens	Cannabis Cocaine, Ecstasy, Ketamine, Legal highs, LSD, Mushrooms, Nicotine
Group 3	Inhalant Drugs	Amyl nitrite, Volatile Substance Abuse
Group 4	Legal Drugs of Daily Use	Alcohol, Caffeine
Group 5	Chocolate	Chocolate

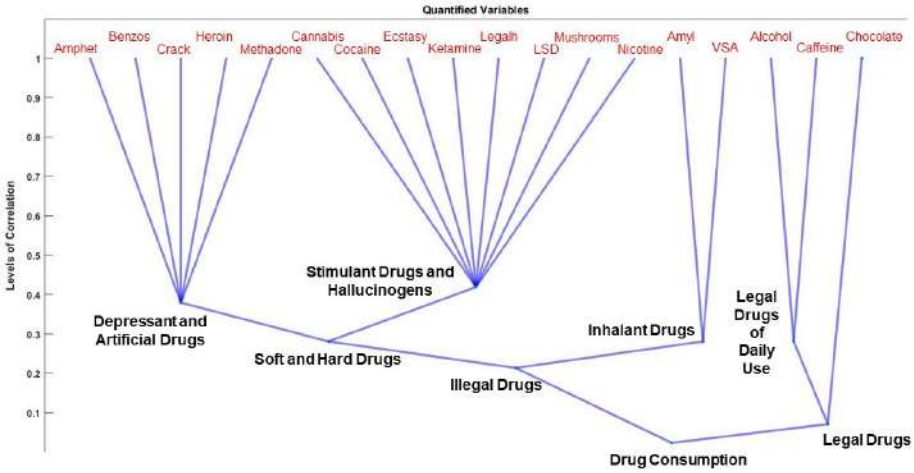


Fig. 2: Path diagram representation of the drug consumption.

proach to analyse correlations between variables can back up the experts' theories on this phenomenon. The initial five groups identified by the model are reported in Table 1. All of them are reliable according to the Cronbach's alpha (α) [4], except for *Inhalant Drugh* and *Legal Drugs of Daily Use*. It is worthy of remark that the Cronbach's alpha of a group is affected by its number of variables.

The hierarchy over the five groups gives rise to broader concepts: *Soft and Hard Drugs* obtained by lumping together Group 1 and Group 2 ($\alpha = 0.87$); *Illegal Drugs* obtained by merging the latter with Group 3 ($\alpha = 0.87$); *Legal Drugs* obtained by lumping together Group 4 and Group 5 ($\alpha < 0.7$). The existence of a general construct representing *Drug Consumption* is assessed through the Cronbach's alpha of the whole data set, which is equal to 0.84. These results turn out to be coherent with the specialised literature on drug consumption (e.g., [6]).

4 Conclusions

In many real applications, the existence of a general concept composed of nested specific ones is often theorised. Manifold sequential methodologies aim at building

a hierarchy of dimensions starting from the observed variables. [2] propose a novel parsimonious and simultaneous model in order to pinpoint latent concepts, each one associated with a variable group, and explore their hierarchical relationships by investigating the correlation matrix of the observed data. In this paper, the aforementioned model is applied to a Drug Consumption data set to study the relationships between groups of drugs. Since its social and economic relevance, a model-based approach to drug consumption analysis can provide a better understanding of the phenomenon which can be fundamental to address policies aimed at reducing it. The results of the application of the model proposed by [2] on the aforementioned data set pinpoint a hierarchy of drug groups which is coherent with the studies on drug consumption (e.g., [6]); this confirms the importance of the UCM in applications where a hierarchical factorial structure can be estimated.

Ranking extraction in ordinal multi-indicator systems

Costruzione di ranking in sistemi multidimensionali di indicatori ordinali

Marco Fattore and Alberto Arcagni

Abstract In this paper, we present a procedure for scoring and ranking statistical units in ordinal multi-indicator systems, by integrating classical dimensionality reduction tools and novel results in Partial Order Theory. Units are ranked based on "dominance" scores, which depend upon both the structure of the partial order and the joint frequency distribution. Dominance scores are complemented with scores of incomparability among units, so to assess the ranking quality. The procedure is computationally light and is here applied to data about financial literacy in Italy.
Abstract In questo articolo, presentiamo una procedura per la costruzione di ranking di unità statistiche, valutate su sistemi multidimensionali di variabili ordinali. La procedura integra algoritmi di riduzione della dimensionalità e recenti risultati della Teoria degli Ordinamenti Parziali, e ordina le unità in base a punteggi di "dominanza", che dipendono dalla struttura dell'ordinamento parziale e dalla distribuzione di frequenze congiunte. Al punteggio di dominanza è affiancato un punteggio di "incomparabilità", per valutare la qualità del ranking. La procedura è computazionalmente leggera ed è qui esemplificata su dati relativi alla competenza finanziaria in Italia.

1 Introduction

Let $\boldsymbol{v}_1,\ldots\boldsymbol{v}_k$ be a system of k ordinal variables, on scales with $m_1,\ldots m_k$ degrees, recorded on n statistical units. Each unit u is associated a score profile $\boldsymbol{u} = (u_1,\ldots,u_k)$, composed of variable scores, among the $m = m_1 \cdot \ldots \cdot m_k$ possible different score configurations. Since the input variables are ordinal, such m score configurations can be partially ordered according to the *product order* rule [1, 2, 4], i.e. given two profiles $\boldsymbol{x}_i = (x_{i1},\ldots,x_{ik})$ and $\boldsymbol{x}_j = (x_{j1},\ldots,x_{jk})$, we put $\boldsymbol{x}_i < \boldsymbol{x}_j$ if and only if $x_{ih} \leq x_{jh} \forall h = 1,\ldots,k$ and there exists an index z such that $x_{iz} < x_{jz}$. Many units can share the same profile and so we are naturally led to consider distributions on product orders, as the typical data structure arising from assessing statistical populations against ordinal multi-indicator systems. The classical problem of ranking units based on their multidimensional profiles is thus the problem of reducing the dimensionality of frequency distributions defined on product orders. In the following, we propose an algorithm to solve this issue.

2 The lexicographic dominance and incomparability matrices

As any finite partially ordered set, a product order π over k ordinal variables can be uniquely reconstructed by means of its set of *linear extensions*, i.e. of linear orders obtained from π, by ordering all non-comparable configuration pairs, in all possible ways. As shown in [6], however, being a product order π can also be reconstructed by using the subset of so-called *lexicographic linear extensions* (LLEs). These are linear orders where score configurations are ordered in "alphabetic fashion", with respect to all possible permutations of the k input variables; thus, there are $k!$ LLEs and these suffice to generate the product order associated to $\boldsymbol{v}_1,\ldots\boldsymbol{v}_k$. LLEs are the key tool for scoring and ranking units, as they bring information on the relative positions of score configurations, in the product order.

Informally speaking, to rank units we want to associate to each of them a dominance score, reflecting to what degree a unit is placed "higher" than the others, in π. As a first step to this goal, we compute the dominance score P_{ij} between two profiles $\boldsymbol{x}_i$ and $\boldsymbol{x}_j$, as the fraction of LLEs in which $\boldsymbol{x}_i$ is placed below $\boldsymbol{x}_j$. Scores P_{ij} are called *lexicographic mutual ranking probabilities* (LMRPs) and can be computed analitically, as shown in the following proposition.

Proposition. Let $\boldsymbol{v}_1,\ldots\boldsymbol{v}_k$ be a system of k ordinal variables, on scales with $m_1,\ldots m_k$ degrees, and let $\boldsymbol{x}_i = (x_{i1},\ldots,x_{ik})$ and $\boldsymbol{x}_j = (x_{j1},\ldots,x_{jk})$ be two profiles on it. Let k_1 be the number of indices h such that $x_{ih} < x_{jh}$ and let k_2 be the number of indices h such that $x_{ih} = x_{jh}$. Then:

$$P_{ij} = \frac{k_1}{k} \sum_{s=0}^{k_2} \frac{k_2!}{(k_2-s)!} \frac{(k-s-1)!}{(k-1)!}. \tag{1}$$

Proof. Since the set of LLEs is in bijective correspondence with that of all permutations of variables, we can identify a LLE λ with a permutation $l_1,\ldots,l_k$ of $\{1,\ldots,k\}$. With this notation, the subset G of LLEs such that $\boldsymbol{x}_i < \boldsymbol{x}_j$, can be partitioned as $G = G_0 \cup \ldots \cup G_{k_2}$, where sets G_s and their cardinalities are given by:

1. $G_0 = \{\lambda \,|\, x_{il_1} < x_{jl_1}\} \rightarrow |G_0| = k_1 \cdot (k-1)!$
2. $G_1 = \{\lambda \,|\, x_{il_1} = x_{jl_1}, x_{il_2} < x_{jl_2}\} \rightarrow |G_1| = k_2 \cdot k_1 \cdot (k-2)!$
3. $G_2 = \{\lambda \,|\, x_{il_1} = x_{jl_1}, x_{il_2} = x_{jl_2}, x_{il_3} < x_{jl_3}\} \rightarrow |G_2| = k_2 \cdot (k_2-1) \cdot k_1 \cdot (k-3)!$
4. $\ldots$
5. $G_{k_2} = \{\lambda \,|\, x_{il_1} = x_{jl_1}, \ldots, x_{il_{k_2}} = x_{jl_{k_2}}, x_{il_{k_2+1}} < x_{jl_{k_2+1}}\} \rightarrow |G_{k_2}| = k_2 \cdot (k_2-1) \cdot \ldots \cdot 1 \cdot k_1 \cdot (k-k_2-1)! = k_2! k_1 \cdot (k-k_2-1)!$.

Summing up all of the cardinalities and dividing by the total number of LLEs ($k!$), we get

$$P_{ij} = P(\boldsymbol{x}_i < \boldsymbol{x}_j) = \frac{|G_0| + \ldots + |G_{k_2}|}{k!} = \frac{k_1}{k}\Big[1 + \frac{k_2}{k-1} + \frac{k_2(k_2-1)}{(k-1)(k-2)} + \\ + \frac{k_2(k_2-1)(k_2-2)}{(k-1)(k-2)(k-3)} + \ldots + \frac{k_2!}{(k-1)(k-2)(k-3)\ldots(k-k_2)}\Big] = \\ = \frac{k_1}{k}\sum_{s=0}^{k_2}\frac{k_2!}{(k_2-s)!}\frac{(k-s-1)!}{(k-1)!}.$$

q.e.d.

LMRPs are used as entries of the *lexicographic dominance matrix* P, which is later used to derive the final dominance scores associated to units. Making all profiles comparable, by means of dominance scores, is unavoidably forcing and stretches the data structure, since it destroys the incomparabilities existing in π. In order to keep control on this kind of "distorsion", we complement matrix P with a *lexicographic incomparability matrix* Q, whose entries are defined as $Q_{ij} = \min(P_{ij}, P_{ji})$ $(i \neq j)$ and $Q_{ii} = 0$. The rationale behind this definition is straightforward: the more one profile dominates the other, the less the two are incomparable (the choice of putting the diagonal elements of Q equal to 0 is to assure the maximum incomparability degree between two profiles to be 0.5: this choice has no essential consequences on the subsequent developments). By the above definition, it follows immediately that Q is symmetric.

3 The scoring functions

As in [7], we assign global dominance (*dom*) and incomparability (*inc*) scores to each profile in the input poset, based on the singular value decompositions of P and Q. However, in order to take into account the distribution of units on π, here we weight P and Q with the relative frequencies over poset profiles. Let s_i be the share

of statistical units with profile $\boldsymbol{x}_i$ and let $S = diag(s_1, \ldots, s_m)$. The i-th column of SP comprises the LMRPs of $\boldsymbol{x}_i$, with respect to all of poset profiles, multiplied by the relative frequency corresponding to each of them. In other words, it comprises the probabilities of randomly and independently extracting a statistical unit u and a LLE λ, such that the profile of u is $\boldsymbol{x}_j$ ($j = 1, \ldots, m$) and $\boldsymbol{x}_j$ is not above $\boldsymbol{x}_i$, in λ. Now, let $SP = UD_PV^T$ be the singular value decomposition of matrix SP. From $D_PV^T = U^TSP$, we see that the i-th component dom_i of the first row of D_PV^T is a weighted sum (with non-negative weights, by the Perron-Frobenius Theorem) of such probabilities and can be then interpreted as an overall dominance score of a unit with profile $\boldsymbol{x}_i$, over the other units. As proved in [7][1], the map associating to $\boldsymbol{x}_i$ the dominance score dom_i is *strictly-order preserving* and can serve as a *dominance score function*. Similarly, we take, as global incomparability degrees associated to poset profiles, the components of the first row of D_QB^T, in the singular value decomposition $SQ = AD_QB^T$. In summary, to each profile $\boldsymbol{x}_i$ of the input poset there corresponds a pair (inc_i, dom_i) of incomparability-dominance scores, computed as the i-th components of the first rows of D_QB^T and D_PV^T, respectively. Finally, each statistical unit in the dataset inherits the score pair of its profile and can be mapped into an incomparability-dominance plane, getting both a ranking and a picture of the stretching of the data.

4 Ranking financial literacy in Italy

We have applied the procedure outlined above to data pertaining to financial literacy of Italian adults, collected by Bank of Italy for year 2018 [3]. The survey involved about 2500 respondents, investigating financial knowledge by means of 7 questions, pertaining to different financial notions[2], whose answers are simply classified as *right* or *wrong*. The resulting product order is called 2^7 and has in fact $2^7 = 128$ binary profiles, with $7! = 5040$ lexicographic linear extensions. Dominance and incomparability matrices have been built weighting the LMRPs by the share of respondents in each knowledge profile, also considering the sample weight of each unit. By performing singular value decompositions, each unit has been finally associated the incomparability-dominance score pair. Figure 1 and 2 reproduce the distributions of such pairs for age classes 18-50 and 51+, spatially smoothed to give a more realistic impression of the score patterns. The two plots are scaled to 0-1 on the dominance axis, and the incomparability axis is scaled to 0-0.3 instead due to the small values observed. Units answering correctly all of the questions are scored 1 on the dominance axis, while those providing all wrong answers are scored 0. The value 1 on the incomparability axis corresponds to the theoretical maximum incomparabilty score of a statistical unit, over all possible distributions on the input poset

[1] The pre-multiplication by S does not affect the proof, since all elements of a row are multiplied by the same non-negative quantity.

[2] Questions check knowledge about *inflation*, *simple/compound interest* and *risk management*.

2^7. Consequentially, the small values reported on the incomparability axis mean that the respondents can be reasonably ranked since most of the observed profiles are "almost" comparable. In both age classes the density tends to be concentrated on middle-hìgh dominance scores (more black areas), with evidences of some polarization and the existence of a group of financially illiterate units, separated by the rest of the distribution. Interestingly, older people seem to have more financial competencies than younger subjects; given the increasing relevance of financial products and services for personal lifelong economic sustainability, this appears as a critical feature of the Italian financial literacy distribution. Finally, notice that having similar incomparability degrees need not imply having similar answer profiles, so that care must be taken in interpreting the plot as revealing homogeneous respondent clusters.

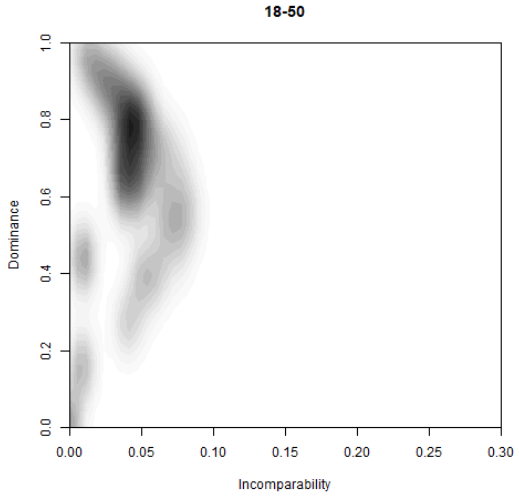

Fig. 1 Smoothed distribution of dominance and incomparability scores related to financial literacy in Italy, for age 18-50. Grey intensity is proportional to frequency density.

5 Conclusions

In this short paper, we have presented a ranking procedure for ordinal multi-indicator systems, which: (i) fully respects the ordinal nature of the data and does not involve any scaling or aggregation of ordinal variables, (ii) is computationally light and can be applied to datasets with a quite large number of variables (possibly, using approximations to the factorial in the computation of LMRPs) and (iii) also provides measures of incomparability among units, so as to keep control on the

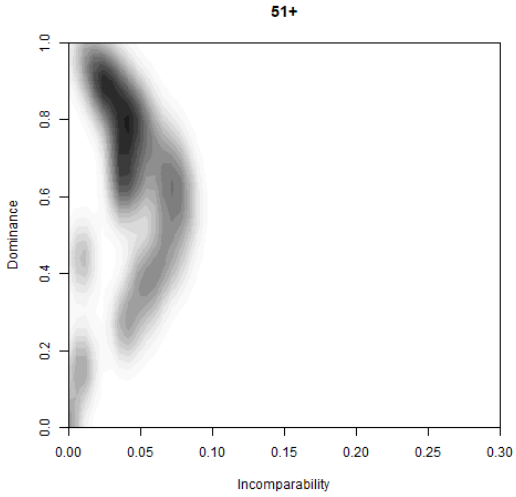

Fig. 2 Smoothed distribution of dominance and incomparability scores related to financial literacy in Italy, for age 51+. Grey intensity is proportional to frequency density.

quality of the ranking process which, as any dimensionality reduction algorithm, unavoidably introduces some distortion into the final data representation. The procedure is freely available in the R package Parsec [5].

Gender statistics

Gender differences in Italian STEM degree courses: a discrete-time competing-risks model

Differenze di genere nelle lauree STEM: un modello a rischi competitivi a tempi discreti

Marco Enea and Massimo Attanasio

Abstract In this paper, we highlight possible gender differences in performance of students attending Italian university STEM degree courses, controlling for socio-demographic and territorial variables. We used the micro-data from the Italian Ministry of Education, Universities and Research database of the 2011-12 freshmen cohort enrolled at an Italian bachelor university degree course. The analysis was dealt with by fitting a discrete-time competing-risks model. Bachelor degree graduation, dropout, and change to non-STEM courses were considered as competing events. The aim is to highlight gender gaps in the student performance, and the STEM courses where this gap is more critical.

Abstract *In questo articolo mettiamo in luce le differenze di genere nelle prestazioni degli studenti italiani che frequentano un corso di laurea STEM, controllando per variabili socio-economiche e territoriali. Abbiamo usato i micro dati del database del Ministero dell'istruzione, dell'universitá e della ricerca della coorte 2011/12 di immatricolati in un corso di laurea triennale. L'analisi é stata effettuata adattando un modello a rischi competitivi e a tempi discreti. Il conseguimento della laurea triennale, l'abbandono e il passaggio di corso verso un non STEM sono stati considerati come eventi competitivi. L'obiettivo é quello di mettere in luce differenze di genere nella performance degli studenti e il corso di laurea STEM in cui tale gap é piú critico.*

Key words: Gender differences, student performances, STEM degree courses

1 Introduction

STEM (Science, Technology, Engineering and Mathematics) is the acronym commonly used to indicate a group of disciplines related to the scientific and technological fields. The Program for International Student Assessment (PISA), an international survey promoted by OECD countries with the objective to periodically assess the levels of education of teenagers of the most industrialized countries, highlights that in most countries, boys outperform girls in science and mathematics. This gap was recently confirmed for the Italian case [1, 2].

In this paper, we investigate about the gender gap in STEM at university following a different approach from PISA survey. PISA consists of scores given to assessment tests, while our research compares gender performances in Italian university courses through dropout and degree completion rates. Our research questions are: is it true that males outperform females at university in STEM courses? Is it true for all STEM courses?

2 Data and preliminary analysis

The data we analyzed were directly provided by the Italian Ministry of Education, Universities and Research (MIUR) through an agreement between the Ministry and some Italian universities [3]. The database consists of around 280.000 records for each cohort from 2008-09 to present. The records are longitudinal micro-level data reporting the students career since his/her enrolment. For the current analysis, we have chosen the 2011-12 freshmen cohort which allows a longer follow-up. We have restricted our analysis to the STEM bachelor (BA) degree courses, excluding the online degree courses, for a total of 61982 freshmen. Because there is not an exact correspondence between 3-year STEM degree courses for all countries, we considered our STEM classification as listed in Table 1, were the percentage of males and females is also reported, as well as the one of the 2015/16 cohort, to have a comparison with a more recent cohort. In that list, we included all the basic scientific courses (following the "Piano Nazionale Lauree Scientific" classification) plus the engineering courses. Among the STEM courses of the 2015/16 cohort, females are under-represented in computer science, engineering, physics, geology and statistics, while they are almost equally represented in chemistry and mathematics. Instead, biology, biotechnology, and environmental and natural sciences are STEM courses were females are numerically more represented than males. The larger difference between the two cohorts concerns a seven points decrease of females enrolments in physics. To detect the effect of socio-demographics and territorial factors, a discrete-time competing-risks model was fitted. Bachelor degree graduation, dropout, and change to non-STEM courses were used as outcomes. Table 2 reports the students' follow up flows by gender and type of competing event. At the end of the first A.Y. the student can dropout but he/she cannot change degree course because early changes are not recordered. Regular BA graduations are, by definition, observed within the end of the third A.Y.

3 The discrete-time competing-risks model

The model selected is a discrete-time multinomial logistic regression model. Data is censored after 6 years since enrolment, as the seventh year follow-up is incomplete. By indicating with $p(t|z)$ the probability of BA graduation at time t, conditioned to a covariates vector z, the model is

$$\log\left(\frac{p^{(j)}(t|x;z)}{p^{(0)}(t|x;z)}\right) = \sum_{t=1}^{6} \alpha_t^{(j)} + \delta^{(j)\prime} X^{(j)}, \tag{1}$$

with $j = 1,2,3$, corresponding to the event "BA graduation", "BA dropout" or "change to a non-STEM degree course", respectively. $p^{(0)}(t|x;z)$ is the probability

for the reference category, that is the probability of being "still at risk" at time t, for the student with covariate profile given by the vector x. At the same way, $p^{(j)}(t|x;z)$ is the probability of the j-th event at time t, for the student's profile specified by x. The parameters $\alpha^{(j)}(t=k), \quad k=1,2,\ldots,6$, are the time-dependent NPO intercepts, $\delta^{(j)\prime}X^{(j)}$ is the NPO linear predictor for the j-th multinomial equation. The intercepts are assumed to vary along with the time, while the covariates effects are assumed time-independent for simplicity. Parameter interpretation is done in terms of *relative risk ratio* i.e. $\exp(\delta^{(j)})$ is the multiplicative effect of a 1-unit increase in x on the risk of event type j versus the risk that no event occurs [4]. Table 3 reports a description of the covariates used in the model.

Table 3 Description of the covariates used in the model for the BA.

Variable	type	Description
Time	discrete	Time (in years) since BA enrolment
Macropath	categorical	Macro-Regional (MR) Path to BA enrolment: <MR before BA enrolment> - <MR of BA enrolment>
STEM	categorical	STEM degree course typology
Irregular_age	binary	1= Student's year of birth $<$ 1992
Gender_M	binary	1= male gender
HighSchool_type	categorical	Classical, Scientific, Technical, Vocational, Other
High School_mark	categorical	High School final mark with three levels [60-70), [70-90),[90,102]

The linear predictor includes several two-way interactions of gender with all covariates, but Irregular_age which was not significant, plus the interaction High-School_mark and HighSchool_type. The baseline student profile is: female, Irregular_age=0, Macropath="North-North", STEM="Biology", HighSchool_mark="$[60,70)$", HighSchool_type="Other liceo". Estimates of this model are reported in Table 4.

Females have more success in terms of BA graduation in geology, biology, biotechnology and statistics, while they seem to suffer all the remaining STEM courses, especially mathematics, where males outperform females. Math has also the highest dropout rates for both males and females, and where females also do decide to change towards non-STEM degrees, while males do not. In general, males and females have similar behaviours about dropping out, while females are more prone than males to change course, except biology and biotechnology, which are the courses where both males and female are highly probable change to non-STEM degrees. However, this latter result is mainly due to a consolidated practice of students to change towards the medicine degree course, because the advantage that biology and biotechnology have similar first-year subjects than can be validated in the new course. HighSchool_mark, HighSchool_type and Macropath play an important role in detecting possible gender differences in students' performance.

Figure 1 highlights macro-regional differences by showing, for a regular-age student coming from the scientific high school with a $[70,90)$ mark, the estimated hazard of the three outcomes distinguishing by Southern and Northern students and by gender and by few courses.

Table 4 Estimates from the discrete-time competing-risks model fitted on the 2011/12 data cohort.

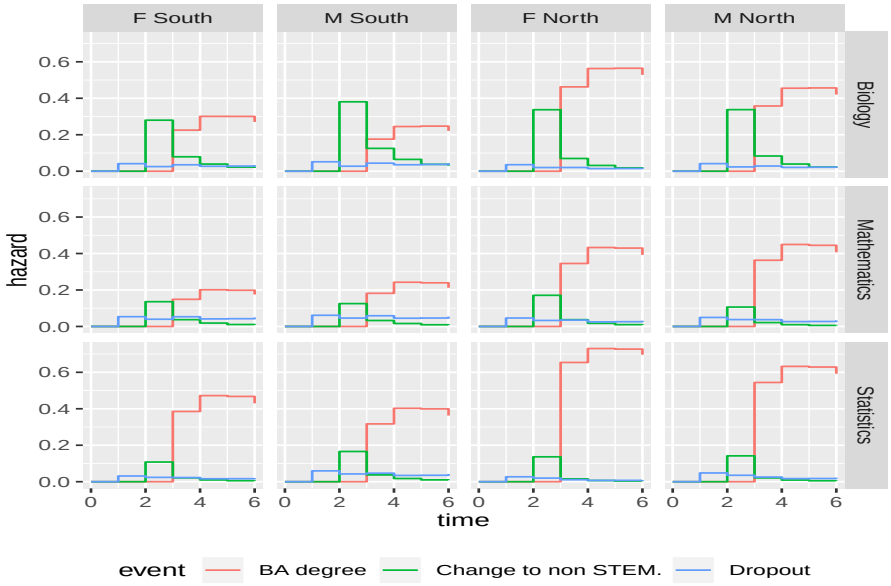

Fig. 1 Probabilities of either BA graduation, BA dropout, or Change to non-STEM degree courses, by macro-region and gender in three STEM courses, for selected students' profiles (regular-age student coming from the scientific high school with a $[70,90)$ mark) .

4 Conclusions

We aimed at detecting possible gender differences in performances of students attending a STEM degree course in an Italian university. Preliminary results highlight the females are under-represented in STEM courses, except for biology, biotechnology, and environmental and natural sciences. Geology, biology, biotechnology and statistics are courses where females have more success in terms of BA graduation are, while they seem to suffer all the remaining STEM courses, especially mathematics, where males outperform males. In general, males and females have similar behaviours about dropping out, while females are more prone to change course.

Some Challenges and Results in Measuring Gender Inequality

Alcune sfide nella misura della disuguaglianza di genere

Fabio Crescenzi, Francesco Di Pede

Abstract In this paper, we show some challenges and results on gender statistics at national and international level. The geo-referencing of statistical information will allow Istat, through the integrated system of registers (SIR), to release statistical and geographical information with a strong territorial detail and will allow users to know more on the longitudinal evolution of data and this will have a potential strong impact also on gender statistics.
Considering the importance given to name of urban places to show the disequilibrium in representing women who have contributed, in all fields, to improving society, we will show some preliminary results obtained analyzing the gender of personalities whose name is in the streets of the National archive of streets.

.

Abstract *In questo articolo mostriamo alcune tra le principali sfide e risultati sulle statistiche di genere a livello internazionale e nazionale. La georeferenziazione delle informazioni statistiche consentirà all'Istat, attraverso il sistema integrato di registri (SIR), di rilasciare informazioni statistiche e geografiche con un forte dettaglio territoriale e consentirà agli utenti di saperne di più sull'evoluzione longitudinale dei dati e questo avrà un potenziale forte impatto anche sulle statistiche di genere.*
Considerando l'importanza data al nome dei luoghi urbani per mostrare lo squilibrio della presenza di donne che hanno contribuito, in tutti i campi, al miglioramento della società, mostreremo alcuni risultati preliminari ottenuti analizzando il genere delle personalità il cui nome è nelle strade dell'archivio nazionale di strade.

Key words: Gender statistics, Geo-referencing, Streets Names, Place Names.

1 Introduction

The Global Gender Statistics Programme is mandated by the United Nations Statistical Commission, implemented by the United Nations Statistics Division (UNSD) and coordinated by the Inter-Agency and Expert Group on Gender Statistics IAEG-GS [4]. The Programme encompasses:

- improving coherence among existing initiatives on gender statistics through international coordination.
- developing and promoting methodological guidelines in existing domains as well as in emerging areas of gender concern.
- strengthening national statistical and technical capacity for the production, dissemination and use of gender relevant data.
- facilitating access to gender relevant data and metadata through a newly developed data portal.

UNSD serves as Secretariat of the Inter-Agency and Expert Group on Gender Statistics (IAEG-GS), the coordinating and guiding body of the Global Gender Statistics Programme. The IAEG-GS was first convened in 2006, meets annually and functions through advisory groups. Presently, the main advisory group's work concentrates on examining emerging and unaddressed key gender issues and related data gap with the aim to develop proposals on how to fill these gaps.

This website[1] serves as a platform for the dissemination of developments in the field of gender statistics and promotes the inclusion of gender statistics into all fields of statistical activities at both the national and international levels[2].

One of the emerging data field collection concern SDGs indicators[3], the main results are presented in the national SDGs report [5]

In the other sections of this paper, we will consider some of the main challenges faced in the field of gender statistics at national level. The geo-referencing of statistical information will allow Istat, through the integrated system of registers (SIR), to release statistical and geographical information with a strong territorial detail and will allow users to know more on the longitudinal evolution of data and this will have a potential strong impact also on gender statistics.

Considering the importance given to name of urban places to show the disequilibrium in representing women who have contributed, in all fields, to improving society, we will show some preliminary results obtained analysing the gender of personalities whose name is in the streets of the National archive of streets.

The use of big data in gender violence analysis was presented and discussed in a Workshop "Big Data e Violenza di Genere, Metodologie a supporto dell'analisi del sentiment " which was held at the National Institute of Statistics (Istat) on February 7, 2020. [1,4,6,7]

[3] 1. https://unstats.un.org/sdgs/indicators/database/

2 The Integrated System of Registers (SIR), a formidable source of data for future gender statistics.

In the modernization plan of Istat data from administrative sources and statistical surveys are integrated in the SIR covering the demographic, social, economic and environmental domains. The Base registers are connected by codes and are maintained updated over time using administrative sources and statistical surveys [2 8 9 10]. A greater use of administrative and statistical data sources will allow minimizing the burden on respondents and costs of field data collection. RSBL, (the Italian Statistical Base Register of Territorial Entities), is one of the pillars of SIR which integrates information from many different sources of geographical data [3], with the aim to improve the geo referencing of data. The aim is to build the register only once, to keep it updated, and to use it in all statistical processes.
The geo referencing of statistical information will allow Istat, through the integrated system of registers, to release statistical and geographical information with a strong territorial detail and will allow users to know more on the structure and composition of the territory of Italy. RSBL is a multidimensional register integrating several components: addresses, regular grids and micro zones, buildings and housing units, administrative zones, statistical and functional zones. In the panorama of statistical registers, it represents an innovative way of considering in an integrated way all the most relevant components of territorial data. Moreover, Istat is moving from a decennial census to a permanent census, which will produce census data every year.
SIR represent a formidable source of data also for future gender statistics. Respecting the need to protect privacy, the potential availability of new data to be studied in their longitudinal evolution and territorial distribution is very rich.

3 What street names tell us about gender inequality?

In Italy an associations named *Toponomastica femminile,* founded on Facebook in January 2012, works with the objective of setting up research, publishing data and putting pressure on the society and local authorities to dedicate to women names of streets, squares, gardens and urban places to compensate for the evident disequilibrium that characterizes the current state of the names of places.
The main objective of the associations, which today includes more than 10,000 members, is to spread gender culture, to give visibility to women who have contributed, in all fields, to improving society. Links to conferences and papers on this topic can be found on the association's website[1].
The address component is one of the most important component of RSBL. Addresses in RSBL comes mainly from the National archive of addresses and urban streets (ANNCSU). The Law of May 30, 1989, n. 223 establishes that each municipality compile and update the list of streets and the list of addresses according to the rules issued by the National Statistics Institute. In addition, the Law of 17 December 2012, n. 221, provides for the institution of the

1. [1] https://www.toponomasticafemminile.com/sito/

ANNCSU, made and managed by Istat and the cadastral data of the Land Property Registry. The ANNCSU is the reference database on streets and addresses, which contains information for the entire country in digital format. Each address is geocoded to the Census Enumeration Areas of the Census Mapping. The National Digital Agency recognizes ANNCSU as a core database for the great impact on the transition to the National Register of Resident Population (ANPR) as well as on the many other uses of public interest.
As part of the data processing of the 2011 population census activities, municipal offices verified the misalignment of data and, when necessary, corrected, integrated and validated them.
In the data processing, the National Statistical Office checked the names of the streets and organized them into a complete dictionary. The dictionary contains names in standardized form, each of which can occur in one or multiple cases in different Italian municipalities.
Although work is still in progress, here we present some preliminary results concerning the extraction from the dictionary of the street names that are names of personalities.
Out of 847 names of personalities, 107 refers to females, 737 refers males with an overall gender ratio (number of females/number of males x100) equal to 14,7%. A really poor result, considering that in order to have gender equality this ratio should be equal to 100%.
We continued the analysis by forming groups in relation to the type of personalities found in street names. We got the ten groups listed in **Table 1**:

Table 1: *Groups of personality types found in street names*

Groups	***Examples***
1. Nations and Churches Leaders	Popes, Kings, Emperors, Presidents
2. State Personalities	Politicians, Patriots, Diplomats and Trade unionists
3. Dynastic and Literary Personalities	Dynastic, Aristocrats, Mythological and Literary personalities
4. Religious Figures	Religious, Theologians, Saints and Blessed, Divinities
5. Explorers, Inventors, Heroes, Soldiers	Explorers, Inventors, Heroes, Soldiers
6. Arts and Literature Personalities	Painters, Poets, Writers, Musicians, Historians, Philosophers, Archaeologists
7. Professionals and Business Workers	Lawyers, Magistrates, Doctors, Engineers, Architects, Entrepreneurs, Economists
8. Scientists	Mathematicians, Physicists, Geologists, Astronomers, etc.
9. Metiers Workers	Jewellers, Engravers, Archivists, Educators, Pharmacists, Insurers, etc.
10. Entertainment, Media, Sports Workers	Actresses / Actors, Publishers, Producers, Directors, Singers, Journalists, Photographers, Athletes

We computed the gender ratio by group shown in **Table 2.** The gender ratio is over the overall figure in the following case: Group 3, Dynastic and Literary Personalities (37,5%), Group 10, Entertainment, Media, Sports Workers (37,0), Group 4, Religious Figures (34,5%), Group 9, Metier Workers (16,7%).
The gender ratio is under the overall figure in the following case: Group 7, Professionals and Business Workers (1,4%), Group 5, Explorers, Inventors, Heroes, Soldiers (5,9%), Group 8,

Scientists (6,7%), Group 1, Nations and Churches Leaders (7,7%), Group 6, Arts and Literature Personalities (8,3%), Group 2, State Personalities (10,4%)..

Table 2: Gender ratio by groups

Type	*Females*	*Males*	*Ratios (x100)*
1. Nations and Churches Leaders	3	39	**7,7**
2. State Personalities	14	135	**10,4**
3. Dynastic and Literary Personalities	6	16	**37,5**
4. Religious Figures	49	142	**34,5**
5. Explorers, Inventors, Heroes, Soldiers	3	51	**5,9**
6. Arts and Literature Personalities	17	204	**8,3**
7. Professionals and Business Workers	1	71	**1,4**
8. Scientists	2	30	**6,7**
9. Metiers Workers	2	12	**16,7**
10. Entertainment, Media, Sports Workers	10	27	**37,0**
Total	**107**	**727**	**14,7**

This is only a preliminary result, in the future it will be useful to map this data and analyse the territorial distribution of the gender ratio.
Recently, an example of a geo referencing of this kind of data showed the aerial photos of Italian cities with the streets dedicated to women highlighted in red. The author of this work, the photographer Alessandro Scotti, called it "The Atlas of Misogyny", because the result of the survey is impressive: in the national map of the name of streets, women are marginal, small, sparse red dashes that just they glimpse in a sea of streets. "It is the testimony of the degree of social recognition attributed to the female gender in the cities where we live"[1].

1 https://www.ilmessaggero.it/mind_the_gap/nomi_strade_citta_donne_uomini_mappa_misoginia_censis-4877458.html

4 Conclusions

Many results have already been achieved on gender statistics, however further impetus will have to be given to the study of longitudinal evolutions and the territorial distribution of data.
The use of new sources such as registers, aerial images, big data will help greatly in this direction.

A modal approach for clustering matrices

Un approccio modale al clustering di matrici

Federico Ferraccioli and Giovanna Menardi

Abstract In this work we propose a modal approach to density-based clustering for matrix-valued data. We introduce appropriate kernels for this type of data and define a kernel estimator of matrix-variate density functions. Additionally, we propose an extension of the mean-shift procedure for the identification of the modes of the estimated density. Given the intrinsic high dimensionality of matrix-variate data and the resulting computational complexity of the algorithm, we discuss a possible solution to handle the problem. We finally present the performance of the proposed method through an application to real world data, also with respect to a plausible competitor.
Abstract In questo lavoro viene proposto un approccio modale al *clustering* basato su densità per dati in forma di matrici. Vengono introdotti *kernel* appropriati per questo tipo di dati e definito uno stimatore di densità *kernel* per dati matrice-variati. Viene inoltre proposta un'estensione dell'algoritmo *mean-shift* per l'identificazione delle mode della densità stimata. Data l'elevata dimensionalità dei dati considerati e la conseguente complessità computazionale, si discute una possibile soluzione per gestire questo problema. Vengono infine presentate le prestazioni della metodologia proposta attraverso un'applicazione ad dati reali, confrontandola con un possibile metodo concorrente.

1 Introduction

The analysis of complex data in the form of matrices represents an active area of research. Examples are image data, connectivity maps, as well as data arising from classical longitudinal studies, or modern scientific applications such as brain scans or multi-tissue genome expressions. In the former cases, the data of interest are represented by a collection of matrices, one for each subject. In the latter cases, the statistical observations are represented by vectors of variables, each of them measured on a subject over different times, thus giving a matrix-valued observation for each subject.

While a vast body of literature has focused on the development of supervised methods for matrix-valued data, especially when multivariate observations are gathered over time or in the specific class of semi-definite matrices, far less attention has been devoted to the unsupervised case. For the aim of clustering, scattered contributions which are worth to mention refer to [5, 4, 6].

In this work we extend the *modal*, or *nonparametric* clustering formulation to the framework of matrix-variate data. Here, clusters are identified as the "domains of attraction" of the modes of the true density underlying the data. The issue of density estimation, usually addressed via nonparametric methods, assumes a key role in order to approximate the ideal population goal of modal clustering, along with the operational search of the modal regions.

After providing an overview on modal clustering ideas, we introduce a kernel estimator for matrix-variate density functions, with a special focus on Normal kernels. We then study its asymptotic properties also with reference to the problem of optimal bandwidth selection. Given the intrinsic high dimensionality of matrix-variate data, impacting on both the accuracy of the estimate and the computational complexity, we explore some solution to handle the problem. Additionally, we propose an extension of the mean-shift procedure for the identification of the modes of the estimated density. Finally we illustrate the performance of the proposed method on a set of real data, also with respect to some plausible competitors.

2 An overview on modal clustering

In a standard multivariate setting, *modal*, or *nonparametric*, clustering relies on the assumption that the observed data $\mathscr{X} = (x_1, \dots, x_n)$, are realizations of a multidimensional random variable $x \in \mathbb{R}^p$ with (unknown) probability density function f. The modes of f are regarded to as representatives of the clusters, which are in turn represented by their domains of attraction. Operationally, clustering involves two main choices, which are overviewed in the following. See [3] and references therein for a comprehensive review.

The first choice concerns the estimation of the density function, which determines the high density regions and, hence, governs the final clustering. A standard choice, within the class of nonparametric methods, is the kernel density estimator

$$\hat{f}_h(x) = \frac{1}{n}\sum_{i=1}^{n} K_h(x - x_i),$$

where $K_h(u) = \frac{1}{h}K\left(\frac{u}{h}\right)$ is a probability density on $\mathbb{R}^p$ symmetric around x_i, and with scale parameter the bandwidth $h > 0$, which defines the degree of smoothing. While the choice of the function K is known not to have a strong impact in the performance of the estimate, choosing h properly turns out to be crucial. A small value of h leads to an undersmoothed density estimate, with the possible appearance of spurious modes, while a value too large results in an oversmoothed density estimate, possibly hiding relevant features.

A further aspect to account for in modal clustering, is to operationally characterize the clusters as the domain of attraction of the density modes. Most of the contributions in this direction take their steps from the *mean-shift* algorithm which, starting from a generic point $y^{(0)}$, recursively shifts it to a local weighted mean, until convergence. Denoted by $w_i(y^{(s)})$ the vector of weights of x_i at step s, at the next step $s+1$,

$$y^{(s+1)} = \sum_{i=1}^{n} w_{i,h}(y^{(s)})x_i \quad \text{with} \quad w_{i,h}(y) = \frac{\nabla K_h(y - x_i)}{\sum_{i=1}^{n} K_h(y - x_i)},$$

namely the weights $w_{i,h}(\cdot)$ are specified as normalized components of the gradient of the kernel function. These arguments motivate the mean shift as a gradient ascent algorithm for some specific kernel functions as, e.g., the Normal kernel.

Operationally a partition of the data points is obtained by grouping in the same cluster those observations ascending to the same mode of the density.

3 Matrix-variate extension of modal clustering

3.1 Kernel density estimation of matrix-variate data

Consider a sample $X_1, \ldots, X_n$, of *i.i.d.* realizations of a $p \times t$ random matrix X, which we shall assume to be defined on the vector space $\mathbb{R}^{p,t}$. The (unknown) distribution underlying X is naturally described by some probability density function $f : \mathbb{R}^{p,t} \mapsto \mathbb{R}^+$, with $\int_{\mathbb{R}^{p,t}} f(X)\mathrm{d}X = 1$, being the component-wise integral of $f(X)$ on its support.

Given a symmetric smooth kernel K_h supported on (a subset of) $\mathbb{R}^{p,t}$, scaled by h and with symmetry to be intended along all the $p \times t$ dimensions, we define the *kernel density estimator* for matrix-variate data as

$$\hat{f}_h(X) = \frac{1}{n}\sum_{i=1}^{n} K_h(X - X_i). \tag{1}$$

Asymptotic theory about kernel density estimation can be shown to extend naturally to the matrix-variate setting. With the established convention on defining matrix-variate integrals, for instance, we may define the Mean Integrated Square Error as in the standard multivariate framework, and show that the integrated variance plus squared bias decomposition still holds, so that under some regularity conditions, and as $n \to \infty$, the Asymptotic Mean Integrated Squared Error (AMISE) for estimator (1) is

$$\text{AMISE}(\hat{f}_h(\cdot)) = n^{-1}h^{-(p\times t)}R(K) + \frac{1}{4}h^4 m_2(K)^2 R(\Delta f).$$

where $m_2(K) = \int_{\mathbb{R}^d} z_i^2 K(z)dz$ and $R(a) = \int_{\mathbb{R}^{p,t}} a(X)^2 dX$, The optimal bandwidth which minimizes the AMISE is

$$h_{\text{AMISE}} = \left(\frac{(p\times t)R(K)}{m_2(K)^2 R(\Delta f)}\right)^{\frac{1}{(p\times t)+4}} n^{-\frac{1}{(p\times t)+4}}.$$

As for the univariate and multivariate settings, in the matrix-variate framework a pivotal role is played by the matrix Normal density [1], which represents a natural candidate for the kernel function. In the general unconstrained covariance case, which allows full flexibility, the summands of (1) take the form

$$K_{U,V}(X - X_i) = (2\pi)^{-\frac{pt}{2}} |V|^{-\frac{p}{2}} |U|^{-\frac{t}{2}} \exp\left(-\tfrac{1}{2}\text{tr}(V^{-1}(X - X_i)^\top U^{-1}(X - X_i))\right) \quad (2)$$

The $U_{p\times p}$ and $V_{t\times t}$ matrices identify a separable covariance structure of the rows and columns of the variable X. In the simplest case, where $U = h_U \mathbb{I}_p$ and $V = h_V \mathbb{I}_t$, the kernel assumes the form

$$K_{h_U,h_V}(X - X_i) = (2\pi)^{-\frac{pt}{2}} h_U^{-p} h_V^{-t} \exp\left(-\frac{1}{2(h_U h_V)^2}\text{tr}((X - X_i)^\top (X - X_i))\right).$$

Due to the separability of the covariance structure, the choice of two distinct smoothing parameters for rows and columns hence results unnecessary.

3.1.1 Adaptive kernel

As an overall problem shared by nonparametric tools, kernel estimators are known to strongly suffer from the curse of dimensionality. On one side, the required sample size to achieve an acceptable accuracy becomes disproportionately large as the dimensions increases, leading to intractable problems, even computationally. On the other side, in high dimensions, the sparsity of data induce much of the probability mass to flow to the tails of the density. This may give rise to the birth of spurious modes and average away features in the highest density regions, thus possibly affecting severely a clustering goal. While these arguments could discourage from the application of modal clustering on matrix-variate data, which are intrinsically

high-dimensional, non-parametric estimates can still be useful to coarsely describe the data structure, and often, allowing different amounts of smoothing to capture local structures of the data is advisable. One example is the *k−nearest neighbours* estimator, defined as

$$\hat{f}_k(X) = \frac{1}{n}\frac{1}{\delta_{(k)}(X)^{p\times t}}\sum_{i=1}^{n} K\left(\frac{X-X_i}{\delta_{(k)}(X)}\right) \tag{3}$$

where $\delta_{(k)}(X)$ is the k-th nearest neighbour distance to X. This is a special case of adaptive kernel, where the bandwidth $\delta_{(k)}(X)$ varies with X, thus determining a larger amount of smoothing in the low density regions. The (3), albeit not smooth for visualization purposes, is shown to be very efficient, since density estimator at a point X reduces essentially to computing $\delta_{(k)}(X)$, and no explicit kernel function evaluations are required.

3.2 Mean shift for matrix-variate data

Once that the density has been estimated via the matrix-variate extension discussed so far, in order to cluster observations, a proper way for the observations to climb the modes is required.

To this aim, the mean-shift algorithm lends itself quite naturally to the generalization to matrix-valued data. Consider the kernel density estimator (1), and, for the sake of simplicity, a Normal kernel (2). Define

$$w_{i,U,V}(Y) = \frac{\exp(\mathrm{tr}(V^{-1}(Y-X_i)^\top U^{-1}(Y-X_i)))}{\sum_{j=1}^{n}\exp(\mathrm{tr}(V^{-1}(Y-X_)^\top U^{-1}(Y-X_i)))}. \tag{4}$$

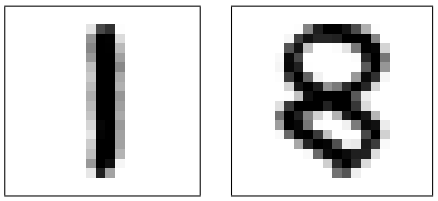
We can now state the following proposition.

Proposition 1. *Starting from a generic $Y^{(0)} \in \mathbb{R}^p \times t$, the sequence $\{Y^{(0)},\dots,Y^{(S)}\}$, defined by the mean-shift update*

$$Y_i^{sj+1)} = \sum_{i=1}^{n} w_{i,U,V}(Y_s^{(j)})X_i$$

converge to a mode of $\hat{f}$.

The main argument justifying this result is that, due to the separability of the covariance matrices U and V, equation (1) boils down to the mean-shift based on a standard multivariate Normal kernel with covariance matrix $U \otimes V$ and built on the vectorization of the involved matrix variables. It can be shown that the mean-shift convergence result to the local modes of $\hat{f}$ applies to a wider set of kernel functions, among which the nearest neighbour estimator (3), that correspond to the special case where $U = \delta_{(k)}(X)I_p$ and $V = \delta_{(k)}(X)I_t$.



Method	ME
Mixture of matrix-variate Normals (2 clusters)	0.09
Mixture of matrix-variate Normals (# of clusters defined via BIC)	0.39
fixed h mean-shift	0.62
NN-based mean-shift	0.12

Fig. 1 Two samples of handwritten digits data(left and middle panel), and the summarizing results of the proposed methods with respect to the competitor in term of misclassification error(right).

4 Application

We applied the proposed methodology to the well known handwritten ZIP codes data [2], described by samples of handwritten digits $(0,\dots,9)$ collected from the ZIP codes on envelopes from US postal mail. Each observation is represented by a matrix of 16×16 pixels, ranging in intensity from 0 to 255. We restrict our attention to the subset of digits (1, 8), with a total of 430 observations (Figure 1).

Two alternative matrix-variate kernel estimators are considered: the (1) with fixed bandwidth selected for optimal estimation of a matrix-variate Normal density, and the (3) with $k = 50$. The procedure is compared with its parametric counterpart, where clusters are identified by the components of a mixture of matrix-variate Normal densities [4]. Results, presented in the right panel of Figure 1, are evaluated in term of misclassification error (ME). While the parametric matrix-normal mixture [4] has the best performance when the number of clusters is correctly specified, in the case of automatic selection via BIC, the procedure is unable to identify different clusters. In the nonparametric case, a fixed bandwidth produce, as expected, multiple spurious clusters, due to the complex geometry of the underlying density and the intrinsic high-dimensionality of the data. The NN-mean shift has far better performances, possibly due to the higher flexibility of the adaptive mean-shift, that results in a higher accuracy in capturing the shape of the underlying density.

A Note on Detection of Perturbations in Biological Networks

Una nota sul rilevamento di perturbazioni in reti biologiche

Vera Djordjilović

Abstract Griffin et al. (2018, *Biometrics* **74**, 1351-1361) have recently addressed the problem of detecting perturbations in multi-omics networks by applying the method of network filtering. They have also introduced two novel testing procedures for detecting the origin of perturbation in Gaussian graphical models. In this work, we argue that the proposed testing procedures, although useful in the exploratory data analysis, lack some desirable statistical properties, including type I error control. We illustrate this issue on a small example, and propose a solution in the form of a modified testing procedure.

Abstract Griffin et al. (2018, *Biometrics* **74**, 1351-1361) hanno recentemente affrontato il problema della rilevazione di perturbazioni nelle reti multi-omiche mediante l'applicazione del metodo del filtro di rete, introducendo due nuove procedure di verifica di ipotesi per rilevare l'origine della perturbazione nei modelli grafici Gaussiani. In questo lavoro dimostriamo che le procedure proposte, sebbene utili nell'analisi esplorativa dei dati, non soddisfano alcune proprietà statistiche desiderabili, compreso il controllo dell'errore di I tipo. Considereremo un semplice esempio per illustrare il problema e verrà proposta una soluzione che modifica la procedura originale.

Key words: FWER control, Gaussian graphical models, likelihood ratio tests, network filtering.

1 Introduction

Comparing biological networks between two conditions is an active area of research in statistics. After identifying all network components that show differing behavior,

Vera Djordjilović
Department of Biostatistics, University of Oslo, Sognsvannsveien 9, 0372 Oslo, Norway e-mail: vera.djordjilovic@medisin.uio.no

the interest is usually in detecting the *origin* of perturbation. A promising tool for addressing this task, *network filtering* [1, 3], has been recently applied to multi-omics networks [2]. The proposed solution and the assumed perturbation model are briefly described in the following.

Data in the control condition are assumed to come from a multivariate normal distribution that is Markov with respect to an unknown graph. The perturbation acts on its target(s) and changes its(their) mean. The effect of perturbation is then propagated through network connections so that further nodes result perturbed. The aim is to detect the site of the original perturbation. This is achieved in two steps: in the first step, data from the control condition are used to estimate the covariance matrix and the graphical structure; in the second step, data from the perturbed condition are transformed in the process of network filtering, and a testing procedure is used to identify the most likely site of the original perturbation.

The focus of the present work is on the testing procedures proposed in [2] and described in Section 2. In Section 3, we show that the single-target procedure suffers from the fact that it is not accompanied by an assessment of uncertainty of the produced ranking. In Section 4, we illustrate how this may cause the multi-target procedure to overestimate the number of targets. In Section 5, we propose a modified procedure that addresses these issues, and, in addition, avoids making any prior assumptions on the number of targets. In Section 6, we draw some general conclusions and recommendations.

2 Testing procedures for perturbation detection

Our focus is on the testing procedure; to this end, we adopt a setting in which the covariance matrix Σ for the considered set of variables is known. Let $\boldsymbol{Y}_1,\dots,\boldsymbol{Y}_n$ be a random sample from the perturbed condition, i.e. a random sample of size n from a p-variate normal distribution $\mathsf{N}(\Sigma\boldsymbol{\mu},\Sigma)$, where $\boldsymbol{\mu}\in\mathbb{R}^p$ is a perturbation vector whose only non-zero components are perturbation targets. [2] consider transformed data $\boldsymbol{Z}_i=\Omega\boldsymbol{Y}_i$, $i=1,\dots,n$, where $\Omega=\Sigma^{-1}$. Since $\boldsymbol{Z}_i\sim\mathsf{N}(\boldsymbol{\mu},\Omega)$, the transformed data can be used to make inference on $\boldsymbol{\mu}$.

2.1 Single-target perturbations

The Authors first consider single-target perturbations that affect only one component of $\boldsymbol{\mu}$. To identify the affected component, they propose testing a hypothesis that a node has been perturbed, conditional on there being only one target. More formally, they propose testing the null hypothesis $H:\boldsymbol{\mu}=0$ against a series of alternatives $H_i:\mu_i\neq 0,\boldsymbol{\mu}_{-(i)}=0$, where $\boldsymbol{\mu}_{-(i)}$ denotes a subvector of $\boldsymbol{\mu}$ obtained by omitting the i-th component representing node i. The components of $\boldsymbol{\mu}$ are then ranked according to the associated log-likelihood ratio test statistic T_i. They show

that if node i has been perturbed, the test statistic T_i will stochastically dominate test statistics of the remaining nodes, so that node i is likely to be top-ranked.

2.2 Multi-target perturbations

Test statistics T_i, $i = 1, \ldots, p$, are different test statistics for the global null hypothesis H, and when the power to reject H is sufficiently high, many p-values, including the one associated to the true perturbation target, will be low. When this is the case, it might be difficult to conclude whether the nodes with low p-values represent multiple perturbation targets or are only significant due to their proximity to the perturbation target.

To resolve this issue, the Authors propose a sequential testing procedure that at each step takes into account the perturbation targets identified in the previous steps. In particular, at step $s+1$, they consider the problem of testing

$$H_S : \boldsymbol{\mu}_{-(S)} = 0 \quad \text{against} \quad H_{(S,i)} : \mu_i \neq 0, \boldsymbol{\mu}_{-(i,S)} = 0, \tag{1}$$

where S is the set of nodes detected up to step s. The test is performed for all nodes not already identified, i.e. for all $i \in \bar{S}$, and the node with the lowest p-value is declared the likely perturbation target at step s. The Authors suggest that the false discovery rate can be controlled by applying the method of Benjamini and Hochberg to the resulting sequence of p-values.

3 Ranking uncertainty

The main aim of the proposed testing procedures is to produce a ranking of likely perturbation targets. Unfortunately, the obtained ranking is not accompanied by an assessment of uncertainty.

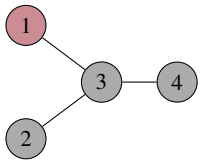

Fig. 1 The graph G used in the example. The perturbation target is highlighted in red.

To illustrate this issue we use a small graph G shown in Figure 1. Let $\Sigma = \left\{\sigma_{ij}\right\}_{i,j=1}^{4}$ be such that $\sigma_{ii} = 1$, $\sigma_{ij} = 0.9$ when nodes i and j are connected in G, and $\sigma_{ij} = 0.81$ otherwise. Then $\Omega = \Sigma^{-1}$ has zeros corresponding to the missing edges of G. Data from the reference condition are assumed to follow a zero-mean

multivariate normal distribution with the covariance matrix Σ. Let the perturbation affect node 1 by shifting its mean from 0 to $\mu_1 = 0.5$, so that μ_1 becomes the only non-zero element of $\boldsymbol{\mu}$. The effect of the perturbation propagates through G, so that after the perturbation data follow a multivariate normal distribution with mean $\Sigma\boldsymbol{\mu}$ and unchanged covariance matrix Σ. We assessed the performance of the single-target testing procedure by simulating 1000 random samples of size $n = 100$ from the perturbed distribution, i.e. from $\mathsf{N}(\Sigma\boldsymbol{\mu}, \Sigma)$. Following the single-target procedure described in Section 2.1, we computed, for each sample, the four p-values for the hypotheses that node i has been perturbed conditional on there being only one perturbation, i.e. the p-values for testing H against H_i.

Figure 2 reports the proportion of Monte Carlo runs in which the p-value of the single-target procedure associated to node i was below the Bonferroni threshold of $\alpha/4$ (wide gray bars; red bars can be ignored for now), where α was set to 0.05. Narrow gray bars show the proportion of Monte Carlo runs in which a node was first ranked. We see that the true perturbation target was first ranked around 80% of times. As a consequence, the first ranked node was not the perturbation target approximately 20% of times.

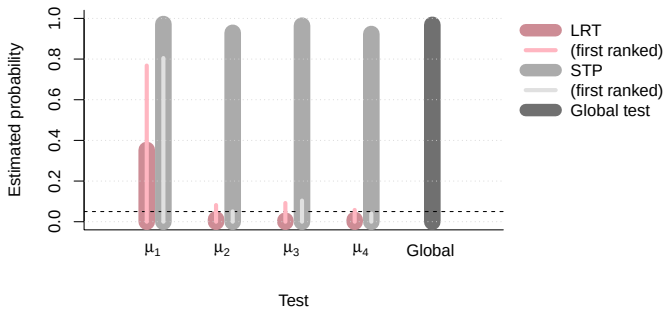

Fig. 2 Estimated probability that a) a node-wise hypothesis is rejected (wide bars); b) a node is first ranked (narrow bars); c) the global null hypothesis H is rejected (Global). STP stands for the single-target procedure; LRT for the unconditional node-wise likelihood ratio test. Horizontal dashed line $y = 0.05$ represents the considered significance level.

4 Type I error control

The lack of statistical guarantees for the obtained ranking affects the multi-target procedure as well. Namely, when the true perturbation target is not ranked first with high probability, the proposed sequential procedure will overestimate the number of targets and correcting the p-values for multiplicity will not resolve this issue.

Let us use again the perturbation of node 1 in G to illustrate this point. We again generated 1000 random samples of 100 observations from the post-perturbation distribution, but this time we applied the multi-target (sequential) procedure. We considered a range of values for $\mu_1 = 0.1, 0.3, 0.5, 0.9$, emulating perturbations of different strength. We investigated the power to detect the true target and the type I error control. For simplicity, we considered the familywise error rate (FWER), and applied the Bonferroni correction to the p-values obtained by the sequential procedure. The power was estimated as the proportion of Monte Carlo runs in which the p-value for node 1 resulted significant; the FWER as the proportion of runs in which at least one p-value of the remaining nodes resulted significant. Hypotheses were tested at level $\alpha = 0.05$. The results are reported in the first column of Table 1. Although the power of the multi-target procedure appears to be very good even

Table 1 Estimated power and FWER multiplied by 10^2 for the multi-target and the node-wise likelihood ratio testing procedure for multiple perturbation strengths. Estimated FWER exceeding the nominal level is highlighted.

	Multi-target		Node-wise LRT	
μ_1	Power	FWER	Power	FWER
0.1	5.1	**6.7**	1.8	2.5
0.3	46.7	**29.1**	12.5	3.2
0.5	82.5	**18.2**	36.4	3.4
0.7	93.3	**8.3**	72.1	3.8
0.9	97.6	**5.4**	92.2	3.7

for mild perturbations (for $\mu_1 \geq 0.3$), applying the Bonferroni correction does not ensure FWER control. In fact, the obtained FWER exceeds the nominal level (0.05) in all considered scenarios, and the result is particularly worrisome in the presence of mild perturbations: for $\mu_1 = 0.3$, the FWER is almost 0.3.

5 Unconditional node-wise likelihood ratio tests

Both issues can be solved with a slight modification of the single-target procedure. It is sufficient to replace the conditional null hypothesis by unconditional node-wise hypotheses

$$H_{0i} : \mu_i = 0, \boldsymbol{\mu}_{-(i)} \in \mathbb{R}^{p-1}, \tag{2}$$

and test them against general alternatives $H_{0i}^c : \mu_i \neq 0, \boldsymbol{\mu}_{-(i)} \in \mathbb{R}^{p-1}$. The modified procedure addresses directly the question of what nodes have been perturbed without making any prior assumptions on the number of targets. Additionally, it allows type I error control by standard multiple testing procedures.

Hypothesis H_{0i} can be tested with a likelihood ratio test. The maximum likelihood estimator of $\boldsymbol{\mu}$ under the null hypothesis is $\hat{\boldsymbol{\mu}}_0$, with $(\hat{\boldsymbol{\mu}}_0)_i = 0$, and $(\hat{\boldsymbol{\mu}}_0)_{(-i)} =$

$\bar{\boldsymbol{Z}}_{(-i)} + \Sigma^{-1}_{(-i,-i)}\Sigma_{(-i,i)}\bar{\boldsymbol{Z}}_i$, where $\Sigma_{(-i,-i)}$ and $\Sigma_{(-i,i)}$ are submatrices of Σ obtained by removing the appropriate rows and columns. The maximum likelihood estimator of $\boldsymbol{\mu}$ under the alternative hypothesis is the unrestricted mean $\bar{\boldsymbol{Z}}$.

Figure 2 compares the single-target procedure with the modified procedure in our small example from Section 3. The original procedure achieves significantly higher power (1 against 0.37 for μ_1) which is not surprising: it is testing the global null hypothesis $H : \boldsymbol{\mu} = 0$. Indeed, it behaves as the likelihood ratio test for H against a general alternative stating that at least one component of $\boldsymbol{\mu}$ is different from zero (the rightmost dark gray bar). Rejecting H and concluding that at lest one component of $\boldsymbol{\mu}$ is non-zero is easier than rejecting H_{01} and concluding that it is the first component of $\boldsymbol{\mu}$ that is different from zero. On the other hand, the modified procedure controls the type I error for nodes 2,3 and 4.

We also considered the modified procedure in the example of Section 4. The second column of Table 1 reports its estimated power and FWER, and shows that it resolves the type I error issue of the multi-target procedure. Namely, the power of the multi-target procedure is higher, but, as already noted, at the expense of type I error control. On the other hand, the modified procedure has lower power but controls FWER across all values of μ_1 (somewhat conservatively: the estimated FWER is around 3.3). When the perturbation is strong, i.e. for $\mu_1 = 0.9$, the performance of the two procedures is very similar, indicating that the conclusions drawn will coincide whenever there is sufficient statistical power.

6 Conclusion

The two testing procedures proposed in [2] appear to be well-suited for the exploratory data analysis concerning the ranking of likely perturbation targets; however, they suffer from the lack of statistical guarantees. In particular, it is the lack of an assessment of uncertainty for a single target procedure and the lack of the type I error control for the multi-target procedure. We proposed a modified testing procedure, based on unconditional node-wise tests, that provides a simple solution to these issues.

Bayesian inference for DAG-probit models

Inferenza bayesiana per modelli DAG-probit

Federico Castelletti

Abstract We consider a binary response variable, e.g. a disease status, together with a set of real-valued variables, such as clinical features of a patient, whereas the interest is in discovering which of these can predict the response. To implicitly account for dependence relationships between all variables, we model the joint distribution of the observables through a particular Directed Acyclic Graph (DAG) structure that we name DAG-probit. We propose a Bayesian methodology for structural learning and parameter estimation of DAG-probit models.

Abstract *Si considera una variabile risposta dicotomica, per esempio una condizione di salute, insieme ad una collezione di variabili reali, come un insieme di caratteristiche cliniche, con l'obiettivo di determinare quali variabili hanno un impatto sulla risposta. Al fine di considerare possibili relazioni di dipendenza tra tutte le variabili di interesse, se ne modella la distribuzione congiunta attraverso un particolare tipo di grafo aciclico direzionato (DAG) denominato DAG-probit. Si propone quindi una metodologia bayesiana per la selezione di modelli DAG-probit e la stima dei relativi parameteri.*

Key words: Graphical model; Directed Acyclic Graph; Probit regression; Bayesian inference

1 Introduction

We consider a collection of real-valued variables which potentially affect a binary response. The interest is in discovering which variables are relevant to predict the

Federico Castelletti

e-mail: federico.castelletti@unicatt.it

response, an issue which can be formalized as a *variable selection* problem for a dichotomous response. Variable selection in binary response models is typically performed using statistical methods based on logistic or probit regression which are widely employed to provide answers to many scientific queries. For instance, in medical sciences one might be interested in discovering which clinical features can predict a disease status and also how much each feature affects the probability to observe the disease. However, standard regression models do not directly account for dependencies among variables which, if neglected, can produce unreliable estimates of regression coefficients or related quantities of interest, such as odds or *causal effects*. In this paper we approach this issue from a graphical model perspective. We adopt Directed Acyclic Graphs (DAGs) which represent a well established tool to investigate dependence relationships among variables, especially in medicine and genomics [4] and in particular *DAG-probit* models to account for the presence of a (binary) response. In particular, we consider a Gaussian framework where the covariance matrix is Markov w.r.t. an unknown DAG and assume that the binary response is obtained by discretization of a continuous (latent) counterpart [1]. Under a Bayesian setting, the normality assumption allows for efficient posterior inference on the covariance matrix, also accounting for model uncertainty, which is gathered from an available posterior distribution on the space of DAG-probit models. DAGs are particularly suited for causal reasoning as well, which is predicated using the notion of *intervention* and the allied *interventional distribution* [9]. Accordingly, the causal effect on the response due to an intervention on a specific node depends on the underlying DAG and can be expressed as a function of the covariance matrix. Therefore, the proposed methodology can be naturally adopted for causal effect estimation under model uncertainty; see for instance [7] and [3].

2 DAG-probit models

Let $\mathscr{D} = (V,E)$ be a DAG, where $V = \{1,\dots,q\}$ is a set of vertices (or nodes) and $E \subseteq V \times V$ a set of edges. The elements of E are $(u,v) \equiv u \to v$ and such that if $(u,v) \in E$ then $(v,u) \notin E$. In addition, $\mathscr{D}$ contains no cycles, that is paths of the form $u_0 \to u_1 \to \cdots \to u_k$ where $u_0 \equiv u_k$. For a given node v, if $u \to v \in E$ we say that u is a *parent* of v (conversely v is a *child* of u). The parent set of v in $\mathscr{D}$ is denoted by $\mathrm{pa}_{\mathscr{D}}(v)$, the set of children by $\mathrm{ch}_{\mathscr{D}}(v)$. We further assume that $\mathrm{ch}_{\mathscr{D}}(1) = \emptyset$ which prescribes that node $v = 1$, which will represent the response variable, has no children.

We now consider a collection of variables $(X_1,\dots,X_q)$ and assume that the joint probability density function $f(x_1,\dots,x_q)$ obeys the Markov property of $\mathscr{D}$, so that we can write the factorization

$$f(x_1,\dots,x_q) = \prod_{j=1}^{q} f(x_j \,|\, \boldsymbol{x}_{\mathrm{pa}_{\mathscr{D}}(j)}), \tag{1}$$

Consider now the Gaussian setting,

$$X_1,\ldots,X_q \,|\, \boldsymbol{\Omega} \sim \mathscr{N}_q(\mathbf{0}, \boldsymbol{\Omega}^{-1}), \tag{2}$$

where $\boldsymbol{\Omega} = \boldsymbol{\Sigma}^{-1}$ is the precision matrix and $\boldsymbol{\Omega} \in \mathscr{P}_{\mathscr{D}}$, the space of symmetric and positive definite (s.p.d.) precision matrices Markov w.r.t. $\mathscr{D}$. For a Gaussian DAG-model factorization (1) becomes

$$f(x_1,\ldots,x_q \,|\, \boldsymbol{\Omega}) = \prod_{j=1}^{q} f(x_j \,|\, \boldsymbol{x}_{\mathrm{pa}(j)}, \boldsymbol{\Omega}). \tag{3}$$

Equation (3) can be also written as a *structural equation model*. Specifically, assuming a parent ordering of the nodes so that $i > j$ whenever j is a child of i we can write

$$\boldsymbol{L}^\top \boldsymbol{x} = \boldsymbol{\varepsilon}, \tag{4}$$

where $\boldsymbol{L}$ is a (q,q) lower-triangular matrix of coefficients, $\boldsymbol{L} = \{\boldsymbol{L}_{ij}, i \geq j\}$, such that $\boldsymbol{L}_{ij} \neq 0$ if and only if $i \to j$ and $\boldsymbol{L}_{ii} = 1$. Moreover, $\boldsymbol{\varepsilon}$ is a $(q,1)$ vector of error terms, $\boldsymbol{\varepsilon} \sim \mathscr{N}_q(\mathbf{0}, \boldsymbol{D})$, where $\boldsymbol{D} = \mathrm{diag}(\boldsymbol{\sigma}^2)$ and $\boldsymbol{\sigma}^2$ is the $(q,1)$ vector of *conditional* variances whose j-th element is $\sigma_j^2 = \mathbb{V}\mathrm{ar}(X_j \,|\, \boldsymbol{x}_{\mathrm{pa}(j)}, \boldsymbol{\Sigma})$. Therefore

$$\boldsymbol{\Omega} = \boldsymbol{L}\boldsymbol{D}^{-1}\boldsymbol{L}^\top. \tag{5}$$

Equation (5) is called the *modified Cholesky decomposition* of $\boldsymbol{\Omega}$ [2]. Let now $\prec j \succ = \mathrm{pa}(j)$ and $\prec j] = \mathrm{pa}(j) \times j$. The modified Cholesky decomposition (5) induces a re-parametrization of $\boldsymbol{\Omega}$ (equivalently, $\boldsymbol{\Sigma}$) in terms of the node-parameters $(\boldsymbol{L}_{\prec j]}, \sigma_j^2)$, $j = 1,\ldots,q$, where

$$\boldsymbol{L}_{\prec j]} = -\boldsymbol{\Sigma}_{\prec j \succ} \boldsymbol{\Sigma}_{\prec j]}, \quad \sigma_j^2 = \boldsymbol{\Sigma}_{jj \,|\, \mathrm{pa}(j)}. \tag{6}$$

Accordingly, Equation (3) can be written as

$$\begin{aligned} f(x_1,\ldots,x_q \,|\, \boldsymbol{\Omega}) &= \prod_{j=1}^{q} f(x_j \,|\, \boldsymbol{x}_{\mathrm{pa}(j)}, \boldsymbol{L}_{\prec j]}, \sigma_j^2) \\ &= \prod_{j=1}^{q} d\mathscr{N}(x_j \,|\, -\boldsymbol{L}_{\prec j]}^\top \boldsymbol{x}_{\mathrm{pa}(j)}, \sigma_j^2). \end{aligned} \tag{7}$$

Let now $Y \in \{0,1\}$ be the binary outcome. Given the threshold $\theta_0 \in (-\infty, +\infty)$, we assume that Y is generated from X_1 (its latent counterpart) as

$$Y = \begin{cases} 1 & \text{if } X_1 \in [\,\theta_0, +\infty), \\ 0 & \text{if } X_1 \in (-\infty, \theta_0); \end{cases} \tag{8}$$

so that $P(Y=1) = P(Z \geq \theta_0)$; see also [1]. Therefore, letting $f(x_1)$ be the p.d.f. of X_1 and using the convention $\theta_{-1} = -\infty, \theta_1 = +\infty$, the joint density of (Y, X_1) can be

written as

$$f(y,x_1\,|\,\theta_0) = f(x_1)\cdot \mathbb{1}(\theta_{y-1} < x_1 \leq \theta_y). \tag{9}$$

We now assume that $(X_1,\ldots,X_q)$ follows the Gaussian DAG-model (2) which implies the factorization in (7). Accordingly the joint density of $(Y,X_1,\ldots,X_q)$ in (9) becomes

$$f(y,x_1,\ldots,x_q\,|\,\boldsymbol{\Omega},\theta_0) = f(x_1,\ldots,x_q\,|\,\boldsymbol{\Omega})\cdot \mathbb{1}(\theta_{y-1} < x_1 \leq \theta_y). \tag{10}$$

Equation (10) defines a Gaussian *DAG-probit model*. Recall now from Equation (7) that the conditional distribution of the latent variable X_1 is $\mathcal{N}(-\boldsymbol{L}_{\prec 1]}^{\top}\boldsymbol{x}_{\mathrm{pa}(1)},\sigma_1^2)$. To guarantee the identifiability of our DAG-probit model we then set $\sigma_1^2 = 1$ as in standard probit regression.

Finally, by considering n independent samples $(y_i,x_{i,2},\ldots,x_{i,q})$, $i=1,\ldots,n$, the augmented likelihood can be written as

$$\begin{aligned} f(\boldsymbol{y},\boldsymbol{x}_1,\ldots,\boldsymbol{x}_q\,|\,\boldsymbol{\Omega},\theta_0) &= \prod_{i=1}^{n} f(y_i,x_{i,1},\ldots,x_{i,q}\,|\,\boldsymbol{\Omega},\theta_0) \\ &= \prod_{i=1}^{n}\prod_{j=1}^{q} f(x_{i,j}\,|\,\boldsymbol{x}_{i,\mathrm{pa}(j)},\boldsymbol{L}_{\prec j]},\sigma_j^2)\cdot \mathbb{1}(\theta_{y_i-1} < x_{i,1} \leq \theta_{y_i}), \end{aligned} \tag{11}$$

where $\boldsymbol{y} = (y_1\ldots,y_n)^{\top}$ and $\boldsymbol{x}_j = (x_{1,j},\ldots,x_{n,j})^{\top}$ for $j=1,\ldots,q$.

3 Bayesian inference

Under a Bayesian framework, we complete our DAG-probit model by specifying prior distributions for precision matrix $\boldsymbol{\Omega}\in\mathscr{P}_{\mathscr{D}}$, DAG $\mathscr{D}$ and cut-off θ_0. For a *complete* DAG $\mathscr{D}$, a prior on $\boldsymbol{\Omega}$ (unconstrained) can be assigned through a Wishart distribution $\mathscr{W}_q(a,\boldsymbol{U})$, where $a > q-1$ and $\boldsymbol{U}$ is a s.p.d. matrix. This induces a prior on $(\boldsymbol{L},\boldsymbol{D})$ such that the node-parameters $(\boldsymbol{L}_{\prec j]},\sigma_j^2)$ are independent and Normal-Gamma distributed. Accordingly, the priors $p(\boldsymbol{L}_{\prec j]},\sigma_j^2)$ are conjugate with the corresponding normal densities in (2), which guarantees closed-form results for the posterior distribution of the model parameters as well as for the marginal likelihood of a complete DAG $\mathscr{D}$.

Consider now the case in which $\mathscr{D}$ is not complete. To assign a prior on $\boldsymbol{\Omega}\in\mathscr{P}_{\mathscr{D}}$ we adopt the procedure of [5] which is based on a set of assumptions which are naturally satisfied under the Gaussian setting (2). Accordingly, we assign a prior to the parameters of each DAG model starting from a unique prior on the parameters of an unconstrained (complete) DAG. In turns, closed-form expressions for the posterior distribution of each DAG model parameters and marginal likelihoods can be also obtained; see also the original paper for details.

Next, a prior on DAG $\mathscr{D}$, $p(\mathscr{D})$, can be assigned through a Bernoulli prior on the elements of the adjacency matrix of $\mathscr{D}$; see for instance [2]. This can be also used to regulate sparsity in the DAG-probit model space by choosing a prior probability of inclusion for each (possible) edge. Finally, for the unknown threshold θ_0 we assume a uniform prior, so that $p(\theta_0) \propto 1$.

4 Computational details

Given the results resumed in the previous sections, an efficient MCMC scheme for posterior inference and model selection of DAG-probit models can be introduced. Specifically, our proposal is based on a collapsed MCMC scheme in which at each iteration we propose and update DAG $\mathscr{D}$ and precision matrix $\boldsymbol{\Omega}$ given the observed data $\boldsymbol{x}_2, \ldots, \boldsymbol{x}_q$ and the latent $\boldsymbol{x}_1$. At each step, the latent $x_{1,i}$, for $i = 1, \ldots, n$, is sampled from its conditional distribution, which corresponds to a normal density truncated at $(\theta_{y_i-1}, \theta_{y_i}]$. The update of θ_0 is performed through a Metropolis Hastings step where a cut-off g_0 is proposed from a $\mathscr{N}(\theta_0, \sigma_0^2)$.

Our algorithm results in a collection of T DAGs and precision matrices visited by the MCMC chain. In particular, we can use the output $\{\mathscr{D}^{(1)}, \ldots, \mathscr{D}^{(T)}\}$ to approximate the posterior distribution of the DAG-probit space or related quantities of interest, such as the probability of inclusion for each edge $u \to v$ which can be estimated as

$$\hat{p}_{u \to v}(\boldsymbol{y}, \boldsymbol{x}_2, \ldots, \boldsymbol{x}_q) = \frac{1}{T} \sum_{t=1}^{T} \mathbb{1}_{u \to v}\{\mathscr{D}^{(t)}\}, \tag{12}$$

where $\mathbb{1}_{u \to v}(\cdot)$ is the indicator function taking value 1 if and only if $\mathscr{D}$ contains $u \to v$. In addition, for each individual i we can provide an estimate of the probability $P(Y_i = 1 \,|\, x_{i,2}, \ldots, x_{i,q}; \boldsymbol{\Omega}, \theta_0) = P(Z_i \geq \theta_0 \,|\, x_{i,2}, \ldots, x_{i,q}; \boldsymbol{\Omega})$ e.g. by computing the expected value of the predictive distribution of Y_i.

5 Application to breast cancer data

In this section we apply the proposed methodology to the breast cancer dataset presented in [8]. The objective of the study was to develop a prediction model which can be used as a biomarker of breast cancer, based on a collection of anthropometric data and parameters gathered in routine blood analysis and measured on $n = 116$ individuals. Accordingly, each individual i is classified as $y_i = 1$ (type 1) in case of breast cancer, $y_i = 0$ (type 0) otherwise. Data are provided as a supplement to the original paper. We implement our methodology to approximate the posterior distribution over the DAG-probit space and the probability of disease for each subject i. As the results, we report in Figure 1 the heat map with estimated posterior probabilities of edge inclusion computed as in (12) and the posterior probabilities of $Y_i = 1 \,|\, \cdot$

computed across the n individuals. Comparisons with frequentist probit regression is also provided.

Variational Bayes for Gaussian Factor Models under the Cumulative Shrinkage Process

Inferenza Bayesiana Variazionale per Modelli Fattoriali Gaussiani dotati di Processo a Contrazione Cumulativa

Sirio Legramanti

Abstract The cumulative shrinkage process is an increasing shrinkage prior that can be employed within models in which additional terms are supposed to play a progressively negligible role. A natural application is to Gaussian factor models, where such a process has proved effective in inducing parsimonious representations while providing accurate inference on the data covariance matrix. The cumulative shrinkage process came with an adaptive Gibbs sampler that tunes the number of latent factors throughout iterations, which makes it faster than the non-adaptive Gibbs sampler. In this work we propose a variational algorithm for Gaussian factor models endowed with a cumulative shrinkage process. Such a strategy provides comparable inference with respect to the adaptive Gibbs sampler and further reduces runtime.
Abstract *Il processo a contrazione cumulativa è una distribuzione a priori a contrazione crescente che può essere impiegata in modelli per i quali si suppone che termini aggiuntivi giochino un ruolo via via più trascurabile. Una sua naturale applicazione è nei modelli fattoriali gaussiani, dove tale processo si è dimostrato efficace nell'indurre rappresentazioni parsimoniose fornendo allo stesso tempo un'inferenza accurata sulla matrice di covarianza dei dati. Il processo a contrazione cumulativa è stato proposto insieme a un Gibbs sampler adattivo che modula il numero di fattori latenti nel corso delle iterazioni, il che lo rende più veloce del Gibbs sampler non adattivo. In questo lavoro proponiamo un algoritmo variazionale per modelli fattoriali gaussiani dotati di processo a contrazione cumulativa. Tale soluzione fornisce un'inferenza paragonabile a quella del Gibbs sampler adattivo e riduce ulteriormente i tempi di calcolo.*

Key words: Shrinkage prior, Spike and slab, Stick-breaking representation

Sirio Legramanti
Bocconi University, Milan, Italy, e-mail: sirio.legramanti@phd.unibocconi.it

1 Introduction

The cumulative shrinkage process [5] is an increasing shrinkage prior based on a sequence of spike-and-slab distributions, with growing mass assigned to the spike. It can be defined for both countable and finite sequences. A definition for the countable case can be found in [5], while the following is a definition for finite sequences.

Definition 1. We say that $\{\theta_h \in \Theta \subseteq \mathbb{R} : h = 1,\dots,H\}$ is distributed according to a cumulative shrinkage process with shrinkage parameter $\alpha > 0$, slab P_0 and spike P_∞ if, conditionally on $\{\pi_h \in (0,1) : h = 1,\dots,H\}$, each θ_h is independent and

$$(\theta_h \mid \pi_h) \sim (1-\pi_h)P_0 + \pi_h P_\infty, \qquad (h = 1,\dots,H), \tag{1}$$

where $\pi_h = \sum_{l=1}^{h} \omega_l$ for $h = 1,\dots,H$ and $\omega_l = v_l \prod_{m=1}^{l-1}(1-v_m)$ for $l = 1,\dots,H$, with $v_1,\dots,v_{H-1}$ being independent Beta$(1,\alpha)$ random variables and $v_H = 1$.

This construction, based on the stick-breaking representation of the Dirichlet process [4], implies that the sequence π_h is non-decreasing and that $\pi_H = 1$.

The cumulative shrinkage process can be used in a variety of models, e.g. Poisson factorization [3], but here we focus on Gaussian factor models, which are ubiquitous in statistics and have been used in [5] as illustrative example. In [5] posterior inference for this model under the cumulative shrinkage process is carried out through an adaptive Gibbs sampler which tunes H as it progresses. This algorithm, together with the ability of the prior to favor the recovery of the number of active latent factors, allows for reduced runtime with respect to the non-adaptive Gibbs sampler. However, the increasing availability of large datasets demands for even faster algorithms. This need for scalability has pushed Bayesian statisticians towards approximate methods for posterior inference, including Laplace approximation, variational Bayes and expectation propagation [2].

In this work we employ mean-field variational Bayes, which is straightforward to derive for Gaussian factor models under a convenient specification of the cumulative shrinkage process which slightly differs from the one in [5]. Such a specification is detailed in § 2, while the variational approximation is described in § 3. Finally, in § 4 we illustrate the performance of the variational algorithm on real data.

2 Model and Prior

We focus on learning the structure of the $p \times p$ covariance matrix $\Omega = \Lambda\Lambda^{\mathrm{T}} + \Sigma$ of the data $y_i \in \mathbb{R}^p$ from the Gaussian factor model $y_i = \Lambda\eta_i + \varepsilon_i$ $(i = 1,\dots,n)$, where $\Lambda = [\lambda_{jh}] \in \mathbb{R}^{p\times H}$, $\eta_i \sim N_H(0, I_H)$, $\varepsilon_i \sim N_p(0,\Sigma)$ and $\Sigma = \mathrm{diag}(\sigma_1^2,\dots,\sigma_p^2)$. As priors, we let $\sigma_j^2 \sim \mathrm{InvGa}(a_\sigma, b_\sigma)$ for $j = 1,\dots,p$ and, differently from [5], we place a cumulative shrinkage process directly on the loadings, with π_h as in Def. 1:

$$(\lambda_{jh} \mid \pi_h) \sim (1-\pi_h)N(0,\theta_0) + \pi_h N(0,\theta_\infty), \qquad (j = 1,\dots,p;\ h = 1,\dots,H). \tag{2}$$

This simpler specification facilitates the derivation of the variational algorithm, while preserving the increasing shrinkage property. In fact, setting $\theta_0 > \theta_\infty$, the loadings are increasingly shrunk towards zero in probability, i.e. $\text{pr}\{|\lambda_{j,h+1}| < \varepsilon\} \geq \text{pr}\{|\lambda_{jh}| < \varepsilon\}$ for any $\varepsilon > 0$, encoding the prior assumption that additional factors provide a decreasing contribution to the model. However, setting both the spike and the slab to Gaussians is suboptimal to the specification in [5], where the Student-t slab is more differentiated from the Gaussian spike, thus facilitating the separation of active and inactive factors.

The derivation of the variational algorithm is further facilitated by the introduction of the augmented data $z_h = (z_{h1}, \ldots, z_{hH}) \sim \text{Mult}\{1, (\omega_1, \ldots, \omega_H)\}$, which exploits the fact that equation (2) can be obtained by marginalizing out z_h from

$$(\lambda_{jh} \mid z_h) \sim \{1 - \textstyle\sum_{l=1}^{h} z_{hl}\} N(0, \theta_0) + \sum_{l=1}^{h} z_{hl} N(0, \theta_\infty), \quad (j = 1, \ldots, p;\ h = 1, \ldots, H).$$

3 Variational Inference

Variational Bayes approximates the posterior density with the density q^* that is closest to it, in Kullback-Leibler (KL) divergence, within a family Q of tractable densities (see [1] for a review). The ideal variational family Q should combine flexibility, that allows for a good approximation, and tractability. Here we choose the mean-field variational family, whose elements factorize as follows:

$$q(\lambda, \eta, \sigma, z, v) = q(\lambda) q(\eta) q(\sigma) q(z) q(v). \tag{3}$$

The KL divergence between such a q and the intractable posterior cannot be computed or minimized directly. Equivalently, we maximize the evidence lower bound

$$\begin{aligned} ELBO(q) &= \log p(y) - KL(q(\lambda, \eta, \sigma, z, v) || p(\lambda, \eta, \sigma, z, v \mid y)) = & (4) \\ &= E_q[\log p(y, \lambda, \eta, \sigma, z, v)] - E_q[\log q(\lambda, \eta, \sigma, z, v)]. & (5) \end{aligned}$$

Equation (4) highlights that, since the KL divergence is always non-negative, the ELBO lower-bounds the log-evidence, thus justifying its name. Moreover, since $\log p(y)$ does not depend on q, maximizing the ELBO is equivalent to minimizing the KL divergence with respect to q. Since (4) involves the intractable posterior, the equivalent expression (5) is used to actually compute the ELBO. The optimization is solved through coordinate ascent, iteratively maximizing the ELBO with respect to each factor on the right-hand side of (3). Following [2, Ch. 10], each factor update is derived as follows (we report only the loadings term for illustrative purposes):

$$\log q^*(\lambda) = E_{\neq \lambda}[\log p(y, \lambda, \eta, \sigma, z, v)] + const,$$

where $E_{\neq \lambda}$ denotes the expectation under q with respect to all variables other than the loadings. With no parametric assumption on the factors in (3), we obtain:

1 **for** *j from 1 to p* **do**
  set $V_j^{(\lambda)} = \{diag(\theta_1^*,\dots,\theta_H^*) + (A^{(\sigma)}/B_j^{(\sigma)})(\mu^{(\eta)\mathrm{T}}\mu^{(\eta)} + nV^{(\eta)})\}^{-1}$,
  where $\theta_h^* = (1-\sum_{l=1}^h \kappa_{hl})\theta_0^{-1} + (\sum_{l=1}^h \kappa_{hl})\theta_\infty^{-1}$, and $\mu_j^{(\lambda)} = (A^{(\sigma)}/B_j^{(\sigma)})V_j^{(\lambda)}\mu^{(\eta)\mathrm{T}}y_{\cdot j}$;

2 Set $A^{(\sigma)} = a_\sigma + n/2$ and **for** *j from 1 to p* **do**
  set $B_j^{(\sigma)} = b_\sigma + 0.5\cdot\sum_{i=1}^n\{y_{ij}^2 - 2y_{ij}\mu_i^{(\eta)\mathrm{T}}\mu_j^{(\lambda)} + \sum_{h=1}^H\sum_{k=1}^H(\mu_{ih}^{(\eta)}\mu_{ik}^{(\eta)} + V_{hk}^{(\eta)})(\mu_{jh}^{(\lambda)}\mu_{jk}^{(\lambda)} + V_{j;hk}^{(\lambda)})\}$;

3 Set $V^{(\eta)} = (I_H + \mu^{(\lambda)\mathrm{T}}diag(A^{(\sigma)}/B^{(\sigma)})\mu^{(\lambda)} + \sum_{j=1}^p(A^{(\sigma)}/B_j^{(\sigma)})V_j^{(\lambda)})^{-1}$;
for *i from 1 to n* **do**
  set $\mu_i^{(\eta)} = V^{(\eta)}\mu^{(\lambda)\mathrm{T}}diag(A^{(\sigma)}/B^{(\sigma)})y_{i\cdot}$;

4 **for** *h from 1 to H* **do**
  for *l from 1 to h* **do** set $\kappa_{hl} \propto \exp\{E(\log\omega_l) - 0.5\cdot p\log\theta_\infty - 0.5\cdot\theta_\infty^{-1}E[\lambda_{\cdot h}^T\lambda_{\cdot h}]\}$;
  for *l from h+1 to H* **do** set $\kappa_{hl} \propto \exp\{E(\log\omega_l) - 0.5\cdot p\log\theta_0 - 0.5\cdot\theta_0^{-1}E[\lambda_{\cdot h}^T\lambda_{\cdot h}]\}$;
  where $E[\lambda_{\cdot h}^T\lambda_{\cdot h}] = \sum_{j=1}^p(\mu_{jh}^{(\lambda)2} + V_{j;hh}^{(\lambda)})$ and, with Ψ being the digamma function,
  $E(\log\omega_l) = \mathbb{1}\{l<H\}\{\Psi(A_l^{(v)}) - \Psi(A_l^{(v)} + B_l^{(v)})\} + \mathbb{1}\{l>1\}\sum_{m=1}^{l-1}\{\Psi(B_m^{(v)}) - \Psi(A_m^{(v)} + B_m^{(v)})\}$;

5 **for** *h from 1 to* $(H-1)$ **do**
  set $A_h^{(v)} = 1 + \sum_{l=1}^H \kappa_{lh}$ and $B_h^{(v)} = \alpha + \sum_{l=1}^H\sum_{m=h+1}^H \kappa_{lm}$.

Algorithm 1: One cycle of the variational algorithm for Gaussian factor models

$$q^*(\lambda,\dots,v) = \prod_{j=1}^p N_H(\lambda_{j\cdot};\mu_j^{(\lambda)},V_j^{(\lambda)})\prod_{i=1}^n N_H(\eta_{i\cdot};\mu_i^{(\eta)},V^{(\eta)})\prod_{j=1}^p \mathrm{InvGa}(\sigma_j^2;A^{(\sigma)},B_j^{(\sigma)})\cdot$$
$$\cdot\prod_{h=1}^H \mathrm{Mult}(z_h;1,\kappa_h)\prod_{h=1}^{H-1}\mathrm{Beta}(v_h;A_h^{(v)},B_h^{(v)}).$$

Notice that each factor further factorizes into exponential-family distributions, thus facilitating computations. The update equations for the parameters are coupled, meaning that each factor update involves expectations with respect to other factors. We then proceed iteratively cycling over the steps of Algorithm 1. This routine converges to a local maximum, hence should be run from several initializations [1]. Convergence of each run can be assessed by monitoring the monotone growth of the ELBO. From the optimal variational parameters we can also compute the variational expectation of the number H^* of factors that are active, in the sense that they are modeled by the slab: $E_{q^*}[H^*] = \sum_{h=1}^H\sum_{l=h+1}^H \kappa_{hl}$.

4 Application to Personality Data

We compare our variational algorithm for the model in § 2 to the adaptive Gibbs sampler for the model proposed in [5], on the same real dataset considered there. Namely, we consider a subset of the dataset `bfi` from the `R` package `psych`, containing the six-point-scale answers of $n = 126$ individuals older than fifty years to

Table 1 Performance of adaptive Gibbs sampler and variational algorithm on the `bfi` dataset

Method	MSE	E[H*]	Running time (s)
Adaptive Gibbs sampler	0.01	2.7	340
Variational inference	0.01	3.0	63

$p = 25$ questions about five personality traits. As in [5], we center the 25 items and, to have coherent answers within each personality trait, we change sign to answers $1, 9, 10, 11, 12, 22$ and 25, as suggested in the documentation of the `bfi` dataset.

For the adaptive Gibbs sampler, the model and the hyperparameters are specified as in [5]. For our variational algorithm, we set $\alpha = 5$, $\theta_0 = 1$, $\theta_\infty = 10^{-6}$ and we conservatively let $H = p + 1$, which coincides with the initial value of H for the adaptive Gibbs sampler and corresponds to at most p latent factors.

We run the variational algorithm from 20 random initializations, stopping each run when the ELBO grows less than 0.05. We then pick the run reaching the highest ELBO. Using the optimal variational parameters of this run, we get a sample of size 2000 for Ω, from which we derive a sample for the correlation matrix $\Omega^* = (\Omega \odot I_p)^{-1/2} \Omega (\Omega \odot I_p)^{-1/2}$, with $\odot$ denoting the element-wise product. From this sample we compute a Monte Carlo estimate of the mean squared deviations $\sum_{j=1}^{p} \sum_{q=j}^{p} E(\Omega^*_{jq} - S_{jq})^2 / \{p(p+1)/2\}$ between Ω^* and the sample correlation matrix S. The same quantity is computed from a posterior sample of equal size obtained running the adaptive Gibbs sampler in [5] for 10000 iterations after a burn-in of 5000 and then thinning every five. The two quantities are reported as MSE (Mean Square Error) in Table 1, together with the expected number of active factors and the total running time for each of the two methods.

With respect to the adaptive Gibbs sampler, the proposed variational algorithm provides the same MSE (rounded off to the second decimal digit) and a similar expected number of active factors, but is more than five times faster.

Measuring poverty and vulnerability

Choosing the vulnerability threshold using the ROC curve

Determinare la soglia di vulnerabilità: un approccio basato sulla curva ROC

Chiara Gigliarano and Conchita D'Ambrosio

Abstract When estimating vulnerability one usually estimates a probability of being poor in the future, which varies between 0 and 1. This leads to the problem of choosing which threshold to use in order to separate the estimated vulnerable from the estimated non-vulnerable individuals. This threshold is usually set at 50 percent. However, this choice appears to be clearly arbitrary. Aim of this paper is to study the optimal choice of vulnerability threshold that is based on the ROC curve, by providing a comparison among three different strategies.

Abstract *Nell'analisi della vulnerabilità si stima la probabilità di essere poveri in futuro, che varia tra 0 e 1. Ciò implica la necessità di individuare una soglia per separare gli individui vulnerabili da quelli non vulnerabili. Questa soglia è di solito fissata pari al 50 percento, e tale scelta appare arbitraria. Scopo del lavoro è individuare una soglia ottimale di vulnerabilità basata sulla curva ROC, mediante un confronto tra tre diverse metodologie.*

1 Introduction

Poverty is an ex-post measure of household welfare. However, the current poverty status may not necessarily be a good indicator of being poor tomorrow. Non-poor households today may have a high probability of becoming poor tomorrow, while some households that are currently poor may be only transiting poverty because of

an unexpected temporary shock. Therefore, it seems important not only alleviating the economic condition of those who are poor today, but also preventing people from becoming poor in the future, adopting a forward looking perspective. The economic literature has recently introduced the concept of vulnerability to poverty, referring to the uncertainty of being poor in the future.

The concept of economic vulnerability introduces the notion of uncertainty: future distributions of incomes are indeed unknown and the vulnerability of households is unobservable to the policy-maker. Due to this complexity, there is still lack of consensus about the definition of economic vulnerability to poverty. In this paper we will use the definition of vulnerability of expected poverty (VEP) approach, which defines vulnerability as the ex-ante risk that an individual will be poor in the future. In contrast with poverty, which is an ex-post measure of a household welfare, vulnerability is a forward-looking measure of household welfare. As suggested by Chaudhuri et al. (2002), whereas the status of poor is observable, the status of vulnerable can only be estimated or inferred.

We include among the vulnerable both families that are non-poor and have a high probability of falling below the poverty line in the future, and families who are currently poor and have a high probability of remaining poor in the future.

When estimating vulnerability we estimate a probability of being poor in the future, which varies between 0 and 1, and not a vulnerability status that can take only the values of 0 or 1. This leads to the problem of choosing which threshold to use in order to separate the estimated vulnerable from the estimated non-vulnerable individuals. This threshold is usually set at 50 percent, so that values above 50 percent indicate that the household has a higher probability of being poor than not. However, a household with 51 percent probability of being poor is not that different from a case with a probability of 49 percent. Aim of this note is, therefore, to determine the optimal vulnerability threshold that simultaneously maximizes true positive rate and minimizes false positive rate. For this purpose, we will discuss the criteria based on the ROC curve.

2 Optimal threshold selection based on ROC curve

The Receiver Operating Characteristic (ROC) curve is one of the most common statistical tools useful to assess classifier performance (Lusted, 1971; Krzanowski and Hand, 2009). This curve is generated by plotting the fraction of true positives out of the positives (true positive rate) versus the fraction of false positives out of the negatives (false positive rate), at various threshold settings.

We are interested in classifying individuals (or households) into two categories: vulnerable or not, according to their estimated vulnerability, that is the estimated probability of being poor tomorrow, given a vector of covariates.

Let the continuous random variable X represent the vulnerability (i.e. the probability of being poor tomorrow), with cumulative distribution function F. The random variable X_{NP} refers to the vulnerability of those who will be actually non-poor to-

morrow with c.d.f. F_P while X_P refers to the vulnerability of those who will be poor tomorrow, with c.d.f F_{NP}. The vulnerability is defined in such a way that individuals who will be poor tomorrow tend to have higher estimated vulnerability, while the individuals non-poor tomorrow tend to have lower vulnerability, with a threshold that divides the scores into the two groups. For a pre-specified cut-off c, individual i will be labelled as poor tomorrow if $x_i \geq c$ and as non-poor tomorrow otherwise.

The performance of a vulnerability model can be summarized in a table (confusion matrix) which compares actual and predicted classifications for a fixed cut-off level c. From the confusion matrix four conditional probabilities can be computed: true positive rate (TP), or *sensitivity*, which corresponds to the proportion of those who will be non-poor tomorrow and predicted today as non-vulnerable; true negative rate, or *specificity*, that is the proportion of the poor tomorrow who are predicted today as vulnerable; false positives rate (FP), or 1- *specificity*, which is the proportion of the poor tomorrow who are predicted as non-vulnerable; false negatives rate, i.e. the proportion of the non-poor tomorrow who are predicted as vulnerable.

Given a set of cut-off points and the corresponding confusion matrices, one of the most common methods to select the best model is the ROC curve. The ROC curve is obtained representing, for any fixed cut-off value, a point in the cartesian plane having as x-value the false positive rate and as y-value the true positive rate.

More formally, the true positive rate is $F_{NP}(c) = Pr(X \leq c|\text{Non-poor tomorrow})$, while the false positive rate is $F_P(c) = Pr(X \leq c|\text{Poor tomorrow})$. The ROC curve is defined as a plot of $\{(u, ROC_X(u)), u \in (0,1)\}$, where

$$ROC_X(u) = F_P(F_{NP}^{-1}(u)),$$

that is, it is a plot of the true positive rate, on the vertical axes, versus its corresponding false positive rate on the horizontal axes, as c varies from $+\infty$ to $-\infty$.

The best curve is the one that is leftmost, the ideal one coinciding with the y-axis. Perfect discrimination corresponds to a ROC curve that passes through the point (0,1). At the other extreme, a model that discriminates not better than random, so that $F_{NP}(c) = F_P(c)$ for any c, will give rise to the diagonal line.

The ROC curve shows the overall performance of a classifier (the vulnerability model) across all possible choices of the cut-off. However, policy interventions aimed at targeting anti-poverty strategies require a unique threshold to be chosen that classifies each individual/household into vulnerable or non-vulnerable.

The most common methods used in the literature for fixing the vulnerability line c are: (i) $c = 0.5$: if the individual probability of being poor tomorrow (vulnerability) is greater than his probability of not-being poor tomorrow, then he will be considered vulnerable; (ii) c equal to the observed poverty rate today: if the individual probability of being poor tomorrow is greater than the average, then the individual will be considered vulnerable; (iii) other authors propose to fix a desirable level of true positive rate (e.g. 80% or 90%) and choose the threshold that minimizes the false positive rate (Celidoni 2015, Landau et al. 2012).

However, these choices appear to be clearly arbitrary, and we propose here to consider methods that are aimed at choosing the optimal threshold based on the

ROC curve. Here we will focus on the Youden index and the Distance index to test which is the optimal threshold to be used in order to separate those who will be poor tomorrow from those non-poor and in order to maximize true positive rate while minimizing false positive rate.

1. *Youden index:* The optimal cut-off is the one that maximizes the Youden index YI
$$YI = \max_{c \in \mathbb{R}} (TP - FP),$$
i.e. the probability of correctly classifying the vulnerable individuals. Graphically, the Youden index is the longest vertical distance between the ROC curve and the chance line (i.e. the positive diagonal).
2. *Distance index.* The optimal cut-off is the one that minimizes the distance d from the scenario of perfect discrimination:
$$d = \left(\sqrt{(1 - S_n)^2 + (1 - S_p)^2} \right),$$
where S_n and S_p are Sensitivity and Specificity, respectively. The optimal cut-off point is the one that minimizes the distance d from the scenario of perfect discrimination (that is the point (0,1)). Graphically, it is the shortest distance between errorless classification (the point (0,1)) and the ROC curve. See Wodon (1997) and López-Ratón et al. (2014).

3 An empirical illustration

The empirical application is based on EU-SILC (European Union Statistics on Income and Living Conditions) 2012 longitudinal dataset. EU-SILC collects comparable longitudinal micro data on households income and living conditions referred to years 2009, 2010, 2011, 2012, for 25 EU member states plus Norway and Iceland. For the analysis we consider a sample of representative countries: Belgium, Denmark, Greece, Spain, France, Italy, Luxembourg, United Kingdom.

As income variable we choose the household equivalent disposable income using the modified OECD scale[1]. We then deflate incomes using the harmonised consumer price indices (base year 2005) provided by Eurostat, and we drop all non-positive incomes. The unit of analysis is the household and we refer to the one-year-ahead vulnerability, that is the probability of being poor in the next year.

As empirical strategy we allow for an autoregressive structure in our prediction model for log of income at time t based on information at time $t-1$ (see Calvo and Dercon, 2013). We consider rolling balanced 3-year panels, keeping in the dataset only the households that remain in the panel for three consecutive years (that is 2009-2011 and 2010-2012). For estimating future income we require two waves

[1] The OECD modified scale assigns value of 1 to the household head, of 0.5 to each additional adult member and of 0.3 to each child in the household.

to forecast household income in the third year and estimate its vulnerability, and a third wave to compute ROC curve and assess the estimate's accuracy. Information available for the first two years of each panel are used to forecast household income in the third year. The observed incomes in the third year are then used to determine which households are poor in that year and which are not. We have to note that in SILC information on income refer to the previous year. The logarithm of income was regressed on lagged log income and a number of explanatory variables. In particular, for forecasting income for year $t+1 = 2011$ and $t+1 = 2010$, we

$$\begin{aligned} \text{estimate } \alpha \text{ and } \beta \text{ using} \quad y_t &= \alpha y_{t-1} + \beta X_t + \varepsilon_t, \\ \text{predict using} \quad \hat{y}_{t+1} &= \hat{\alpha} y_t + \hat{\beta} X_{t+1}. \end{aligned}$$

The covariates included are both at household and at head of the household[2] level: log income of the previous year, number of children (0-17 years old), number of elderly (65+), number of member 18-34 years old and number of member 35-64 years old tenure status, number of rooms, number of fully employed and number of part-time workers in the household, gender, marital status and education of the householder. Using these predictions, one-year-ahead household vulnerability can be estimated. Due to space constraints, in this paper we will show only results related to vulnerability estimation for the year 2011.

The vulnerability is here estimated using a parametric approach proposed in the literature: the vulnerability, $p(\tilde{y} < z)$, where z is the poverty line, is estimated using a normal distribution with mean corresponding to the predicted future income and standard deviation put equal to 1 for each household (Celidoni, 2015). As poverty line we consider the 60% of the median income in each country.

The ROC curve is obtained by comparing the true positive and false positive rates in the third year of the panel for each possible cut-off applied to the predicted income for the third year. Next, we compute the Youden index and the Distance index illustrated in the methodological section. In general, the two indicators may suggest different optimal thresholds. In our case, the Youden and Distance index provide exactly the same values for all countries but the UK. Since the ROC curve is symmetric around the negative diagonal of the unit square, the two decision rules point to the same optimal threshold. That means that, if we consider as poor the cases whose predicted probability is greater than the optimal threshold and as non-poor the cases below this optimal cut-off point, we are minimizing both the distance from the perfect discrimination scenario and maximizing the trade-off between true alarm rate and false alarm rate. For each country considered, Table 1 provides the optimal cut-off point, together with the corresponding true positive rate and the false positive rate.

[2] The householder is here defined as the person responsible for the rent or mortgage interest.

New advances in applications, a Bayesian nonparametric perspective

Bayesian Mixture Models for Latent Class Analysis

Modelli mistura bayesiani per l'analisi delle classi latenti

Raffaele Argiento, Bruno Bodin and Maria De Iorio

Abstract Bayesian mixture models provide rich and flexible class tools which are particularly useful when there is unobserved heterogeneity in the data. When the number of subpopulations, called components, is assumed random, we allow the data to determine the complexity of the model. The latter property allows us to include a finite mixture model with a random number of components into the wider class of Bayesian nonparametric models. In this paper we consider multivariate discrete data, so that the class of mixtures is also referred to as *latent class* models. In particular, we let the number of latent classes to be random, and resort to Bayesian nonparametric techniques to devise a MCMC algorithm. The model is illustrated on an benchmark application dealing with *role conflict*.

Abstract *Le misture costituiscono una famiglia estramamente ricca e flessibile di modelli per analizzare dati provenienti da fonti etorogenee. In ambito bayesiano, quando il numero di sottopopolazioni (ovvero di componenti) è assunto aleatorio, sono i dati a determinare la complessità del modello. Quest'ultima proprietà rende una mistura con numero di componenti aleatorio un modello non parametrico. Un* modello a classi latenti *è un modello mistura per dati mutivariati e discreti. In questo lavoro ricorriamo a delle tecniche bayesiane non parametriche per costruire un algoritmo MCMC per l'analisi a posteriori di un modello a classi latenti bayesiano. Le prestazioni del modello sono illustrate mediante un applicazione riguardante lo studio di diversi comportamenti in caso di* conflitto fra ruoli.

1 Introduction

Mixture models are a very powerful and natural statistical tool to model data from heterogeneous populations. Under this class of models, observations $Y_1, \ldots, Y_n$ are assumed to have arisen from one of M (finite or infinite) groups, each group being suitably modelled by a density typically from a parametric family. A Bayesian mixture model for a set of observation in $\mathbb{R}^d$ with $d \geq 1$ is usually expressed as follow

$$\begin{aligned} &Y_i|\tau_1, \ldots, \tau_M, \mathbf{w}, M \overset{\text{iid}}{\sim} \sum_{m=1}^{M} w_m f(y \mid \tau_m), \qquad i = 1, \ldots, n \\ &\tau_m \mid M \overset{\text{iid}}{\sim} p_0(\tau_m) \qquad m = 1, \ldots, M \\ &\mathbf{w} \mid M \sim p_W(\mathbf{w}) \\ &M \sim q_M(m), \qquad m = 1, 2, \ldots \end{aligned} \tag{1}$$

where the *kernel* $f(\cdot \mid \tau_m)$ belongs to a parametric family of density on $\mathbb{R}^d$, with finite dimensional parameter τ_m, while the vector $\mathbf{w} = (w_1, \ldots, w_M)$ is such that $\sum_{m=1}^{M} w_m = 1$ and is referred as vector of the *weights* of the mixture, w_m being the weight of the $m-$th component in the population density. The vector of parameters τ_m assumes values in $\Theta \subset \mathbb{R}^s$, $s \geq 1$ and is assigned a prior density p_0. In a fully Bayesian approach the number of components of the mixture is assumed random with a prior here denoted by q_M. Moreover, conditionally on M a prior distribution with the support on the $M-1$ dimensional simplex should be assumed to the vector of weights $\mathbf{w}$, to ensure that its components represent the probability that an observation belongs to the corresponding component. Data $\{Y_i\}$ generated from a mixture can be univariate or multivariate, continuous, discrete-valued or mixed-type, outcomes of a regression model, or even time series data; see [3] for a comprehensive review of finite mixture distributions. When data are multivariate discrete a mixture model is also known as *latent class analysis* [5].

Recently in [2] we have developed a new theoretical framework for finite mixture model (i.e. $M < \infty$ almost surely). The latter work is based on the key observation that the hierarchical parametric distribution q_M, p_W, p_0 introduced in Eq. (1) define the law of an almost surely (a.s.) finite-dimensional random probability measure on the parameter space Θ. Indeed, given a realization $M, \boldsymbol{w}, \boldsymbol{\tau}$ we can define

$$P(d\theta) = \sum_{m=1}^{M} w_m \delta_{\tau_m}(d\theta) \tag{2}$$

This implies that the joint probability distribution on M, $\mathbf{w}$ and $\boldsymbol{\tau}$ induces a distribution on P defined in Eq. (2), whose support is the space of the a.s. finite-dimensional random probability measures on Θ. From this observation, the link between infinite (nonparametric) and finite mixture models becomes evident as the model in Eq. (1) can be easily rewritten as

$$\begin{aligned} &Y_1,\dots,Y_n|\theta_1,\dots,\theta_n \overset{ind}{\sim} f(y;\theta_i) \\ &\theta_1,\dots,\theta_n|P \overset{iid}{\sim} P \\ &P \sim \mathscr{P} \end{aligned} \tag{3}$$

where P is defined in Eq. (2) and $\mathscr{P}$ is the law of P defined via q_M, P_W, P_0. In [2] a constructive definition of $\mathscr{P}$ is provided by considering the weights $\{w_m\}$ as the normalised jumps of a *finite point process* and the parameters $\{\tau_m\}$ are defined in terms of realisations of the same point process. As in any mixture, the parameter θ_i's in Model (3) are equal to one of the τ_m in Eq. (2), depending on which component the i-th observation is assigned to.

2 Normalized independent finite point processes

Let Θ be the space of parameter of the family of the kernel components $f(\cdot,\tau)$. We consider the collection of random variables $\{(S_1,\tau_1),\dots,(S_M,\tau_M)\}$ such that $(S_m,\tau_m) \in \mathbb{R}^+ \times \Theta$ for any m and $M \geq 1$. The law of the random variables is assigned hierarchically so that

$$\begin{aligned} \mathscr{L}((S_1,\tau_1),\dots,(S_M,\tau_M)) &= \mathscr{L}((S_1,\tau_1),\dots,(S_m,\tau_m)|M=m)P(M=m) \\ &= \prod_{l=1}^{m} \mathscr{L}(S_l,\tau_l|M=m)P(M=m), \quad m=1,2,\dots \end{aligned}$$

Moreover we assume that S_l and τ_l are conditionally independent with density $h(s)$ and p_0 respectively, while we denote with q_M the probability mass function of M. Since we are assuming $q_M(0)=0$, the random variable $T := \sum_{j=1}^{M} S_j$ is almost surely different from 0, so that we can give the following definition.

Definition 1. A normalized independent finite point process (Norm-IFPP) with parameter h and q_M and p_0 is the discrete probability measure on Θ defined by

$$P(\cdot) = \sum_{m=1}^{M} P_m \delta_{\tau_m}(\cdot) \overset{d}{=} \sum_{m=1}^{M} \frac{S_m}{T} \delta_{\tau_m}(\cdot) \tag{4}$$

where $T = \sum_{m=1}^{M} S_m$. We will use the notation $P \sim Norm-IFPP(h, q_M, p_0)$.

Let $(\theta_1,\dots,\theta_n)$ be a sample from a Norm-IFPP; we denote by $\theta_1^*,\dots,\theta_K^*$ the unique values of this sample (observed with probability greater than 0). In this way we define a random partition by letting $\boldsymbol{\rho}_n := \{C_1,\dots,C_K\}$ on the set $\mathbb{N}_n := \{1,\dots,n\}$ where $C_j = \{i : \theta_i = \theta_j^*\}$ for $j = 1,\dots,K$.

3 Latent Class analysis

In this paper we consider the case when data $Y_i = (Y_{i1}, \cdots, Y_{id})$ are vectors of dichotomous responses, i.e. $Y_i \in \{0,1\}^d$ and the kernels for the components of the mixture are assumed to be multivariate Bernoulli distribution. Therefore, the component specific parameter vector is $\tau_m = (\tau_{m1}, \cdots, \tau_{md}) \in [0,1]^d$, where τ_{mj} denotes the probability that $Y_{ij} = 1$, for $j = \{1, \ldots, d\}$ in the m-th component (subpopulation).

When data are multivariate discrete, the mixture is referred to as *Latent Class model* [5, 4]. In the Latent Class analysis there are d possible characteristics, and τ_{mj} represents the probability (in the m-th subpopulation) that an individual endorses the $j-$th characteristic.

In what follows we set the kernels of the mixture as

$$f(y_i \mid \tau_m) = \prod_{j=1}^{d} \tau_{mj}^{y_{ij}} (1-\tau_{mj})^{1-y_{ij}}$$

Moreover, as mixing distribution, we assume $P \sim Norm - IFPP(h, q_M, p_0)$ where the prior for the locations, p_0, is the density of independent beta priors with parameters $\boldsymbol{\alpha} = (\alpha_1, \cdots, \alpha_d)$ and $\boldsymbol{\beta} = (\beta_1, \cdots, \beta_d)$:

$$p_0(\theta \mid \boldsymbol{\alpha}, \boldsymbol{\beta}) = \prod_{j=1}^{d} \pi_{\theta_j}(\theta_j \mid \alpha_j, \beta_j) = \prod_{j=1}^{d} \frac{\Gamma(\alpha_j + \beta_j)}{\Gamma(\alpha_j)\Gamma(\beta_j)} \theta_j^{\alpha_j - 1} (1-\theta_j)^{\beta_j - 1}, \quad 0 \le \theta_j \le 1,\ j = 1, \ldots, d$$

This prior is conjugate to the multivariate Bernoulli density and, as such, greatly simplifies computations. The prior on the weights is obtained by normalizing M conditionally iid gamma variables with same shape parameter γ and rate 1, so that

$$h(s;\gamma) = \frac{s^{\gamma-1} e^{-x}}{\Gamma(\gamma)} \qquad s > 0, \ \text{ for } \gamma > 0 \tag{5}$$

Finally, for the number of components we assume a Negative Binomial density with parameters $0 \le p \le 1$ and $r > 0$ and support on $\{1, 2, \ldots\}$, i.e.

$$q_M(m) = \frac{\Gamma(r+m-1)}{(m-1)!\Gamma(r)} p^{m-1} (1-p)^r, \quad m = 1, 2, \ldots \tag{6}$$

The posterior distribution of our latent class model can be approximated using a blocked Gibbs sampling scheme by a straightforward modification of the *conditional* algorithm described in [2]. The algorithm has been implemented `cpp` and is included the R package `AnTMAN` [1].

Latent Class Analysis to study *role of conflict*. The *role conflict* data consist of four observed dichotomous variables. These variables describe the response patterns for $n = 216$ individuals to four questionnaire items in which four different situations (denoted by A, B, C,and D) of role conflict are considered. The respon-

dents are cross-classified (see Table 1) with respect to whether they tend toward "universalistic" values (coded by + or 1) or "particularistic" values (coded by − or 0) when confronted by situations of role conflict.

A	B	C	D	Obs. Freq.	A	B	C	D	Obs. Freq.
+	+	+	+	42	-	+	+	+	1
+	+	+	-	23	-	+	+	-	4
+	+	-	+	6	-	+	-	+	1
+	+	-	-	25	-	+	-	-	6
+	-	+	+	6	-	-	+	+	2
+	-	+	-	24	-	-	+	-	9
+	-	-	+	7	-	-	-	+	2
+	-	-	-	38	-	-	-	-	20

Table 1 The data collect responses of individuals to a questionnaire concerning four different situations of role conflict (situations A, B, C, and D). The respondent tends either towards universalistic values (+) or toward particularistic values (-) when responding to the situation with which he or she is confronted. Source of the data: [4].

The dataset has been initially analysed by [5] who employ a particular latent class model that has five latent classes. Further analysis of the dataset is also discussed in [4], which highlight the importance of inferring the number of classes for the data, since the interpretation of the latent classes can drastically change. In this work we allow the number of possible classes M to be random, and let the data drive the inference on this parameter. To fit the data we use the R package `AntMAN` [1]. We set $\boldsymbol{\alpha} = \{1,...,1\}$, $\boldsymbol{\beta} = \{1,...,1\}$, and we add an extra level to the hierarchy by assuming $\gamma \sim Gamma(1,1)$, $p \sim Beta(1,1)$ while $r = 1$ (see Eq. (5) and (6)). All the results discussed here are based on a posterior sample of size 5000 obtained after a burn-in period of 5000 iterations and with a thinning of 50 iterations.

The posterior distribution on the number of K clusters (i.e. active classes) is displayed in the first panel of Figure 1. The posterior mode of the latter distribution is 2. The estimated clustering configuration is obtained by minimizing the Binder loss function, obtaining two active classes which cover 32.4% and 67.6% of the data respectively. We refer to [6] and [7] for more details on the Binder loss function and on the computational strategies to minimize it.

To better interpret the groups obtained under the mixture model, we estimate cluster specific parameters, i.e. the parameters $\theta_k^\star$ for $k = 1,\dots,\hat{K}$ that represent the probability of an individual to be universalistic in the four situation A, B, C and D given that it belongs to cluster k. These estimates are obtained by *conditioning* to the estimated clusters, the results are displayed in the last two panels of Figure 1.

We can interpret the two classes as a "universalistically inclined" latent class and a "particularistically inclined" latent class. The probability of a universalistic response in situation A is 0.90 for those who are in the universalistically inclined latent class; for situations B, C, and D, the corresponding probabilities are 0.77, 0.76, and 0.59, respectively. In addition, the probability of a universalistic response in situation A is 0.716 for those who are in the particularistically inclined latent class;

for situations B, C, and D, the corresponding probabilities are 0.34, 0.37, and 0.15, respectively. In situation A, the modal response is always universalistic, but the corresponding probability of a universalistic response is reduced in the particularistic latent class from 0.90 to 0.71.

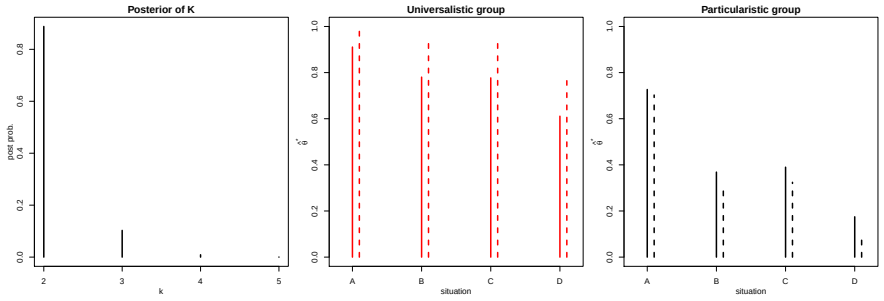

Fig. 1 Posterior inference on clustering. The first panel displays the posterior distribution of the number of active classes. The second and third panels report the posterior probabilities (continuous lines) of observing a 1 for the four situations and the corresponding empirical relative frequencies (dashed lines).

In Figure 1, the observed frequencies of 1 in each class are reported as dashed lines. We can see how, especially for the "universalistic group", the Bayesian parameter estimates are lower than the observed frequencies, due to the correlation induced by the latent class model, the uncertainty on cluster estimation as well as the prior specification. Further investigation is needed to better understand the latter issue. In fact, the problem of estimating a partition of the data using the posterior samples of a MCMC algorithm in a mixture model is still object of active research. We refer to [6] and [7] for recent discussions of this problem.

Non-Parametric Inference and Forecasting of Functional and Object Data

An interpretable estimator for the function-on-function linear regression model with application to the *Canadian weather* data

Uno stimatore interpretabile per il modello di regressione lineare con regressore e risposta funzionale con un'applicazione ai Canadian weather data

Fabio Centofanti and Matteo Fontana

Abstract An interpretable estimator for the functional linear regression model, where values of the response function depend on the whole trajectory of the covariate function, is described. It is able to increase the interpretability of the model by better identifying domain regions where the covariate does not influence the response. This property is ensured by a functional LASSO penalty and two roughness penalties. The application of the proposed estimator to the well known *Canadian weather* dataset shows its practical advantages.

Abstract *In questo lavoro viene introdotto uno stimatore del modello di regressione lineare con regressore e risposta funzionali. Lo stimatore proposto è in grado di migliorare l'interpretabilità del modello identificando in maniera più accurata le parti del dominio dove la covariata non influenza (significativamente) la risposta. Tale proprietà viene ottenuta mediante un opportuno termine di penalizzazione LASSO funzionale e due termini di penalizzazione della rugosità. I vantaggi pratici dello stimatore proposto sono evidenziati mediante applicazione ai dati Canadian weather.*

1 Methods

The development in data acquisition systems allow massive amounts of data to be recorded at high-rate and modelled as functions defined on compact domains, i.e., *functional data* . Functional data analysis (FDA) is the set of tools to deal with this type of data [12, 7, 8, 9]. In this paper, we consider the generalization of the classical linear regression analysis to the case where either the covariate or the response or both are functional data, i.e. functional linear regression (FLR) [11, 12, 7, 5, 3, 10, 6, 2]. In particular, we study the Function-on-Function (FoF) linear regression model, where both the predictor and the response variable are functions and each value of the latter, for any domain point, depends on the full trajectory of the former that is, for $i = 1, \ldots, n$,

$$Y_i(t) = \int_{\mathscr{S}} X_i(s)\,\beta(s,t)\,ds + \varepsilon_i(t) \quad t \in \mathscr{T}. \tag{1}$$

The pairs (X_i, Y_i), $i = 1, \ldots, n$, are independent realizations of the covariate X and response Y, that are smooth random functions with mean zero defined on the compact domains $\mathscr{T}$ and $\mathscr{S}$, and ε_i are independent random functional errors with mean zero and variance function σ^2 that are independent of X_i. The bivariate function β is the *coefficient function*.

In this work, we consider an interpretable estimator of the coefficient function β, named S-LASSO (Smooth plus LASSO), that has been proposed in [4]. It is locally sparse, i.e., is zero on the region where β is zero (*null region*), and, smooth on the region where β is different from zero (*non-null region*). The S-LASSO estimator $\hat{\beta}_{SL}$ is obtained as the minimum of an objective function, composed by the usual sum of squared errors added to two smoothness penalties and a functional LASSO penalty, where the latter ensures sparseness of the estimator.

From a computational point of view, $\hat{\beta}_{SL}$ is computed by means of a modified version of the *orthant-wise limited-memory quasi-Newton* (OWL-QN) algorithm [1], after the introduction of a suitable finite dimensional approximation of the optimization problem.

2 Real-Data Examples: Canadian Weather Data

In this section, we apply the S-LASSO estimator to the Canadian Weather data. The S-LASSO estimator is compared with a the estimator proposed by [12], referred to as SMOOTH, with regularization obtained by introducing two roughness penalties. We aim to demonstrate that the S-LASSO estimator has advantages in terms of both prediction accuracy and interpretability, over the SMOOTH estimator. The Canadian weather data have been studied by [12] and [13]. The data set contains the daily mean temperature curves, measured in Celsius degree, and the log-scale of the daily rainfall profiles, measured in millimeter, recorded at 35 cities in Canada

(Figure 1). The aim is to predict the log-daily rainfall based on the daily temper-

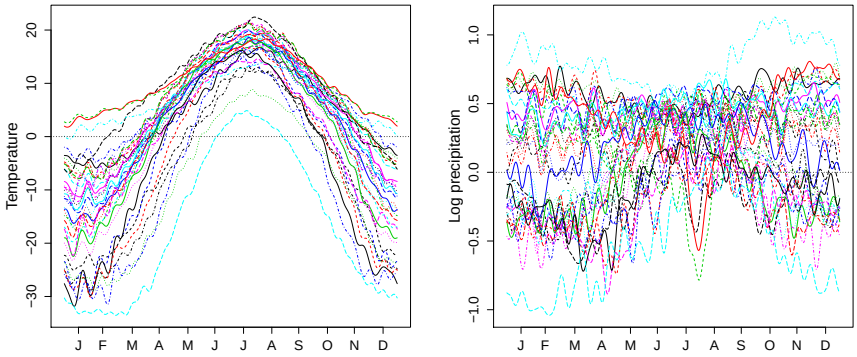

Fig. 1 Daily mean temperature and log-daily rainfall profiles at 35 cities in Canada over the year.

ature using the model reported in Equation (1). Figure 2 shows the S-LASSO and SMOOTH estimates of the coefficient function β. The SMOOTH estimate is ob-

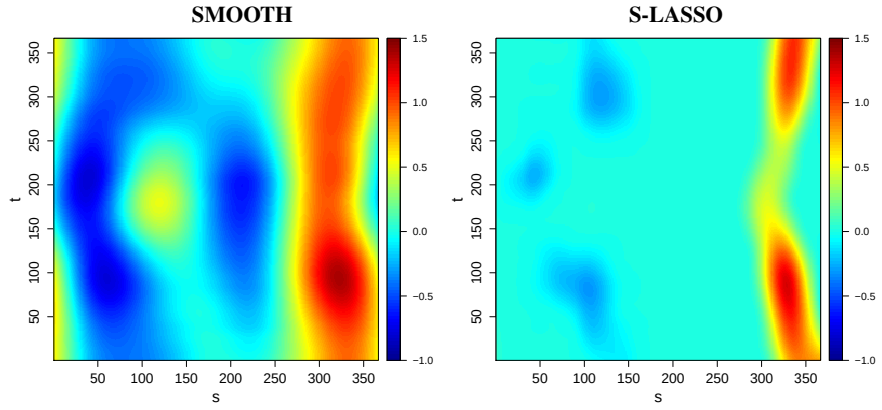

Fig. 2 SMOOTH (on the right) and S-LASSO (on the left) estimates of the coefficient functions β at different days for the Canadian weather data.

tained using a Fourier basis and roughness penalties were chosen by using 10-fold cross-validation over an opportune grid of values. The S-LASSO estimates is zero over large domain portions. In particular, except for values from July through August ($t \in [210,240]$), it is always zero in summer months ($s \in [180,270]$) and in January and February ($s \in [1,58]$). Thus, in those months rainfalls are not significantly affected by daily temperature during the year. In addition, temperature in

October, November and December ($s \in [300, 365]$) has a positive effect on the daily rainfalls. That is, the higher (the lower) the temperature is in October, November and December, the heavier (the lighter) the precipitations are during the year. The S-LASSO estimate in spring months ($s \in [90, 150]$) is negative form January through April ($t \in [1, 120]$), and from October through December ($t \in [305, 365]$). Thus, the higher (the lower) the temperature is in the spring the lighter (the heavier) the daily rainfalls are from October through April. Finally, the S-LASSO have better prediction performance than the SMOOTH one, that is, 10-fold cross-validation mean squared errors are 22.314 and 22.365, respectively.

Statistical process monitoring of multivariate profiles from ship operating conditions

Monitoraggio statistico di processo delle condizioni operative di una nave basato su analisi di dati funzionali

Christian Capezza

Abstract Motivated by CO_2 emissions monitoring from maritime transportation, we propose and apply statistical methods for industrial process monitoring of scalar quality characteristic in presence of multivariate functional covariates. The two main objectives are (i) the prediction of CO_2 emissions based on covariates' profiles describing the ship operating conditions at each voyage and (ii) the statistical process monitoring of ship operating conditions and CO_2 emissions based on functional control charts. We aim to provide industrial practitioners with interpretable tools that give clear indications of anomalies by identifying the related causes, possibly in real-time. We show the evolution of the methods proposed in our research from multivariate methods, to feature-oriented and functional data analysis approaches.

Abstract *Motivati dal problema del monitoraggio e la previsione di emissioni di CO_2 nel trasporto marittimo, vengono proposti metodi statistici per il monitoraggio di processi industriali. I due obiettivi principali possono essere ricondotti (i) alla previsione di emissioni di CO_2 basata sui profili di covariate che descrivono le condizioni operative della nave ad ogni viaggio e (ii) al monitoraggio statistico di processo delle condizioni operative e delle emissioni di CO_2 basato su carte di controllo funzionali. L'obiettivo del lavoro è la definizione di carte di controllo interpretabili dagli ingegneri navali riguardo le possibili anomalie e l'identifiazione delle relative cause. I metodi di analisi statistica affrontati vengono presentati per livello di complessità crescente: a partire da metodi di analisi multivariata, approcci feature-oriented, fino all'analisi di dati funzionali.*

1 Introduction

Moving from the multivariate data analysis setting [1, 3, 6, 10, 12, 13, 15], the aim of this work is to provide statistical methods for industrial process monitoring of a scalar quality characteristic in presence of multivariate functional covariates. The industrial context is the prediction and monitoring of CO_2 emissions from maritime transportation. Specifically, the two main objectives are (i) the prediction of CO_2 emissions on the basis of covariates' profiles describing the ship operating conditions at each voyage and (ii) the statistical process monitoring of ship operating conditions and CO_2 emissions based on functional control charts.

The relevance of the industrial scenario is highlighted at international level by the EU regulation 2015/757 [7], which urges shipping operators to set up systems for the monitoring, reporting and verification of CO_2 emissions. The aim is to give greater transparency to operations and public access to CO_2 emissions data in the shipping sector. On the other hand, modern ships allow the continuous acquisition of operational data, which calls for the application of opportune statistical methods for high-dimensional data. In fact, multi-sensor systems installed on board of modern ships stream massive amounts of observational data with high frequency. For each voyage, these data can be considered to be varying over a continuous domain, then ship operating conditions can be described by sensor signals and stored as profiles. However, currently there is no standard solution or method available in the shipping industry that can be robustly adopted in real environments.

In the following sections, we show the evolution of the methods proposed in our research from multivariate methods, to feature-oriented and functional data analysis approaches. In particular, in Section 2 we describe the dataset used in the proposed approaches. In Section 3 we describe methods for the prediction of ship CO_2 emissions, while in Section 4 we describe methods for statistical process monitoring of ship performance.

2 Data description

In the following, we briefly describe the navigation data set analyzed using the proposed approaches. The data are acquired from a Ro-pax ship sailing over different route. Each model is built for a specific route, and each observation corresponds to a voyage. The response variable is the total CO_2 emissions in the navigation phase per each voyage, measured in tons. The covariates are stored as profiles since observations are available at five minute frequency, we list them as follows. The *cumulative sailing time* variable measures the voyage navigation time. The *speed over ground* (SOG) variable is the ratio between the distance travelled by the ship and the cumulative sailing time. The *acceleration* variable is obtained as the derivative of SOG. The *power difference between port and starboard propeller shafts* indicates possible anomalies or malfunctioning in the main engines, when one of the main engines is turned off. The *Distance from the nominal route* variable is the distance

from the nominal route of the current position of the vessel. The *longitudinal wind component* and *transverse wind component* variables are obtained on the basis of the wind speed direction relative to the ship acquired by the anemometer sensor. The *air temperature* variable is the average of the temperatures measured from the sensors installed on the four main engines. The *Trim* variable is obtained through the inclinometer sensor measurements. Additional information about the variables can be found in [1, 5, 6].

3 Methods for the prediction of ship CO_2 emissions

The marine engineering literature mainly relies on the use of white-box models for prediction of CO_2 emissions. The most common example is the speed-power curve [18, 20], which describes an ideal univariate relationship between the engine power, which is related to the CO_2 emissions, and the vessel speed and is usually calibrated through dedicated tests. However, this curve overlooks other factors affecting the vessel during navigation and leads to poor predictions of CO_2 emissions. Nowadays, the statistical and data science domains offer potentially interesting tools to circumvent this limitation.

3.1 Feature-oriented methods

The profile of variables automatically acquired at each voyage by multi-sensor systems is typically complex, unstructured, intrinsically collinear and with non-stationary behavior. In this scenario, classical approaches used in the naval literature may fail or are at least suboptimal, since they are limited to the analysis of averages per voyage. However, in spite of the easier interpretability, compressing a variable profile into a single average value may lead to significant information loss and to discarding most of the relevant dynamic patterns.

In the opposite spectrum of complexity, multivariate statistical methods commonly used for monitoring batch processes usually require the implementation of data pre-processing techniques that constitute an additional challenge for practitioners and may hamper their practical usability. For example, data needs to be correctly unfolded to handle its three-way structure, resulting in a very large number of pseudo-variables and model parameters. Furthermore, complex synchronization methods are required in order to ensure that the voyages' major landmarks are aligned and that all voyages have the same number of observations.

The batch process monitoring literature is vast and another class of approaches that is growing in importance is the class of feature-oriented methods. These methods are simpler to apply because they do not require synchronization and tend to be more parsimonious since the number of model parameters is smaller. Examples of feature-oriented methods include profile-driven features, recently proposed by

[17], and statistical pattern analysis, proposed by [8]. These techniques compress each variable into a small number of features that can be utilized for data-driven model building. We showed the successful implementation of these techniques in a shipping industry application in [16].

3.2 Scalar-on-function regression

The most complex approach to the prediction problem avoids the simplification of feature-oriented methods that extract relevant features from the profiles, but it treats the data describing the operating conditions of a ship over each voyage as unique, complex mathematical objects, such as functions or vectors of functions. In this context, functional data analysis techniques, in particular scalar-on-function regression, can be used to predict the CO_2 emissions at each voyage.

Denote by y the scalar response variable representing the CO_2 emissions at each voyage, let $\{(\boldsymbol{X}_i, y_i)\}_{i=1,\ldots,n}$ be a random sample from $(\boldsymbol{X}, y)$, with $\boldsymbol{X}_i = \boldsymbol{X}_i(t) = (X_{i1}(t), \ldots, X_{iP}(t))$ being a vector of functional covariates. The conditional distribution of y_i given the corresponding observation of the functional covariates $\boldsymbol{X}_i$ can be modeled by means of the following scalar-on-function regression model

$$y_i = \beta_0 + \sum_{p=1}^{P} \int_{\mathscr{T}} X_{ip}(t)\beta_p(t)dt + \varepsilon_i, \quad i = 1, \ldots, n, \tag{1}$$

where $\beta_0 \in \mathbb{R}$, $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_P)$, with $\beta_p \in L^2(\mathscr{T})$, the space of square integrable functions, are the coefficient to be estimated, and $\varepsilon_1, \ldots, \varepsilon_n$ are the error terms, which are assumed to be independent identically distributed. Estimation of these types of models requires to deal with the infinite dimensionality of the dataset and is based on multivariate functional principal component analysis. More details on the methodology can be found on [4, 5].

4 Methods for statistical process monitoring of ship operating conditions and CO_2 emissions

There are two relevant aims related to statistical process monitoring of ship performance and CO_2 emissions: (*i*) statistical monitoring of ship fuel consumption and CO_2 emissions for anomaly detection and (*ii*) quantifying CO_2 emissions reduction consequent to energy efficiency initiatives or dry-dock operations. Many of the available methods for prediction and monitoring have strong limitations when applied to high-dimensional and correlated data, or they do not fully exploit all of the available information. There is a common framework among all the methods proposed in this work for statistical process monitoring, which can be summarized in the following steps:

1. the starting point is a regression model where the ship CO_2 emissions are the response variable to be predicted using one of the approaches described in the previous section;
2. since the predictor variable space is characterized by high or infinite dimensionality, dimensionality reduction is applied to both stabilize the estimation of regression coefficients in the prediction problem and to describe covariates in a more efficient and interpretable way, in a lower dimensional subspace; functional principal component analysis and partial-least squares methods are used for this purpose;
3. the dimension reduction provides a nice split of the covariate space into two complementary subspaces: correspondingly, two control charts are used. Usually the Hotelling T^2 statistic is calculated on the variables obtained from the projection of covariates onto the subspace of the components retained in the model, while a squared prediction error statistic monitors the squared distance of the covariates in the original space from the projection subspace; finally a third monitoring statistic looks at the prediction error on the response variable based on the regression model;
4. on the basis of the monitoring statistics and a reference sample of in-control observations, control charts are built to monitor future observations
5. when some control charts detect out-of-control observations, contribution plots are built in order to decompose the monitoring statistics as sums over the covariates, in order to identify the variable(s) responsible of anomalies.

The main advantage of considering profiles instead of single observations per each voyage is the possibility to give real-time predictions and indications on possible anomalies in ship operating conditions during a voyage and on the instant at which anomalies may have occurred. Two main approaches are presented in this work to profile monitoring. Both of them are able to monitor profiles with different length at different voyages (due to the different duration). The first approach is presented in [11, 9] and uses multi-way partial least-squares (PLS) regression [14] and a multilinear version of PLS proposed by [2, 19], which is called three-way PLS. They require a three-dimensional array that contains ship operational reference profiles at given domain points with the following three dimensions: the number of replications, the number of variables, and the number of evaluation points. The second approach is presented in [5] and is based on multivariate functional principal component analysis.

Prior choice in Bayesian Modelling (SISbayes)

Bayesian Learning of Multiple Essential Graphs

Apprendimento Bayesiano di Grafi Essenziali Multipli

L. La Rocca, F. Castelletti, S. Peluso, F.C. Stingo and G. Consonni

Abstract Structural learning of graphical models is a well-established approach to the identification of complex dependencies in biological networks. We here present a Bayesian methodology for learning directed networks from observational data when distinct subgroups of a population are observed.

Abstract *L'apprendimento strutturale di modelli grafici è un approccio consolidato all'identificazione di dipendenze complesse in reti biologiche. Presentiamo qui una metodologia bayesiana per l'apprendimento di reti orientate da dati osservazionali quando si osservino sottogruppi distinti di una popolazione.*

Key words: Markov equivalence, Markov random field, objective Bayes

1 Introduction

Understanding the genome, in terms of structure and function, is at the foundation of genomic medicine [5, 13]. The identification of complex dependencies in biological networks, such as co-expression, gene regulatory and protein interaction networks, plays a major role in this effort and graphical models have been successfully applied to infer the dependence structure of *omics* variables [8, 18, 20]. An important case is that of observations collected from a population divided into groups. For instance, gene expression measurements can be available both for cancer and normal tissue samples. In this case, both differences and similarities are expected between the distinct groups and their networks should be learned together. A few proposals to tackle this problem are available in the literature, including the joint lasso [7], direct estimation of differential networks [23] and Bayesian methods [15, 19].

The above proposals learn undirected networks. However, in genetic analyses, there is a special interest for directed pathways. Furthermore, in graphical modeling, acyclic directed graphs provide an effective data generating mechanism. Motivated by these reasons, we contribute to the literature on learning multiple directed structures [14, 22] a Bayesian method that explicitly deals with *Markov equivalence*: the fact that some directed structures cannot be distinguished through observational data, at least in the Gaussian setting we consider; see Wang & Drton [21] for non-Gaussian observations. Our method learns partially directed structures: if possibile it detects the direction of an association, otherwise it acknowledges that a direction cannot be detected. Sect. 2 provides the necessary background on graphical models and formalizes our structural learning problem; we refer to Drton & Maathuis [9] for a broader presentation of graphical models and structural learning.

2 Structural Learning of Graphical Models

A *simple graph* $\mathbb{G} = (V, \mathcal{E})$ consists of a finite set of vertices $V = \{1, \ldots, q\}$ together with a set of edges $\mathcal{E} \subseteq V \times V$ such that $u \neq v$ for all $(u, v) \in \mathcal{E}$ (no loops). We say that $\mathbb{G}$ contains the *line* $u - v$ if both $(u, v) \in \mathcal{E}$ and $(v, u) \in \mathcal{E}$, while we say that $\mathbb{G}$ contains the *arrow* $u \to v$ if $(u, v) \in E$ but $(v, u) \notin E$. If $u \to v$ is contained in $\mathbb{G}$, we say that u is a *parent* of v. Now let A be a nonempty subset of V. The *parent set* of A is defined as $\mathrm{pa}(A) = \{u \in V | u \text{ is a parent of some } v \in A\}$. The *subgraph* of $\mathbb{G}$ induced by A is defined as $\mathbb{G}_A = (A, \mathcal{E}_A)$, where $\mathcal{E}_A = \mathcal{E} \cap (A \times A)$. An *immorality* is a subgraph of the form $u \to v \leftarrow w$, while a *flag* is a subgraph of the form $u \to v - w$. A sequence of distinct vertices $v_0, v_1, \ldots, v_k$ is a *path* of length k from v_0 to v_k in $\mathbb{G}$ if $\mathbb{G}$ contains $v_{j-1} - v_j$ or $v_{j-1} \to v_j$ for all $j = 1, \ldots, k$. A *cycle* is defined like a path, but with $v_0 = v_k$. An *undirected path* is a path where there are only lines, a *directed cycle* is a cycle where there is at least one arrow.

An *Undirected Graph* (UG) is a simple graph containing only lines. The *skeleton* of $\mathbb{G}$ is the UG obtained from $\mathbb{G}$ by replacing all its arrows with lines. An UG is *chordal* if every cycle of length $k \geq 4$ admits a *chord*, that is, two nonconsecutive

vertices joined by a line. A *directed graph* is a simple graph containing only arrows. A directed graph without cycles is called a *Directed Acyclic Graph* (DAG). A *Chain Graph* (CG) is a simple graph without directed cycles. For a CG $\mathbb{G}$, we call *chain component* an inclusion maximal set of vertices $\tau \subseteq V$ such that all its pairs of vertices are joined by an undirected path. The set of all chain components of a CG, denoted by $\mathcal{T}$, is a partition of V, and all arrows between two chain components share the same direction, so that every CG can be seen as a DAG containing *meta-arrows* between chain components [16]. Both UGs and DAGs are special cases of CGs: UGs have no meta-arrows, while DAGs have singleton chain components.

A *graphical model* is a multivariate statistical model specified by conditional independence constraints that can be read from a graph through a *Markov property* suitable for that kind of graph [9]. We are interested in DAG models, as we explain in Sect. 1, but it turns out that we need a broader class of CG models to deal with observational data: any two DAGs with the same skeleton and the same immoralities specify the same model as their *essential graph*, which is a CG with no flags, whose chain components induce chordal subgraphs and whose meta-arrows have weakly sunsubstantial arrowheads, using the characterization of Roverato [16], so that such a CG is all that can be learned from data collected without interventions. Details and historical information can be found in [16], while interventional data are dealt with by Hauser and Bühlmann [10]; see also Castelletti & Consonni [2].

Now let $Y_1, \ldots, Y_q$ be our observables of interest, in a given population, stacked in a column vector $\mathbf{Y}_{1:q}$ with joint probability density function $f(\mathbf{y}_{1:q})$, $\mathbf{y}_{1:q} \in \mathbb{R}^q$. We assume that f is Gaussian and Markov with respect to an essential graph $\mathbb{G}$:

$$f(\mathbf{y}_{1:q}) = \prod_{\tau \in \mathcal{T}} f_{\mathbb{G}}(\mathbf{y}_\tau | \mathbf{y}_{\mathrm{pa}(\tau)}, \mathbf{B}_{[\tau]}, \boldsymbol{\Omega}_{[\tau]}), \tag{1}$$

where $\mathbf{y}_\tau$ denotes the subvector of $\mathbf{y}$ indexed by τ, $\mathbf{B}_{[\tau]}$ is a $\{|\mathrm{pa}(\tau)|+1\} \times |\tau|$ matrix, $\boldsymbol{\Omega}_{[\tau]}$ is a $|\tau| \times |\tau|$ positive definite matrix, whose entries associated to lines that are not contained in $\mathbb{G}_\tau$ are equal to zero, and $f_{\mathbb{G}}(\mathbf{y}_\tau | \mathbf{y}_{\mathrm{pa}(\tau)}, \mathbf{B}_{[\tau]}, \boldsymbol{\Omega}_{[\tau]})$ denotes the $|\tau|$-dimensional Gaussian density having $\mathbf{B}_{[\tau]}^\top (1, \mathbf{y}_{\mathrm{pa}(\tau)}^\top)^\top$ as mean vector and $\boldsymbol{\Omega}_{[\tau]}^{-1}$ as covariance matrix. Anderson et al. [1] discuss the underlying Markov property and data generating mechanism.

We observe $\mathbf{Y}_{1:q}$ in K subgroups of a population. Let $\mathbf{Y}_{[k]}$ be the $n_k \times q$ data matrix from group k, for $k = 1, \ldots, K$, and denote by $\mathbf{Y}_{[1:K]}$ the full data matrix, obtained by stacking $\mathbf{Y}_{[1]}, \ldots, \mathbf{Y}_{[K]}$ on top of one another. Assuming independent sampling, within and across subgroups, the i-th row of $\mathbf{Y}_{[k]}$, denoted by $\mathbf{y}_{[k]i}^\top$, for $i = 1, \ldots, n_k$, contributes to the likelihood a factor like (1), but with a group specific graph $\mathbb{G}_{[k]}$, as well as group specific matrices $\mathbf{B}_{[k,\tau]}$ and $\boldsymbol{\Omega}_{[k,\tau]}$. We aim at learning the graphs, whose ensemble we denote by $\mathbb{G}_{[1:K]}$ and call a multiple essential graph, while we regard the matrices $\mathbf{B}_{[k,\tau]}$ and $\boldsymbol{\Omega}_{[k,\tau]}$ as nuisance parameters.

We adopt a Bayesian approach and assign a *parameter prior* $\pi_{\mathbb{G}_{[k]}}(\boldsymbol{B}_{[k,\tau]}, \boldsymbol{\Omega}_{[k,\tau]})$ to the nuisance parameters, independently over $k = 1, \ldots, K$ and $\tau \in \mathcal{T}_k$, where $\mathcal{T}_k$ denotes the set of all chain components of $\mathbb{G}_{[k]}$. We can thus eliminate the nuisance parameters by computing the *marginal likelihood*

$$m(\mathbf{Y}_{[1:K]}|\mathbb{G}_{[1:K]}) = \prod_{k=1}^{K} \prod_{\tau \in \mathcal{T}_k} m_{\mathbb{G}_k}(\mathbf{Y}_{[k]\tau}|\mathbf{Y}_{[k]\mathrm{pa}(\tau)}), \tag{2}$$

where $\mathbf{Y}_{[k]\tau}$ is the submatrix of $\mathbf{Y}_{[k]}$ formed by the columns of $\mathbf{Y}_{[k]}$ indexed by τ, while $m_{\mathbb{G}_k}(\mathbf{Y}_{[k]\tau}|\mathbf{Y}_{[k]\mathrm{pa}(\tau)})$ is obtained by integrating out $\boldsymbol{B}_{[k,\tau]}$ and $\boldsymbol{\Omega}_{[k,\tau]}$ from the expression $\pi_{\mathbb{G}_{[k]}}(\boldsymbol{B}_{[k,\tau]}, \boldsymbol{\Omega}_{[k,\tau]}) \prod_{i=1}^{n_k} f_{\mathbb{G}_{[k]}}(\mathbf{y}_{[k]i\tau}|\mathbf{y}_{[k]i\mathrm{pa}(\tau)}, \boldsymbol{B}_{[k,\tau]}, \boldsymbol{\Omega}_{[k,\tau]})$. We also assign a prior distribution $\Pr(\mathbb{G}_{[1:K]})$ on the set of all multiple essential graphs, which can be updated with the evidence gauged by (2), using a version of Bayes' theorem, to the posterior distribution $\Pr(\mathbb{G}_{[1:K]}|\mathbf{Y}_{[1:K]}) \propto m(\mathbf{Y}_{[1:K]}|\mathbb{G}_{[1:K]}) \Pr(\mathbb{G}_{[1:K]})$. The latter can eventually be summarized through the *projected median probability graph model* described in [3]. Sect. 3 presents our priors and their computational implications.

3 Prior Choice and Posterior Computation

We deal with nuisance parameters using an objective Bayes approach. Specifically, we assign the parameter prior $\pi_{\mathbb{G}_{[k]}}(\boldsymbol{B}_{[k,\tau]}, \boldsymbol{\Omega}_{[k,\tau]})$ as suggested by Consonni et al. [6], which produces a closed-form expression for the term $m_{\mathbb{G}_k}(\mathbf{Y}_{[k]\tau}|\mathbf{Y}_{[k]\mathrm{pa}(\tau)})$ in (2) and thus prevents a significant computational issue; see also [4]. As for the multiple essential graph $\mathbb{G}_{[1:K]}$, we first specify a prior for the skeletons of $\mathbb{G}_1, \ldots, \mathbb{G}_K$, whose ensemble we represent by a collection of K-dimensional vectors $\mathbf{s}_{ij}$, $1 \le i < j \le q$, such that $s_{ijk} = 1$ if $i - j$ is contained in the skeleton of $\mathbb{G}_{[k]}$ and $s_{ijk} = 0$ otherwise. We then assume that all multiple essential graphs with given skeletons are equally probable. In this way, we can encourage similarity in the skeletons as suggested by Peterson et al. [15] for UGs and thus borrow strength across groups.

The prior in [15] is a hierarchical Markov random field specified as follows:

$$\pi(\mathbf{s}_{ij}|\nu_{ij}, \boldsymbol{\Theta}) \propto \exp(\nu_{ij} \mathbf{1}_K \mathbf{s}_{ij} + \mathbf{s}_{ij}^\top \boldsymbol{\Theta} \mathbf{s}_{ij}), \tag{3}$$

independently over $1 \le i < j \le q$, where ν_{ij} is a scalar sparsity parameter, $\boldsymbol{\Theta}$ is a $K \times K$ symmetric matrix, whose entries measure pairwise group associations, $\mathbf{1}_K$ is a K-dimensional vector of ones, and the normalizing constant can be analytically calculated, as a function of ν_{ij} and $\boldsymbol{\Theta}$, for reasonably small values of K. We denote by $\boldsymbol{\nu}$ the vector of all sparsity parameters and by $\boldsymbol{\theta}_{km}$ the generic entry of $\boldsymbol{\Theta}$.

The entries of $\boldsymbol{\Theta}$ follow a spike and slab prior, independently of the sparsity parameters, because $\boldsymbol{\theta}_{km} = 0$ identifies conditional independence between group k and group m, given the other groups, which is an interesting lack of association. The spike $\boldsymbol{\theta}_{km} = 0$ has probability w, independently over $1 \le k < m \le K$, while the slab distribution (a gamma distribution) has positive support to encourage similarity. The sparsity parameters are independent and $e^{\nu_{ij}}/(1 + e^{\nu_{ij}})$, which can be interpreted as a baseline inclusion probability for the line $i - j$, follows a beta distribution, whose parameters express prior information on sparsity.

We compute a Monte Carlo approximation of the posterior distribution on the set of all multiple essential graphs by marginalizing a Markov chain that targets the joint

posterior distribution of $\mathbb{G}_{[1:K]}$, $\boldsymbol{\Theta}$ and ν, using a Metropolis-Hastings algorithm. Following He et al. [11], when we propose a new essential graph, we make local changes to its structure through *perfect operators*, so as to guarantee that the chain has good theoretical properties. We update the essential graphs one at a time and the same we do with the entries of $\boldsymbol{\Theta}$, toggling between the spike and the slab, as well as with the sparsity parameters. The acceptance ratio for a new essential graph depends on the ratio between the number of DAGs that share its skeleton and the same quantity for the current skeleton; these quantities are hard to compute and we resorted to a simple heuristic approximation [4]. Sect. 4 highlights our results.

4 Results

We first validated our approach in the same simulation setting used by Castelletti et al. [3] for single essential graphs. Our simulations showed that the proposed method compares favorably to state-of-the-art methods for learning single essential graphs: we achieve comparable performance when the simulated networks are independent and a gain in reconstruction accuracy when the simulated networks are close to each other. Details of our simulations and their outcomes are reported in [4].

We then analyzed two datasets from multiple protein networks [12, 17]. We found networks consistent with the literature, but a few alternative regulatory mechanisms emerged, which warrant further investigation. Details of our analyses and their outcomes are reported in [4]. We here only comment on sparseness and overlap for the networks reconstructed from the data of Kornblau et al. [12], which consist of the levels of $q = 18$ proteins in $K = 4$ subtypes of leukemia patients. Table 1 reports the number of edges shared between pairs of networks, with the number of edges in each network on the diagonal. Out of $q(q-1) = 306$ possible edges (UG with all edges) a maximum of 15 is selected (for the subtype $M2$). The sparser networks show a significant amount of overlap with the denser ones, with a minimum of 2 edges in the network $M1$ that are not present in the network $M2$. These results show the value of formulating this learning problem in terms of multiple structures.

Table 1 Shared edge counts for the reconstructed leukemia protein networks

Subtype	$M0$	$M1$	$M2$	$M4$
$M0$	9	6	7	6
$M1$		9	6	5
$M2$			15	6
$M4$				12

Bayesian post-processing of Gibbs sampling output for variable selection

Analisi bayesiana del Gibbs sampling per la selezione di variabili.

Stefano Cabras

Abstract We consider the problem of variable selection in general, but with specific focus on ordinary linear regression model where the number of covariates is larger and big enough to prevent exploration of all possible models. In this context, a stochastic model exploration with Gibbs-sampling is usually needed. With the aim of estimating the model inclusion probability (or including other interesting feature), the empirical estimator is consistent for a large number of steps with respect to the size of model space. However, we found that there is still space to improve such estimation in even a low number of steps with respect to the size of the model space. The focus is then here on post-processing Gibbs-sampling output using within a proper Bayesian analysis of such output. In particular a Dirichlet Process (DP) prior is used on the space of all possible models. The probability distribution on all model space is thus estimated combining the DP prior and the output of the Gibbs-sampling.

Abstract *Consideriamo il problema della selezione di variabili in generale e con particolare riferimento al modello lineare quando il numero delle covariate è sufficientemente grande da impedire l'esatto confronto tra tutti i possibili modelli. In questo contesto, lo spazio dei modelli è esplorato mediante il Gibbs-sampling. L'obiettivo è ottenere una stima della probabilità di inclusione a posteriori delle covariate. La stima empirica è consistente quando il numero di passi del Gibbs-sampling è sufficientemente elevato rispetto alla dimensione dello spazio dei modelli. Abbiamo osservato che è possibile migliorare le stime rispetto alla versione empirica. L'obiettivo del lavoro è analizzare l'output del Gibbs-sampling mediante procedure bayesiane non-parametriche utilizzando il processo di Dirichet come distribuzione a priori su tutto lo spazio dei modelli. La probabilità di inclusione è quindi stimata combinando tale a priori con l'output del Gibbs-sampling.*

1 Introduction

Consider the usual problem in regression analysis consisting in finding a suitable set of predictors for a response variable y chosen among a fixed design matrix X with p columns. In a Bayesian setting we have to evaluated the posterior probability $\pi(\mathscr{M}_\gamma|y)$ of each regression model $\mathscr{M}_\gamma$, where $\gamma = (\gamma_1, \ldots, \gamma_p)$, with $\gamma_j = 1$ if the jth column of X_p is in $\mathscr{M}_\gamma$, namely $\pi(\mathscr{M}_\gamma|y)$ for all $\gamma \in \Gamma$ and Γ has cardinality 2^p.

Each $\pi(\mathscr{M}_\gamma|y)$ is obtained, exactly, by means of all Bayes Factors (BF) $BF_{\gamma 0}$ in which each possible model $\mathscr{M}_\gamma$ is compared against a common null nested model $\mathscr{M}_0$, usually the regression with only the intercept. To obtain $\pi(\mathscr{M}_\gamma|y)$ a prior on model space, $\pi(\mathscr{M}_\gamma)$ must be chosen. We consider the uniform $\pi(\mathscr{M}_\gamma) = 2^{-p}$, although other alternatives are possible. Different definitions of $BF_{\gamma 0}$ can be employed depending on the prior on model parameters. For instance, the conventional prior approach in [5] provides a closed form expression of $BF_{\gamma 0}$ with suitable properties. An important one is the predictive matching property which assures that $BF_{\gamma 0} = 1$ if there is not enough information in the data to distinguish between $\mathscr{M}_\gamma$ and $\mathscr{M}_0$. Closed form expression of the $BF_{\gamma 0}$ can be also achieved by using non-local priors on model parameters as detailed in [11] which again as other interesting properties. Beyond choices of model parameters prior and/or model prior, the point is that even under closed form expression of BFs an exhaustive exploration of Γ is not possible and thus a stochastic model search must be employed in order to obtain an estimation of $\pi(\mathscr{M}_\gamma|y)$. Along with such estimation, other interesting features can be derived from $\pi(\mathscr{M}_\gamma|y)$. The one of main interest here is the inclusion probability of a covariate j, τ defined on marginalizing $\pi(\mathscr{M}_\gamma|y)$ over all γ such that $\gamma_j = 1$. τ is necessary in order to define the median probability [4] model defined as the model such that $\tau > 0.5$ for all covariates in it. If this model exists, it is proved to be very near to the true model even under strong collinearity [3]. Under the scenario in which Γ cannot be fully explored, stochastic model search is usually employed in lieu of heuristic algorithms. In the case of normal linear regression model the stochastic approach is done by means of the well known the Gibbs-sampling algorithm discussed in [9]. Such an algorithm provides a dependent sequence of $\mathscr{M}^{(S)} = \left(\gamma^{(1)} \in \Gamma, \ldots, \gamma^{(S)} \in \Gamma\right)$ supposed to be a sample of size S from $\pi(\mathscr{M}_\gamma|y)$.

The aim of this paper is to use such a sample to obtain an estimation of τ, namely $\widehat{\tau}$. Different definition of $\widehat{\tau}$ derived from the Gibbs-sampling algorithm have been studied in [8] applying known concept of sampling theory. In particular, two estimators are compared:

i) the intuitive *empirical* proportion of the sampled models containing covariate j, $\widehat{\tau}_{\mathrm{e}} = S^{-1} \sum_{\gamma \in \mathscr{M}^{(S)}}^{S} \mathbf{1}(\gamma)_{\gamma_j=1}$, called the empirical estimator;

ii) the *renormalized* proportion of the sampled models containing covariate j, $\widehat{\tau}_{\mathrm{r}} = \frac{\sum_{\gamma \in \mathscr{M}^{(S)}} \mathbf{1}(\gamma)_{\gamma_j=1} \pi(\mathscr{M}_\gamma) BF_{\gamma^{(s)}0}}{\sum_{\gamma \in \mathscr{M}^{(S)}} \pi(\mathscr{M}_\gamma) BF_{\gamma^{(s)}0}}$, called the renormalized estimator.

It results that both are consistent estimators of τ for $S \to \infty$ and that the error of $\widehat{\tau}_{\mathrm{r}}$ is the sum of two components: the error of $\widehat{\tau}_{\mathrm{e}}$ plus (or minus) a term that depends on the correlation between posterior probability of a $\mathscr{M}_\gamma$ and its occurrence as a visited model. Basically, if the Gibbs-sampling moves very little around a model $\mathscr{M}_\gamma$ just because it has highest posterior probability (not necessarily a large one), $\widehat{\tau}_{\mathrm{r}}$ will be more biased than $\widehat{\tau}_{\mathrm{e}}$.

The idea of this paper is to rethink about all these estimators of τ and use a proper Bayesian approach to analyze the sequence $\mathscr{M}^{(S)}$. In practice, $\mathscr{M}^{(S)}$ can be viewed as a sequence of non ordinal categorical variables with two levels which gives raise to a *very sparse* contingency table of dimension 2^p whose cells probabilities are $\pi(\mathscr{M}_\gamma|y)$. This is the same setup as in [7]. Deriving the posterior distribution of cells probability is the same as deriving an estimation of $\pi(\mathscr{M}_\gamma|y)$ and thus the τ. That is, from $\pi(\tau|\mathscr{M}^{(S)})$ we define $\widehat{\tau}_{\mathrm{b}} = E_{\pi(\tau|\mathscr{M}^{(S)})}\tau$ and this is the estimator we will compare against $\widehat{\tau}_{\mathrm{e}}$ and $\widehat{\tau}_{\mathrm{r}}$ allowing also for properly account the uncertainty around the obtained value of $\widehat{\tau}$.

The following sections will illustrate the Bayesian model used to obtain $\widehat{\tau}_{\mathrm{b}}$ along with examples on simulated and real data. Some final remarks are left in the last section.

2 Post processing with the Dirichlet process prior

Using the notation in [7] let $\pi = \left\{\pi_{\gamma_1\gamma_2\cdots\gamma_p}, \gamma_j = 0,1, j = 1,\ldots,p\right\} \in \Pi$ be the set of all probabilities tensor of on Γ of size 2^p (all joint probabilities), where $\|\pi\|_1 = \sum_{\gamma_1=0}^{2} \cdots \sum_{\gamma_p=1}^{d_p} \left|\pi_{\gamma_1\gamma_2\cdots\gamma_p}\right| = 1$ and every $0 \le \pi_{\gamma_1\gamma_2\cdots\gamma_p} \le 1$. In this notation and without loss of generality we denote the two categories of $\gamma_j^{(s)}$, by $c_j = 0,1$. Probability π can be decomposed as an addictive mixture of k sets of probabilities,

$$\pi = \sum_{h=1}^{k} v_h \Psi_h, \quad \Psi_h = \psi_h^{(1)} \otimes \psi_h^{(2)} \otimes \cdots \otimes \psi_h^{(p)}$$

where $\mathbf{v} = (v_1,\ldots,v_k)'$ is the probability vector of the k sets, $\Psi_h \in \Pi_{1\ldots p}$, with $\psi_h^{(j)}$ being the probability for covariate j to be in the suitable set of predictors given a certain probability distribution over all Γ labeled by a specific value of h. The likelihood of $\mathbf{v}$ and ψ is

$$\Pr\left(\gamma_1^s = c_1,\ldots,\gamma_p^s = c_p|\mathbf{v},\psi\right) = \pi_{c_1\cdots c_p} = \sum_{h=1}^{k} v_h \prod_{j=1}^{p} \psi_{hc_j}^{(j)}.$$

Introducing the latent class indicator $z_s \in \{1,\dots,k\}$, the conditional probability to a specific set h is $\Pr\left(\gamma_j^s = c_j | z_s = h\right) = \psi_{hc_j}^{(j)}$ we have that ψs are just the inclusion probabilities of covariates for a given distribution on all model space. Thus the marginal distribution of $\tau = \psi^{(j)} = \sum_{h=1}^{k} \Pr\left(\gamma_j^s = 1 | z_s = h\right) \Pr(z_s = h)$, is the distribution of interest which leads to the definition of our estimator

$$\widehat{\tau}_{\mathrm{b}} = E_{\pi(\tau|\mathscr{M}^{(S)})}\tau = E(\psi^{(j)}|\mathscr{M}^{(S)}) = \sum_{h=1}^{k} \Pr\left(\psi_{hc_j}^{(j)}|\mathscr{M}^{(S)}\right) \Pr\left(v_h|\mathscr{M}^{(S)}\right).$$

The larger the k is the better is the representation of π, thus we allow for $k = \infty$ by using the following non-parametric prior:

$$\begin{aligned} \pi &= \sum_{h=1}^{\infty} v_h \Psi_h, \quad \Psi_h = \psi_h^{(1)} \otimes \cdots \otimes \psi_h^{(p)} \\ \psi_h^{(j)} &\sim P_{0j}, \quad \text{independently for } j = 1,\dots,p \text{ and } h = 1,\dots,\infty \\ \mathbf{v} &\sim Q, \end{aligned} \tag{1}$$

where P_{0j} corresponds to a Dirichlet measure and Q to a Dirichlet process.
The usual stick-breaking stochastic representation of the model is

$$\begin{aligned} \gamma_j^s &\sim \text{Multinomial}\left(\{0,1\}, \psi_{z_i}^{(j)}, \dots, \psi_{z_i d_j}^{(j)}\right) \\ z_i &\sim \sum_{h=1}^{\infty} V_h \prod_{l<h} (1 - V_l)\, \delta_h, \quad V_h \sim \text{beta}(1,\alpha) \\ \psi_h^{(j)} &\sim \text{Dirichlet}\left(a_{j1},\dots,a_{jc_j}\right) \\ \alpha &\sim \text{Gamma}(a_\alpha, b_\alpha), \end{aligned}$$

where the Multinomial notation is actually over-engineered as observations are Bernoulli r.v.. Parameters $a_{j1} = \ldots = a_{jc_j} = 1$ induce non informative *a priori* information about the probabilities of each covariate of being in the model. α is the usual concentration parameter on the space of latent classes of model probability distributions. That is for small values of α the probability of having many classes of different probability distributions decreases. Hiperparameters are thus chosen such that the prior sample size is low, $a_\alpha + b_\alpha = 1/2$ and $a_\alpha = 1/4$.

Such a stochastic representation suggests the Gibbs sampling exposed in [7] to obtain simulations from the posterior distribution of ψs and vs. However, this algorithm can be very slow for large p and the benefits of $\widehat{\tau}_{\mathrm{b}}$ can be compensated by just calculating $\widehat{\tau}_{\mathrm{e}}$ or $\widehat{\tau}_{\mathrm{r}}$ on larger value of S. To avoid this we make use of a recent and faster variational algorithm proposed in [1] and also implemented in the R package `mixdir`. The algorithm relies on using approximated distribution, for the posterior of $\mathbf{v}$ and ψ, derived by applying the mean field theory to variational inference

(see [10]). These distributions lay down to be mixtures of Dirichlet distributions (for more details see [1]).

3 Examples and Simulations

In what follows we will consider the Riboflavin dataset (see [6]) related to the riboflavin production by Bacillus subtilis. We have 71 observations and $p = 4088$ predictors (gene expressions) and a one-dimensional response (riboflavin production), y. We assume the normal linear model where $BF_{\gamma 0}$ are obtained from the conventional prior approach (R package: `BayesVarSel`). $\pi(\mathscr{M}_\gamma)$ is the Uniform prior. The Gibbs algorithm starts at the null with $S = 1000$ steps after a burn in of 100 steps. In the first scenario we analyze the data set in its original version in order to compare $\widehat{\tau}_{\mathrm{e}}$, $\widehat{\tau}_{\mathrm{r}}$ and $\widehat{\tau}_{\mathrm{b}}$ from a biological perspective. In the second scenario we keep comparing by simulating many times y making depending it on only 2 out of the p predictors.

The following table 1 reports the median probability models with specific genes and their corresponding τ according to the three estimators.

Table 1 Estimated of τ larger than 0.5 (definition of the median probability model) along with estimated posterior distribution of τ (right hand side).

Gene	$\widehat{\tau}_{\mathrm{e}}$	$\widehat{\tau}_{\mathrm{r}}$	$\widehat{\tau}_{\mathrm{b}}$	Mentioned$^{(*)}$	v_h 0.8737	0.126	1e-04
YOAB_at	1.00	1.00	1.00	*	0.996	1.000	1.000
YXLD_at	0.44	0.69	0.55	*	0.486	1.000	1.000
YXLE_at	0.54	0.31	0.56	*	0.496	1.000	1.000
ARGH_at	0.17	0.59	0.29				
GYRA_at	0.04	0.54	0.17				
YFII_at	0.17	0.54	0.30				
YLXQ_at	0.08	0.71	0.20				

$^{(*)}$ Whether or not genes have been mentioned in [2].

The proposed approach provides smoothed results than $\widehat{\tau}_{\mathrm{e}}$ and apparently less false discoveries than $\widehat{\tau}_{\mathrm{r}}$. However, we can also provide an entirely probability distribution of τ as reported in the right-hand side of Table 1.

We simulated 100 data sets where $y = \sum_{i=1}^{2} i \times X_{p_i} + \varepsilon$, $\varepsilon \sim N(0,1)$ and p_1, p_2 are 2 columns of X_p picked at random in each data set. Results are showed in Figure 1

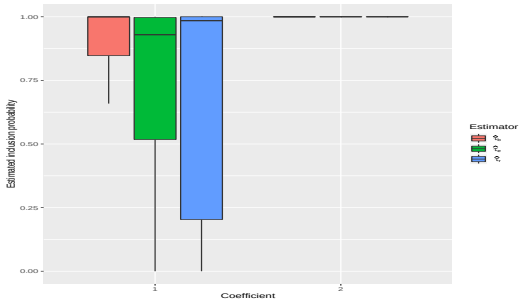

Fig. 1 Simulation results. Distributions of $\widehat{\tau}_{\mathrm{e}}$, $\widehat{\tau}_{\mathrm{r}}$ and $\widehat{\tau}_{\mathrm{b}}$ over the 100 datasets for covariates inside the model and ordered by the magnitude of their corresponding coefficients.

4 Remarks

We have presented a post processing approach of Gibbs-sampling output. However, the Bayesian NP model suggested here to derive an estimation of $\pi(\mathscr{M}_\gamma|y)$ could be further used by directly incorporating the NP prior into the Gibbs-sampling in order to match π in (1) with $\pi(\mathscr{M}_\gamma)$ as also done with $\widehat{\tau}_{\mathrm{r}}$ in [8]. GitHub code of this paper is reported at `https://github.com/scabras/varseldmmp`.

Priors on precision parameters of IGRMF models

Distribuzioni a priori sui parametri di precisione nei modelli IGRMF

A. Gardini, F. Greco and C. Trivisano

Abstract When intrinsic Gaussian random Markov field (IGRMF) priors are assumed for random effects of a latent Gaussian model, a notable issue concerns prior elicitation for the precision hyperparameters. In fact, the structure of the precision matrix could lead to the undesired feature that the same prior for different precisions imply different marginal priors for the random effects. The work is aimed at investigating this problem following a rigorous mathematical procedure, in order to propose a new strategy and compare it to a widespread solution based on matrix scaling. Finally, an application of the proposed method to a real data problem is presented.

Abstract *Nell'ambito della stima di modelli Gaussiani latenti, vengono spesso impiegate distribuzioni a priori appartenenti alla famiglia dei campi Gaussiani Markoviani intrinseci. In questo contesto, l'elicitazione della distribuzione a priori sul parametro di scala rappresenta una criticità ben nota in letteratura. La struttura della matrice di precisione può portare a strutture di variabilità a priori differenti per gli effetti casuali a parità di prior sul parametro di precisione. Il lavoro è finalizzato allo studio di tale problema attraverso un rigoroso approccio matematico: si propone una nuova strategia per l'elicitazione della prior. In conclusione, viene presentato un caso di studio e un confronto con un approccio molto diffuso in letteratura.*

1 Introduction

Several popular statistical models could be expressed as *latent Gaussian models* [7]. In fact, they are able to express additive regression models incorporating flexible relations with covariates (e.g. penalised splines), structured random effects (such as spatial or temporal ones) and unstructured error terms.

A latent Gaussian model is based on the assumption that the response variable $\mathbf{y} \in R^n$ follows an exponential family distribution with the i-th ($i = 1, ..., n$) conditional expectation μ_i that is related to the linear predictor η_i through a link function $g(\mu_i) = \eta_i$. The most general structure of the predictor is:

$$\eta_i = \beta_0 + \sum_{l=1}^{p} \beta_l c_{li} + \sum_{j=1}^{q} f_j(z_{ji}) + \varepsilon_i, \tag{1}$$

where β_0 is the intercept, β_j are the fixed effect coefficients related to the covariate values $\mathbf{c}_l$, $f_j(\cdot)$ are smooth functions that allow to model the dependence between the response and a set of covariates $\mathbf{z}_j$. Finally, ε_i is an unstructured error term.

If the estimation of such a model is carried out into the Bayesian framework, a prior distribution for the parameters must be specified. In this paper we consider the case in which intrinsic Gaussian random Markov field (IGRMF) [6] is set as prior for the structured effects. Labelling with $\mathbf{x} \in R^n$ the IGRMF specified as prior for an effect $f_j(\cdot)$, then it is defined as a random vector distributed according to a zero-mean improper Gaussian density, i.e. having a precision $\tau_x \mathbf{K}$, where $\mathbf{K}$ is a sparse matrix not full rank and τ_x is a further scalar parameter that represents a precision. The rank of $\mathbf{K}$ is $n-k$, and k is the order of the IGRMF, whose density can be expressed as proportional to:

$$\pi(\mathbf{x}|\tau_x) \propto \exp\left\{-\frac{\tau_x}{2}\mathbf{x}^T\mathbf{K}\mathbf{x}\right\}. \tag{2}$$

The prior specification for $\mathbf{x}$ must be completed with the choice of a prior for the precision parameter τ_x. An issue that arises when an IGRMF prior is specified is that the structure of $\mathbf{K}$ influences the total variability expressed by the conditional prior $\pi(\mathbf{x}|\tau_x)$. As a direct consequence, the same prior distribution for the precision parameter $\pi(\tau_x)$ could lead to different marginal priors $\pi(\mathbf{x})$ for diverse $\mathbf{K}$ precision matrices. Moreover, the relation between the sparseness pattern of the matrix and the marginal prior variability is not straightforward. An empirical strategy used to overcome the problem is to scale the prior of τ_x with the geometric mean of the diagonal entries of the generalized inverse $\mathbf{K}^-$ [4, 8].

This work is aimed at proposing a new prior specification strategy for models involving IGRMF priors based on the solution of an integral equation that allows the user to have full control on the prior. From a technical point of view, the equation is solved by means of the Mellin transform and a brief overview is provided in section 2. The popular Besag, York and Mollié (BYM) model [1] has been considered in

section 3 to show how the proposed method works, whereas results of a real data application are shown in section 4.

2 Some mathematical tools

To develop the theory that is presented in the following sections, the distribution of a linear combination of r Chi-squared random variables with 1 degree of freedom and positive weights l_j $(j = 1, ..., r)$ is of interest. The density function of the variable $X = \sum_{j=1}^{r} l_j \chi_1^2$ has been derived by Ruben [5] as:

$$f_X(x) = \sum_{k=0}^{\infty} a_k \frac{x^{r/2+k-1} \exp\left\{-\frac{x}{2\beta}\right\}}{(2\beta)^{r/2+k} \Gamma(r/2+k)}, \tag{3}$$

where the coefficients a_k are defined recursively and are functions of the weights, and β is a parameter that rules the speed of convergence of the series.

Another relevant tool used in the work is the Mellin transform of a function $f(x)$ having positive support. It is an integral transform strictly related to the Fourier transform and is defined for $z \in \mathbf{C}$ as:

$$\hat{F}(z) = \int_0^{+\infty} f(x) x^{z-1} \mathrm{d}x. \tag{4}$$

It has been used in statistics and in probability for its appealing properties, particularly to deal with the product of random variables [2].

3 The BYM model

The BYM model is a widely used model in disease mapping applications. Moreover, it has been frequently taken as example for the development of prior specification strategies useful when both structured and unstructured random components are considered.

A study region that is partitioned into n areas is considered. For each area $i = 1, ..., n$ the observed count Y_i and the expected count E_i of cases for a given disease are available. The BYM model is defined as:

$$Y_i | \mu_i \sim \mathscr{P}(\mu_i E_i), \; i = 1, ..., n; \tag{5}$$

$$\log(\mu_i) = \eta_i = \mathbf{x}_i^T \beta + s_i + u_i, \tag{6}$$

where $\mathbf{x}_i$ is a vector of observed covariates, β are the corresponding coefficients, $\mathbf{s} = (s_1, ..., s_n)$ is a vector of spatially structured random effects and $\mathbf{u} = (u_1, ..., u_n)$ is the vector of unstructured random effects. The chosen priors for the random effects

are:

$$\mathbf{s}|\tau_s \sim \mathscr{N}_n\left(\mathbf{0}, \tau_s^{-1}\mathbf{Q}^-\right), \tag{7}$$

$$\mathbf{u}|\tau_u \sim \mathscr{N}_n\left(\mathbf{0}, \tau_u^{-1}\mathbf{I}_n\right), \tag{8}$$

where $\mathbf{Q}^-$ is the generalized inverse of the structure matrix $\mathbf{Q} = \mathbf{D} - \mathbf{W}$. The matrix $\mathbf{D}$ is diagonal with generic entry equal to n_i, that is the number of neighbourhoods for area i, whereas the elements of the adjacency matrix $\mathbf{W}$ are defined as $w_{ij} = 1$ if i and j are neighbour areas and $w_{ij} = 0$ otherwise.

The prior (7) for vector $\mathbf{s}$ is a first order IGRMF on an irregular grid and the precision matrix $\mathbf{Q}$ has rank $n-1$.

To complete the model specification, the hyperpriors $\pi_{\tau_s}(t_s)$ and $\pi_{\tau_u}(t_u)$ are required. For the precision of the structured effect, it is common to assume a gamma prior $\tau_u \sim \mathscr{G}(a,b)$, whereas the prior on τ_s is the subject of the following discussion.

Sørbye and Rue [8] underline that the precision matrix $\mathbf{Q}$ of the IGRMF prior should be accounted in specifying the prior for the precision hyperparameter τ_s. They suggest to assign the prior on $\tau_s/\sigma^2_{\text{ref}}(\mathbf{s})$ instead of τ_s, assuming that the proposed distribution can be directly compared to the one on τ_u. The quantity $\sigma^2_{\text{ref}}(\mathbf{s})$ is a reference standard deviation for $\mathbf{u}$, computed for the IGRMF prior assuming $\tau_s = 1$ and is the geometric mean of the diagonal entries of $\mathbf{Q}^-$.

3.1 Our proposal: balanced priors

The proposed prior specification strategy is based on the prior independence of the random effects and it allows to control the total prior variance set for the linear predictor η and its partition between the structured and unstructured effect:

$$\frac{\eta^T\eta}{n} = \frac{\mathbf{u}^T\mathbf{u}}{n} + \frac{\mathbf{s}^T\mathbf{M}\mathbf{s}}{n} = V_u + V_s; \tag{9}$$

where $\mathbf{M}$ is a centering matrix that accounts for the rank deficiency of $\mathbf{Q}$. Recalling the prior of the random effects (7) and (8), it can be shown that the distribution of the vectors variances conditioned with respect to the respective scalar precisions are:

$$V_u|\tau_u \sim \mathscr{G}\left(\frac{n}{2}, \frac{n\tau_u}{2}\right); \;\; V_s|\tau_s \sim \frac{1}{\tau_s}\sum_{i=1}^{n-1}\frac{\lambda_i}{n}\chi^2_1, \tag{10}$$

where λ_i are the reciprocals of the non-zero eigenvalues of $\mathbf{Q}$.

Under the proposed $\mathscr{G}(a,b)$ prior for τ_u, the marginal prior on V_u is a generalized beta distribution of the 2^{nd} type (GB2) that has parameters $V_u \sim GB2(1,n/2,2b/n,a)$.

On the other hand, due to the structure of $\mathbf{Q}$, if a gamma prior on the precision is assumed, then the marginal prior of V_s is not GB2. In this work we assume that the user wish to achieve the complete prior balance by specifying the same marginal prior for V_u and V_s: the consequent underlying prior for τ_s must be computed. To

reach this target, the proposed strategy is to solve a Fredholm integral equation of the first kind. By exploiting the particular structure of the involved function, it is possible to find the desired prior density by inverting a Mellin transform [3].

4 An application

To show an application of the proposed prior specification procedure and compare it to the widely used INLA's scaled priors, the counts of deaths registered in the $n = 341$ municipalities of the Emilia-Romagna Region due to a particular cause are analysed. The total amount of cases is 2095. The BYM model under the compared prior strategies was fitted in R using INLA [7].

For the unstructured precision τ_u a gamma prior with $a = 1$ and $b = 1/2$ is chosen. As a consequence, the scaled prior on τ_s is a gamma with $a = 1$ and $b = \sigma^2_{\text{ref}}(\mathbf{s})/2$, with $\sigma^2_{\text{ref}}(\mathbf{s}) = 0.79$ for the map of the Emilia-Romagna Region. On the other hand, our prior is obtained numerically by solving the integral equation aimed at obtaining the prior that mixed with the IGRMF prior implies the same marginal GB2 prior for V_s and V_u. The deduced priors are compared in figure 1, and it can be noted that the distance from our exact balanced prior is larger for the scaled prior with respect to the $\mathscr{G}(1, 0.5)$ prior. In particular, posterior balancing between structured and unstructured random effects is affected by prior specification. Some interesting quantities fitted through the BYM model under the two prior strategies are compared in figure 2.

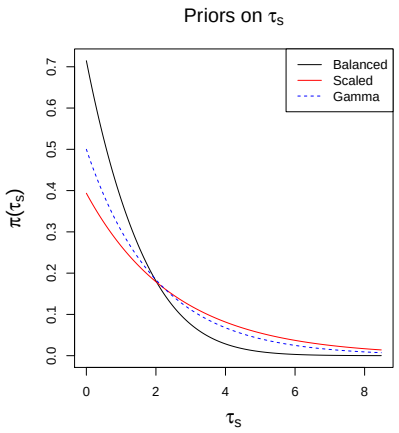

Fig. 1 Hyperpriors for the precision parameter τ_s: the black line reports the proposed balanced prior obtained by solving the Fredholm integral equation; the red lined is the prior used by INLA when the scalded matrix is considered. Finally, the dashed blue line is the gamma prior with $a = 1$ and $b = 0.5$.

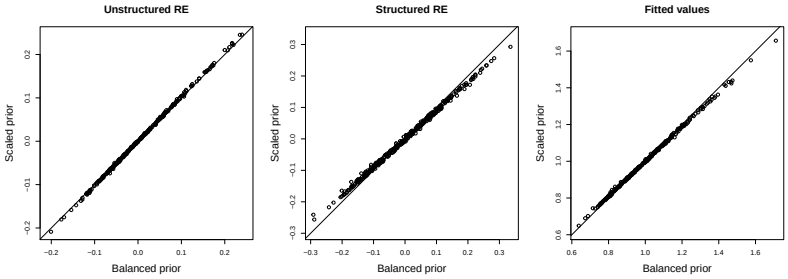

Fig. 2 The BYM model estimates obtained using INLA's scaled prior and our balanced priors approach are compared. From left to right the following quantities are shown: unstructured random effects (**u**), structured random effects (**s**) and fitted relative risks.

Sequence Analysis: methods and applications

Internal migration, family formation and social stratification in Europe. A life course approach.

Migrazioni interne, formazione familiare e stratificazione sociale in Europa attraverso un'analisi dei corsi di vita.

Roberto Impicciatore, Gabriele Ballarino and Nazareno Panichella

Abstract Geographical mobility trajectories generally intersects other life course patterns such as student career, job experiences and family choices. Life course approach emphasizes that different events are not separate experiences, but are linked to each other. Focusing on 11 European countries (Austria, Czech Republic, Denmark, France, Germany, Greece, Italy, Poland, Spain, Sweden, and Switzerland), this analysis has three main aims: describing the life patterns experienced by internal migrants, analyzing the selection into different migration trajectories, and identifying the association with different occupational achievements and social mobility pathways. To achieve these goals, we applied Sequence and Cluster Analysis to SHARELIFE data (2008-09 and 2017). Preliminary results reveal that different migration patterns are characterized by a marked selectivity of movers (mainly based on education), particularly in contexts where migration works well as an escalator strategy. In addition, specific life trajectories are associated to better occupational returns.

Abstract *Le traiettorie di mobilità geografica generalmente intersecano altri percorsi di corsi di vita come l'istruzione, la carriera lavorativa e le scelte familiari. L'approccio del corso di vita pone l'attenzione sul fatto che eventi diversi non sono esperienze separate ma collegate tra loro. Concentrandosi su 11 paesi europei (Austria, Repubblica Ceca, Danimarca, Francia, Germania, Grecia, Italia, Polonia, Spagna, Svezia e Svizzera), questa analisi ha tre obiettivi principali: descrivere i modelli di vita sperimentati dai migranti interni, analizzare il processo di selezione sulle diverse traiettorie di migrazioni e identificare l'associazione con specifici*

risultati lavorativi e con le tratiettorie di mobilità sociale. Per raggiungere questi obiettivi, abbiamo applicato una Sequence and Cluster Analysis ai dati SHARELIFE (2008-09 e 2017). I risultati preliminari rivelano che i diversi percorsi migratori risultano caratterizzati da una marcata selettività (basata principalmente sull'istruzione), partciolarmentenei contesti dove la migrazione funziona bene come strategia di ascesa sociale. Inoltre, alcune specifiche traiettorie di vita risultnao associate a migliori opportunità in campo lavorativo.

Key words: internal migration, social stratification, life course, sequence analysis

1 Introduction

Spatial mobility and family are intertwined from early through later life. Life course theory emphasizes that life events are not separate experiences, but are linked to one another (Giele & Elder, 1998). On this respect, the analysis of geographical mobility is crucial because it intersects with other life course patterns such as student career, job experiences and family choices. The positive impact on occupation given by internal migration has already underlined in the literature mainly suggesting that chances of obtaining higher socio-economic status later in life than those who did not move (van Ham, 2003), in particular when migration is directed to areas with higher educational and labour-market opportunities such as large cities (Fielding, 1992). However, the timing of migration is also relevant since the advantages tend to be higher if the migration takes place in the early stages of the labour career. In other words, it is likely that the migration, as an investment in human capital, will pay off in the long run (Mulder and van Ham, 2005). Furthermore, the decision to move is related to other life events such as family events (including family reunification), childbearing and change in family size (Kulu & Milewski, 2007). This creates substantial heterogeneity in migration experiences and trajectories, which are based on a huge interrelation of biographical events, and which may have different effects on the integration of migrants.

Our approach is based on the idea that mobility is a crucial step in the life pattern as embedded into the process of the transition to adulthood and thus intrinsically linked with the achievement of residential autonomy, economic independence and family formation (Impicciatore and Panichella 2019). We mainly focus on the following three research questions: a) which are the life patterns experienced by internal migrant in Europe? b) Does the selection into migration change when it occurs at different phases of life-course events? c) Do different types of life trajectories are associated with specific outcomes in the labour market?

However, there is a substantial lack of literature of comparative analyses on the effect of life trajectories on occupational outcomes. We aim at contributing to the existing literature by analyzing the relations between geographical mobility, education, occupational career and family behavior focusing on the internal migration in 11 European countries. The comparative perspective used, ensured by using standardized data, allows to evaluate whether the life patterns of internal tend

to be similar in different European countries or, alternatively, there are peculiarities at country-level.

2 Data and method

The analysis is based on SHARELIFE, i.e. third and the seventh wave of SHARE (Survey on Health, Ageing and Retirement in Europe) held, respectively, on 2008-09 and 2017. Selected data provide life-history information about a representative sample of about 45,000 respondents aged 50 and over living in Europe (21,800 for Wave 3 and 23,500 for wave 7). The selected subsample is composed by individuals born between 1920 and 1960 living at the interview in the following countries: Austria, Czech Republic, Denmark, France, Germany, Greece, Italy, Poland, Spain, Sweden, and Switzerland. Respondents are asked to report all the changes in accommodation (at regional level for internal moves) they had throughout their lives. We focus on interregional moves, namely among NUTS-2 level regions. The domains of interests also include family relationships history, housing, educational career and working history.

We applied a method called sequence analysis for social sciences (Abbott, 1983, 1995; Abbott and Forrest, 1986). The basic idea is to represent each life course trajectory as a string of characters (one for a specific time unit), resembling the one used to code DNA molecules in biological sciences. After having defined the set of sequences, a dissimilarity measure between each pair of sequences can be computed. Among different possible methods, we used the Longest Common Subsequence metric (LCS) proposed by Elzinga (2006) and based on the length of common distinct sub-sequences between life course trajectories. Compared to the commonly used Optimal Matching strategy (OM), the LCS metric does not require the definition of costs. The following step is to group similar sequences (according to their dissimilarities) through a hierarchical cluster analysis. In our case, we used the Ward linkage and we fixed the number of cluster by observing the hierarchical tree diagram also known as dendrogram.

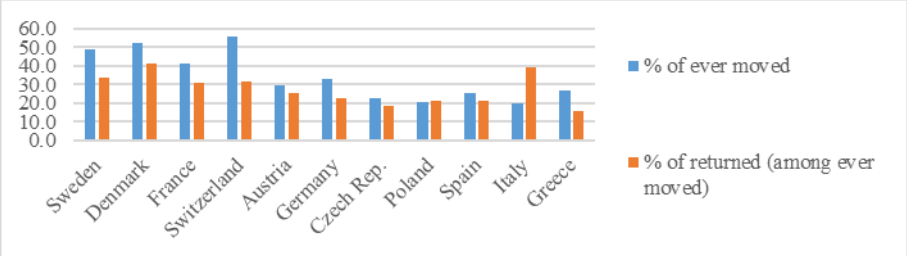
Our window of observation is the age range between 15 and 40 years. For each of this age, an individual can assume one specific state. The set of all possible states (state space) is given by the combination of the following characteristics: in education (yes/no); working (yes/no), in couple (yes/no), with children (yes/no), moved to another region (no/yes/returned), resulting in potentially states. This dimension requires a simplification of the complexity. One efficient strategy is the so-called multichannel sequence analysis approach (Gauthier, 2010; Pollock, 2007), which makes it possible to specify multiple domains in order to construct a single matrix of dissimilarities by locally aligning distinct life trajectories simultaneously. In our analysis, we distinguished between transitions in the study-work domain and transitions in the family domain. The sequence analysis was performed using the TraMineR package, which is available in the open source statistical environment R (Gabadinho et al., 2011).

Once the cluster has been identified, they can be used an additional variable in multivariate regression. In particular, we focused on the social selectivity of internal migrants, estimating the probability of being a mover using a binomial logistic regression model and the probability of being included in each cluster of mobility (conditional on the probability of being a mover) by means of multinomial logit. Finally, we develop binomial logistic models by considering the probability of having a specific labour market position (distinguishing among service, middle and lower class) at 50 years of age according to the previous life pattern.

3 Preliminary findings

In our subsample, one every three individuals experienced at least an interregional move between 15 and 40 years of age. Across countries (Fig. 1), it emerges a quite high heterogeneity with higher values in Switzerland and the Scandinavian area (around 50%) and a lower propensity to move in the Eastern and Mediterranean area (around 23%). Even though this rough comparison is somewhat dependent to the number and the dimensions of regions within each countries, the differences among European countries in the propensity to move internally tend to confirm what have been underlined in the existing literature (Bell et al. 2018). The propensity to move back to their region of origin (among ever moved) is higher in the countries with a higher mobility even though differences across countries are less marked. The most evident exception is Italy where the (few) migrants often returned to their region of origin.

Figure 1: Percentage of individual who experienced at least one inter-regional move between 15 and 40 years of age and percentage of those returned to their region of origin before 40 years of age (among ever moved). Individuals born between 1920 and 1960.



Source: Own elaboration on SHARE wave 3 (2008-09) and wave 7 (2017).

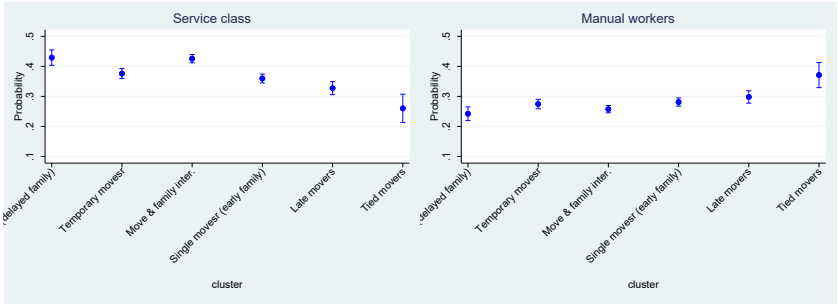
Through the cluster analysis applied to sequence of states, we found six clusters that can be briefly described as follows: *Single movers* (cluster 1: individual moved as single with union formation occurred relatively late and often childless; 9% of cases); *Temporary movers* (cluster 2: migrants returned to their region of origin and family formation after the return; 19% of cases); *Move & family interrelation* (cluster 3: delayed move and a strong interrelation between migration, union and childbirth; 29% of cases); *Single movers (early family formation)* (cluster 4: early

mover as a single and then a rapid family formation with children; 25% of cases): *Late movers* (cluster 5: rapid family transition and a slow migration not connected to other, i.e. movers as a family unit; 11% of cases); *Tied movers* (cluster 6: late movers as inactive (in few cases returned), family formation usually after the move but with no children; 7% of cases).

Our preliminary suggests that the overall different migration patterns are characterized by a marked selectivity of movers and the 'positive' selection of internal migrants found by other research may hide important differences based on the type of life course pattern.

Figure 2 considers inclusion in the occupational structure at 50 years of age. *Tied movers* (cluster 6) and, to a lesser extent, *late movers* (cluster 5) show a clear disadvantage in the labor market given the lower probability of being in the service class and, at the same time, a higher probability of being a manual worker. Conversely, two patterns emerge as the most advantaged, namely cluster 1 (moved as a single and delayed family formation) and cluster 3 (interrelated events).

Figure 2: Probability of entering the service class and the lower class (manual workers) among workers at 50 years of age. Logit models, predictive margins and 95% confidence intervals.



Source: Own elaboration on SHARE wave 3 (2008-09) and wave 7 (2017).
Note: control variables in the model: country; gender; birth cohort; level of education; social class of origin according to the job position of the main breadwinner when 10 years of age; international migrant (born abroad or arrived before 15 years of age); area of origin.

These first results suggest that mobility can have good occupation returns following two very distinct patterns. Firstly, when migration is experienced early in the life course but independently by family formation. This pattern is mobility experienced mainly as a human capital investment both in education and in order to better exploit the potentialities of the labor market in the area of arrival. Given that it includes costly geographical movements, this cluster identifies a mechanism of social closure, since it allows the reproduction of the upper class from the region of origin to the region of destination. Secondly, good outcomes can be obtained through a general postponement. Mobility and family formation can be experienced later in the life course after having obtained a good position in the labor market in the context of departure.

In conclusion, provisional results suggest that the adoption of a family viewpoint on internal migration represents a powerful empirical strategy for contributing to the existing literature. However, further analysis should be added in order to shed light on the heterogeneity across European countries. For example, in some countries, such as those in the Northern Europe, the internal migration may works well as an escalator strategy. Additional analysis will also consider the inter-generational social mobility and emphasize the gender roles in migration.

Socio economic integration of migrants

A study on the characteristics of spouses who intermarry in Italy

Uno studio delle caratteristiche dei matrimoni misti in Italia

Agnese Vitali and Romina Fraboni

Abstract This contribution compares the characteristics of spouses in endogamous vs. exogamous marriages in Italy using marriage registers for 2017. We model the probability of observing an endogamous vs. exogamous marriage between a native and foreign spouse coming from different migrant origins. The marriage patterns that we find are consistent with a (mismatched) marriage market where men and women's expectations are changing at different rhythms.

Abstract *Questo contributo confronta le caratteristiche degli sposi nei matrimoni endogami e in quelli esogami osservati in Italia nel 2017. Studiamo la probabilità di osservare un matrimonio endogamo rispetto ad uno esogamo tra uno sposo/a italiano/a e una sposa/o straniera/o con diverse origini migratorie. Emergono dei modelli matrimoniali coerenti con un mercato matrimoniale squilibrato in cui le aspettative di uomini e donne cambiano in modo differente.*

Key words: Intermarriage, Marriage, homogamy, assortative mating, marriage market

1 Background and Hypothesis

The abundance of high-educated women and the scarcity of high-educated men may create mismatches in the marriage market (Grow and Van Bavel, 2015). In the Italian context, where the male breadwinner family type is persistent, the emergence of a reversal of the gender gap in education contrasts sharply with a still prevailing

[1] Agnese Vitali, Dipartimento di Sociologia e Ricerca Sociale, Università di Trento; email: agnese.vitali@unitn.it

Romina Fraboni, Istituto Nazionale di Statistica; email: fraboni@istat.it

gendered ideology permeating family life. Contrary to what found for other settings, in Southern Europe high-educated women have the lowest likelihood of being in a union (Kalmijn, 2013) and, together with low-educated men, are most exposed to the risk of lifelong singlehood (Bellani et al., 2017).

The growing migrant population may improve the marriageability of those groups whose marriage opportunities are being shrunk, i.e. high-educated women and low-educated men (Van Bavel, 2012). Low-educated men and high-educated women, we argue, will be more likely to intermarry (vs. marrying a native spouse) if compared to better-educated men and lower-educated women, respectively. Indeed, if the preference for homogamy cannot be satisfied in the national marriage market (e.g. there are too few low-educated women and too few high-educated men), native spouses may be willing to marry out of their group in exchange of a certain attribute viewed as a 'compensating differential' (Grossbard-Shechtman and Fu, 2002). We distinguish between different migrant groups so to account for differences in their cultural and economic characteristics. Following Medrano et al. (2014), we consider spouses coming from Western Europe, North America and Oceania as having a prevailing gender-egalitarian ideology, while we consider spouses coming from Eastern Europe, Africa, Asia and Latin America as having a prevailing traditional gender ideology.

We expect low-educated native men to be willing to marry foreign wives from traditional contexts, in exchange of their traditional gender ideology, while we expect high-educated native women to be willing to marry foreign husbands from gender-egalitarian contexts.

2 Data and Methods

We study the population of Italian men and women who married for the first time in 2017, using marriage register data (Rilevazione dei Matrimoni, ISTAT).

We are interested in comparing the characteristics of spouses in exogamous marriages with those in endogamous marriages. To do so, using a multinomial logistic regression model, we model the probability that a native man or woman with

certain socio-demographic characteristics will marry a native vs. a foreign spouse from a given country of origin. Our variable of interest is constituted of seven categories: a native woman (man) marrying a native spouse (ref.), or intermarrying with a spouse from North America and Oceania, Western Europe, Eastern Europe, Africa, Asia, or Latin America. As independent variables we consider: age of the native spouse (linear and quadratic term); age difference between native and foreign spouse (same age –ref.–, native spouse is older, and younger); education of the native spouse (low, medium, high), educational difference between native and foreign spouse (same education –ref.–, native spouse is more educated and native spouse is less educated), employment status of the couple (both employed, jobless,

only man employed, only woman employed) and order of marriage of the foreign spouse (first –ref.–, second or higher order). We run separate models by gender of the native spouse.

3 Results

In this section we identify the profiles of native spouses who intermarry. Such profiles differ between men and women and vary with the origin of the foreign spouse.

About one third of Italian women intermarry with Western-European husbands, whereas about half of Italian men intermarry with Eastern-European wives (Table 1). Results of the multinomial regression show that native men and women who marry spouses coming from areas characterized by a gender-egalitarian ideology tend to be highly educated, whereas those who marry spouses coming from areas characterized by a traditional gender-egalitarian ideology tend to be low educated (Tables 2 and 3). The educational differential among spouses also matters: whereby marriages among natives are associated with homogamy, intermarriage is associated with hypergamy when native men marry wives from traditional areas and with hypogamy when they marry wives from gender-egalitarian areas. Men who intermarry tend to be older than men who marry a native wife. Native women who intermarry with husbands from gender-egalitarian areas are more likely to intermarry with a spouse who has achieved at least the same educational level as they did, and tend to be older than women who married a native husband. As for low-educated men, high-educated women might have spent some time searching for a similarly high-educated spouse before turning to foreign spouses. Instead, native women who intermarry with husbands from traditional areas tend to be less educated and younger than women who marry a native husband. Here, the gradient in the educational gap between spouses is less clear, except for a departure from homogamy.

Table 1: Intermarriages by gender of the native spouse and origin of the foreign spouse. First marriages of Italian husbands, 2017

Our initial hypotheses are therefore confirmed: for men, the probability of marrying a wife from traditional areas vs. a native wife increases as his educational attainment decreases; for women, the probability of marrying a husband from gender-egalitarian areas vs. a native husband increases as her educational attainment increases. This contribution confirms results in Gabrielli and Paterno (2016) and Maffioli, Paterno and Gabrielli (2014) on different data sources and extends their findings highlighting the heterogeneous patterns that exist across different migrant origins. Furthermore, the perspective we propose in this contribution shows that intermarriage not only can be used, as traditionally done, as an indicator of integration of migrants, but can also shed light on the marriage patterns of the native population.

Statistical Analysis for mobility and transportation

A multilevel Analysis of University attractiveness in the network flows from Bachelor to Master's degree

Un'analisi multilivello dell'attrattività delle Università nel flusso di passaggio dalla Laurea Triennale alla Magistrale

Silvia Columbu and Ilaria Primerano

Abstract In this work we aim to study the mobility choices of Italian students in the transition from bachelor to masters degree in order to assess the role played by the field of study. We consider micro-data from the Italian National Student Archive on a cohort of students enrolled for the first time at the university in a.y. 2011-12 who enrolled to a master degree program in the a.y. 2014-15 or 2015-16. We study the incoming and outgoing flows of students moving from bachelor to master's degree between provinces and universities. We then assess the effects on mover choices of network centrality measures in terms of hub and authorities adopting a multilevel multinomial logit model.

Abstract *Con questo contributo ci proponiamo di studiare le scelte di mobilità per gli studenti italiani nel passaggio tra Laurea Triennale e Magistrale in base all'indirizzo di studi. Si considerano micro-dati provenienti dall'Anagrafe Nazionale Studenti relativi alla coorte di studenti immatricolati in una triennale nell'a.a. 2011-12 e iscritti a una Laurea Magistrale nell'a.a. 2014-15 o 2015-16. Studiamo i flussi di studenti in entrata ed uscita tra province e università italiane nel passaggio alla Laurea Magistrale. Inoltre, analizziamo l'influenza delle misure di centralità in termini di hub e authority applicando un modello multilivello multinomiale.*

1 Introduction

In the Italian University System there is a growing interest in understanding the dynamics of internal mobility for students. This aspect is relevant given that the attractiveness of university students coming from other territories and/or institutions is considered one of the criteria for the distribution of public financial resources.

Exploratory studies on internal student mobility have been carried out mainly considering macro-geographical and interregional flows of students in order to analyze the attractiveness of different territories [5] [2] rather than those of universities. If we consider the students' internal migration in the transition from the first (Bachelor) to the second (Master) level of university studies, the literature is quite limited. A recent contribution [4] focuses on the flows from the South to the North of Italy.

In this work we analyze students' mobility flows to detect and understand the main migration patterns in the transition from Bachelor's to Master's degree between Italian provinces accross the country and the universities. We adopt a two step procedure of analysis. At first, we use social network centrality measures to investigate the role and position of each University/Province in the network. Then, we define a multilevel multinomial logit model to assess the effects of these measures on students' mobility choices conditionally to the specificity of the field of study undertaken. The paper is structured as follows. The data we use are presented in section 2, while the methodological approach is described in section 3. First results and concluding remarks are given in section 4.

2 Data

The micro-data used to analyze the Italian mobility student flows are provided by the Italian National Student Archive (NSA) [1]. We focus on a longitudinal cohort of 46,127 students, clustered in 53 fields of study, enrolled for the first time at university in the a.y. 2011-12. We use these data to study the incoming and the outgoing flows of students in the transition from bachelor's to master's degree between provinces and universities. We, therefore, consider only the students who have completed an undergraduate program and enrolled to a master degree program in the a.y. 2014-15 or 2015-16.

Looking at the main regions and provinces of destination of graduates, it arises that about 84% of regional *mover* students are spread in six regions (namely, Lombardy, Emilia Romagna, Lazio, Tuscany, Piedmont, and Veneto) and about 54.13% are concentrated in four provinces (Milan, Rome, Bologna, and Turin). We defined a regional *mover master* variable by taking into consideration all the possible alternative paths in the student mobility choices at bachelor and master degree. We distinguished among students who migrated only for their bachelor, only for the

[1] The micro-data at student level are available by the NSA archive for the universities involved in the Italian Ministerial grant PRIN 2017 CUP: B78D19000180001.

master or for both levels of study. In particular, we classified students with respect to their mover history in five categories: 1) Stayer I (Bachelor) & II Level degree (Master); 2) Mover I & Stayer II; 3) Stayer I & Mover II; 4) Mover I & II (same region) and 5) Mover I & II (different region). We observe that overall 11% of students changes region for the first time in the transition from bachelor's to master's degree, with losses in terms of outgoing bachelor graduates for each region (with respect to the number of graduated) that vary from the 23% and 25% of Sardinia and Sicily to the 6% and 5% of Lombardy and Piedmont. The proportion of first level mover graduates enrolling for the master in their region of origin is trascurable (1.37% of the total).

3 A two-step strategy of analysis

3.1 First step: Network data and centrality measures

Students mobility flows in the transition from Bachelor's to Master's degree can be represented as a network data structure, where the universities and the provinces are the nodes and the students exchanges between them are the edges. The number of students involved in these exchanges define the weight of each edge. The corresponding adjacency matrix **A** is directed and weighted (with a link from the origin to the destination). Formally, we are dealing with a valued directed graph $\mathscr{G}_v(\mathscr{N},\mathscr{L},\mathscr{V})$ consisting of three sets of information: a set of nodes, $\mathscr{N} = \{n_1,n_2,\ldots,n_g\}$, a set of edges (or arcs), $\mathscr{L} = \{l_1,l_2,\ldots,l_L\}$, and a set of values, $\mathscr{V} = \{v_1,v_2,\ldots,v_L\}$ attached to the edges (or arcs). In particular, to explore the second level mobility flows, we consider as origin the provinces (or universities) where students achieved the Bachelor's degree and as destination the provinces (or universities) where students enrolled for their Master's degree.

Among the network centrality measures, we adopt the Hub and Authority scores [3] to shade some lights on the role played by the territories and the universities in the master students' mobility network. Specifically, the authority score is here perceived as an indicator of the reputation of a given province or university, thus of its attractiveness; whereas the hub score is interpreted as an indicator of awareness of students' mobility choices.

In this context, the classification of nodes in hub and authority allow us to define as good hubs the universities/provinces which are pointing to many good authorities (i.e. good exporter). At the same time, good authorities are the universities/provinces which are pointed to by many good hubs (i.e. good importers).

Descriptive statistics on hub and authority measures, as discussed in [1], highlight that there is an exchange of students across few leading provinces mainly located in the North of Italy. Similar observations can be make looking at the flows among universities. This result is confirmed also from a medium correlation among the measures of hub and authority in the province network (0.49) as well as in the

university one (0.58), i.e. the exchange of students at second level is driven by a limited number of provinces and/or universities.

3.2 Second Step: Multilevel approach

We apply a two level random intercept multinomial logistic model [6] [7] to study the probability of bachelor graduates, clustered in fields of study, to be in a specific *mover* status. Let us denote with Y_{ij} a categorical variable which indicates the mobility status k ($k = 1,\dots,K$) of student i ($i = 1,\dots,n$) in the field of study j ($j = 1,\dots,J$). We assume for the response Y_{ij}, conditional on the random effects, a multinomial distribution of parameters $(\pi_{ij}^{(1)},\dots,\pi_{ij}^{(K)})$. The estimated model can be specified using a multinomial logistic function as follow

$$\log\left(\frac{\pi_{ij}^{(k)}}{\pi_{ij}^{(1)}}\right) = \tau^{(k)} + \boldsymbol{X}_{ij}^{T}\boldsymbol{\beta}^{(k)} + \boldsymbol{Z}_{ij}^{T}\boldsymbol{\gamma}^{(k)} + \theta_{j}^{(k)} = \eta_{ij}^{(k)} \quad k = 2,\dots,K \qquad (1)$$

where the probability of the response to belong to one of the k categories is specified as

$$\pi_{ij}^{(k)} = P(Y_{ij} = k) = \frac{\exp(\eta_{ij}^{(k)})}{1 + \sum_{k=2}^{K}\exp(\eta_{ij}^{(k)})}.$$

In equation (1), $\boldsymbol{X}_{ij}$ is a vector of individual explanatory variables, $\boldsymbol{Z}_{ij}$ is the vector of the network measures, $\theta_{j}^{(k)}$ is the 2-level random component for the contrast of response category k with reference category $k = 1$. The parameters in equation (1) are specific to the category k. We assume that the random effects $(\boldsymbol{\theta_j}^{(2)},\dots,\boldsymbol{\theta_j}^{(K)})$ follow a multivariate normal distribution with mean $\mathbf{0}$ and matrix of covariance Σ. The model has been estimated with the runmlwin routine which calls MLwiN scripts from Stata [8] by adopting Monte Carlo Markov Chain algorithm.

The parametrization adopted aims to assess the effect of network measures on the different typologies of *mover* students enrolled in different fields of study. We therefore consider as explanatory variables the measures of authority and hub at University and Province level. We consider also some demographic characteristics of students such as age, gender, whether students had a highschool diploma from a Lyceum or from another school, the region where is located the University where they enrolled for their master, the geographical macro-area from where they originally come. In the model estimation we consider $K = 4$ (the group of Mover I & Stayer II was not considered in the estimation). We compare all the possible mobility choices with the only one representing the non-mobility (the reference category was Stayer I & II Level degree).

4 First results and concluding remarks

Model estimates, reported in Table 1, suggest that there is a field of study effect in the student mobility conditions, as the values of the between field of study variability display for all mover category status (k=2,..,4) with respect to students not in mobility (k=1). In particular, this variability is higher in those groups of students that make the stronger decision (k=2 and k=4). We observe also that there are some associations among students in mobility enrolled in the same field of study. In particular, based on random effects variances and covariances estimates, we find that there is a high positive correlation (0.97) among students in mobility at the second level for the first time (k=2) and those already in mobility that choose to make another migration (k=4). It is moderate also the sharing between the two groups of always mover students (k=3 and k=4), with a correlation of 0.41.
Estimates of fixed effects coefficients confirm that measures of network centrality can contribute to explain the mobility choices of master students conditional upon the field of study they enrolled. In particular, we observe that the authority of the territory (Authority Province) is one of the major factors of attractivity for students in mobility. Once we have controlled for the specific field of study, it arises that the power of authoritative universities (Authority University) in attracting master students affects with a negative sign the log-odds of being in mobility at both levels of study inside the same region, whereas it vanishes in the other two groups of movers. Furthermore, bachelors graduated in universities that proved to be good exporters (Hub University) are less inclined to make a mobility choice at the new enrollement, except for movers at both levels changing region. On the other hand, for this last group of students, coming from an exporter province decreases the propensity to be in mobility. This last result suggests that, for students in the same field, the decision to undertake a new mobility choice is strictly linked to the University of origin rather than to the Province of origin. The demographic students characteristics do not reveal unexpected results. The estimates show that older students sharing similar choices in their study path are less inclined to the mobility, there is a gender effect and it is confirmed the typical italian North-South divide.

Analysis of mobility data through a novel Cheng and Church algorithm for functional data

Analisi di dati di mobilità estendendo il modello di bi-clustering di Cheng e Church ai dati funzionali

Marta Galvani[1] , Agostino Torti[2,3] and Alessandra Menafoglio[3]

Abstract The aim of this work is to discover spatio-temporal patterns on the usage of a generic mobility system through bi-clustering algorithms. Since mobility data are continuously dependent on time, it seems natural to treat them as continuous functions over a temporal domain. Many different algorithms have been developed with the aim of clustering functional data; however, a lack of techniques occurs when these functional data are intrinsically ordered in a matrix structure and the interest is to simultaneously group the rows and the columns of the functional data matrix. In this work, we developed a new bi-clustering technique for functional data, extending the well known Cheng and Church algorithm for multivariate data. This new algorithm has been applied on a real dataset describing the flows of users on a mobility network. As results we are able to discover groups of stations and days with similar behavior, thus characterizing the mobility demand and identifying the presence of eventual issues in the system.

Abstract *Lo scopo di questo lavoro è di studiare i pattern spazio-temporali in un sistema di mobilità utlizzando tecniche di bi-clustering. Poichè i dati di mobilità hanno una dipendenza continua nel tempo, appare naturale trattarli come funzioni su un dominio continuo. Diversi algoritmi sono stati proposti allo scopo di clusterizzare dati funzionali; tuttavia la letteratura relativa a tecniche di bi-clustering per dati funzionali risulta ancora carente. In questo lavoro viene proposto un nuovo algoritmo di bi-clustering per dati funzionali che estende l'algoritmo introdotto da Cheng e Church per dati multivariati. Questo nuovo modello viene applicato su un dato reale relativo ai flussi di mobilità. In questo modo siamo in grado di raggruppare blocchi di stazioni e giorni con coportamenti simili, caratterizzando così la domanda di mobilità e evidenziando eventuali criticità nel sistema.*

1 Introduction

In the last years, due to urbanization and globalization, the demand for transportation has been increased like never before. In order to design the mobility of the future, companies operating in the transportation field have started to collect a huge quantity of data monitoring the evolution of mobility flows. The analysis and managing of these data represent a new challenge in the development of new statistical methods as these data are characterize by a high spatio-temporal dependence.
The recent increase in the collection of high frequency data represents a new challenge in the development of novel statistical methods. In this context, the statistics community developed a wide number of algorithms considering these new data as functional data, i.e. continuous functions over a domain, see [5].
Many different algorithms have been developed with the aim of clustering this type of data. However, a more particular case, with respect to standard clustering problems, appears when data are intrinsically ordered in a matrix structure and the interest is to simultaneously group the rows and the columns of a data matrix. This problem is knew as bi-clustering and was first introduced in [2] for the bi-clustering of expression data. For a complete review of bi-clustering methods for multivariate data see [4].
The aim of this work is to discover spatio-temporal patterns on the usage of a bike sharing mobility system identifying areas and days with a similar behavior. In addition, since a mobility datum is continuously dependent on time and we would like to characterize its within day variability, we decide to see it as continuous function of time. To this end we developed a new bi-clustering technique for functional data, grouping simultaneously locations and days with the same daily function.
Bi-clustering models need to be extended when considering a functional data matrix, i.e. where each element is a function. New proposals of bi-clustering methods for functional data are introduced by [6] and [1]. These two works both proposed a procedure which generalizes the classical latent block model ([3]) for multivariate data. These procedures are model-based and assume the existence of a latent-block structure in the data-matrix, therefore they are both semi-parametric. In addition the output of these models is an exhaustive bi-clustering of the data matrix with a check-board structure.
In this work, we would like to introduce a novel flexible bi-clustering algorithm for functional data extending the method first introduced by [2] for multivariate data. The concept of bi-clustering and the measure of goodness of a bi-cluster are here extended to functional data. The new obtained model is non parametric, thus it does not assume any prior modeling assumptions on the data and obtains as final result a functional non exclusive bi-cluster, thus allowing some elements not to belong to any bi-cluster.
The functional bi-clustering model has been applied on a real dataset about the Bike sharing system of Lyon called Vélo'v, with the aim of discovering spatio-temporal patterns in the daily usage of the system. Launched in 2005, Vélo'v is the first bicycle-sharing system in France, with a network of more than 3000 bikes spread over 345 stations across the city. Specifically, we analysed data for one week

in March 2014, discovering groups of stations and days with similar behavior, thus characterizing the mobility demand.
Notice that, in this work, we briefly report the methodology and the results that have been deeply presented in [7].
In Section 2 the methodological framework is presented coupled with obtained results on the analysed data. Conclusions are presented in Section 3.

2 Methods and Analysis

In this work, we extend the definition of bi-cluster and the well know Cheng and Church algorithm [2] to the case of a functional data matrix A. The aim of the Cheng and Church bi-clustering algorithm is to find a submatrix $A' \in A$, corresponding to a subset of rows I and a subset of columns J, with a high similarity score. In particular, in the Cheng and Church algorithm, an *ideal bi-cluster* is a set of rows I and a set of columns J such that each element in the bi-cluster can be expressed by the average value in the bi-cluster plus the residue of rows and columns average value and the total average value. A particular measure of goodness is evaluated for a bi-cluster $A'(I,J)$ considering a score H which is the *Mean Squared Residue* between all the real values in $A'(I,J)$ and their representative values in the bi-cluster.
Extending these concepts to FDA, each element of the dataset matrix A is a function $f_{ij}(t)$ defined on a continuous domain T. In such framework we define an ideal bi-cluster A' as a subset of rows I and columns J such that each function belonging to the bi-cluster $A'(I,J)$ can be defined as follows:

$$f_{ij}(t) = f_{IJ}(t) \quad \forall i \in I \quad and \quad \forall j \in J$$

where $f_{IJ}(t) = \frac{1}{|I||J|} \sum_{i=1}^{|I|} \sum_{j=1}^{|J|} f_{ij}(t)$.
For easiness of interpretation we define the bi-cluster template observing only the average function in the bi-cluster.
Consequently, the extended H-score of a bi-cluster $A'(I,J)$ is:

$$H_{IJ} = \frac{1}{|I||J|} \sum_{i=1}^{|I|} \sum_{j=1}^{|J|} \int_T \left\{ f_{ij}(t) - [f_{IJ}(t)] \right\}^2 dt$$

The algorithm starts considering the whole dataset and following an iterative procedure tries to find the biggest bi-cluster with a H-score value lower then a given threshold δ. In deteils to find a bi-cluster an iterative procedure is performed first removing the rows and the columns that contribute more to the H-score and then adding the rows and columns that contribute less. These steps are a natural extension of the node addition and deletion phases contained in the original Cheng and Church algorithm [2] to the functional framework. Each time a bi-cluster is found the algorithm proceeds looking for new bi-clusters in the remaining part of the data

matrix. The procedure stops when no more bi-clusters are found. The output of the algorithm is a non exhaustive bi-clustering, thus some elements do not belong to any bi-cluster.
We apply this algorithm on a real dataset about the Bike sharing system of Lyon called Vélo'v with the aim of discovering spatio-temporal patterns in the daily usage of the system. Notice that the system is a fixed stations service where bikes are picked up and dropped off in specific bike docks located around the city. For each station and for each day we now the hourly loading value (number of available bike over the number of available docks). Firstly we treat the available raw data as continuous functions, thus we model the bike station loading profile during the entire day by means of a point belonging to a space of continuous functions representing the number of available bikes divided by the total number of bike docks at each timestamp on the time domain (0,24). In this way we obtain 2415 curves, i.e. 345 stations per 7 days, representing all the elements of a dataset matrix A with the same dimensions (345x7).
After obtaining a functional data matrix of 2415 elements we apply the functional Cheng and Church algorithm obtaining 53 bi-clusters.

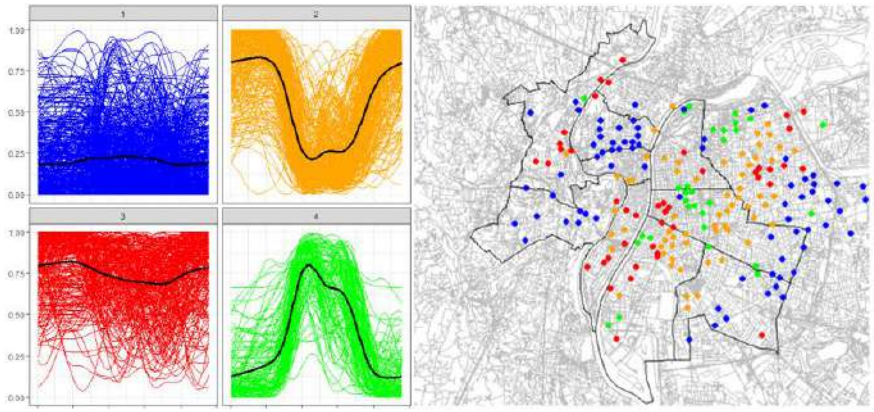

Fig. 1 The first four bi-clusters with in black the representative function of the bi-cluster (left) and the position on the map of Lyon of bike stations belonging to the first four bi-clusters (right)

In Figure 1 the first four bi-clusters, covering almost the 50% of the dataset, are reported. In particular, bi-cluster 1 and 3 represent constant profile which are respectively always empty or always full bike stations during the whole week. Bi-cluster 1 is composed by bike-stations located in the suburbs where people could not find a bike, while bi-cluster 3 represents bike-stations where people could not leave a bike. They both underlay an issue in the system identifying not used bike-stations. Bi-cluster 2 and 4, instead, represent two opposite users interactions with the system. They cover only working days and represent, respectively, bike stations always empty during the day and full during the night, and bike stations always full during the day and empty during the night. These particular behaviour could be explained

observing that bike-stations in bi-cluster 2 are almost all located in residential areas while, as opposite, bike stations in the bi-cluster 4 are mainly located in industrial areas.

3 Conclusions

In this paper, we analysed a real dataset concerning the daily loading profile of bike stations in the city of Lyon with the aim of discovering spatio-temporal patterns. A novel functional bi-clustering method is introduced extending the Cheng and Church algorithm for multivariate data. The application of this model to the data at hand allows us do discover sub-groups of stations following the same loading profile in a subgroup of days, underlying particular users behaviour and identifying some issue in the system.

Bridge closures in a transportation network: analysis of the impacts in the region of Lombardy

Chiusura di ponti in una rete stradale: analisi degli impatti in Lombardia

Agostino Torti[1,2], Marika Arena[3], Giovanni Azzone[1,3] and Piercesare Secchi[1,2]

Abstract This paper introduces a methodology to evaluate the socio-economic impacts of closures for maintenance of one or more infrastructures of a large and complex road network. Motivated by a collaboration with Regione Lombardia, we focus on a subset of bridges in the region, although we aim at developing a method scalable to all road infrastructures of the regional network, consisting of more than 10000 tunnels, bridges and overpasses. The final aim of the endeavor is to help decision-makers in prioritizing their interventions for maintaining, repairing and extending infrastructure segments. We develop two different levels of impact assessment, both providing a unique global score for each bridge closure and investigating its spatio-temporal effects on mobility. We take advantage of a functional data analysis approach enhanced by a complex network theory perspective, thus modelling the roads of Lombardy as a network in which weights attributed to the edges are functional data. Results reveal the most critical bridges of Lombardy; moreover, for each bridge closure, the most impactful hours of the day and the most impacted municipalities of the region are identified. The proposed approach develops a flexible and scalable method for monitoring infrastructures of large and complex road networks.

Abstract *In questo lavoro viene analizzata e discussa una nuova metodologia per la stima degli impatti socio-economici dovuti alla chiusura al traffico di una o più infrastrutture in una rete stradale complessa. Motivati da una collaborazione con Regione Lombardia, vengono condotte delle analisi su un caso studio di più ponti della regione, il cui obbiettivo a lungo termine è quello di sviluppare una metodologia scalabile e applicabile a tutte le infrastrutture stradali lombarde, ovvero più di 10000 fra tunnel, ponti e cavalcavia. Lo scopo ultimo è fornire degli strumenti che*

[1]Center for Analysis Decisions and Society, Human Technopole, Milano
[2]MOX - Department of Mathematics, Politecnico di Milano
[3]Department of Management, Economics and Industrial Engineering, Politecnico di Milano, Italy

permettano di pianificare al meglio la gestione della rete stradale. Nel lavoro svolto vengono forniti più indici di impatto, definendo sia un indice globale univoco per la chiusura di ogni ponte sia analizzandone gli effetti spazio-temporali sulla mobilità. A tal fine, vengono adottati allo stesso tempo strumenti modellistici dell'analisi di dati funzionali e della teoria dei network, modellizzando quindi la rete stradale della Lombardia come un network, il cui peso sugli archi è un dato funzionale. I risultati rivelano i ponti più critici della Lombardia individuando per ogni ponte le ore più impattanti della giornata e i comuni più colpiti. La metodologia sviluppata, grazie alla sua flessibilità e scalabilità, è pronta ad essere applicata per il monitoraggio di qualsiasi tipo di infrastrutture in altre reti stradali.

Key words: Bridge Closure, Spatio-Temporal, Network, Functional Data.

1 Introduction

Civil road infrastructures play a pivotal role in the modern society and are generally considered one of the main drivers of socio-economic development. However, these structures are naturally subject to deterioration caused by the effects of natural hazards, environmental conditions and aging ([1], [2]). In order to allow these infrastructures to be safe over their entire life, monitoring and maintenance activities are necessary. In a situation where resources are limited, it is clear the importance of planning maintenance interventions based on some priorities, for defining which facilities should be visited, when and how maintenance should be carried out, respecting budget and other resource constraints ([3]. This paper aims to address the issue of determining the socio-economic impacts of closures of one or more road infrastructures so to handle and prioritize maintenance activities. The problem of evaluating the impacts of road closures in transportation networks is not new in the literature. Over the years, several measures of impact assessment have been introduced looking at different indicators (e.g. [4]; [5]). However, all these works do not address two issues which we consider to be important for the correct management of human mobility in a damaged network: the temporal and the spatial aspects. Hence, this paper proposes a novel two-way approach which investigates the impacts of a bridge closure from a spatio-temporal perspective: from the temporal point of view, we analyze how the impact of a road closure varies according to the hour of the day; from the spatial point of view, we identify the areas most affected by the closure. Specifically, we provide two different levels of impact assessment, investigating the spatio-temporal effects of a bridge closure and providing, for each bridge, a unique global score which can be used for ranking. The case study illustrated in the paper refers to the region of Lombardy in Italy, following a research project financed by Regione Lombardia, the regional government, to Politecnico di Milano. The project has the final aim of developing a scalable method for the assessment of the impacts of the closure of all the about 10000 bridges of the region. The results reported in this paper, however, relate a pilot study focusing on a sample of 290 bridges. Notice

that in this work we briefly report the methodology and the results that have been deeply presented in [6].
In Section 2 the methodological framework is presented coupled with analyses and results on the case study of Lombardy. Conclusions are presented in Section 3.

2 Methods and Analyses

Lombardy is one of the twenty administrative regions of Italy with an area of 23,844 square kilometres and a resident population of about 10 million people, forming one-sixth of Italy's population. Every day in Lombardy there are about 17 million trips across the region with different means of transport, 75% of which involves a motor vehicle on the road. For our analyses, we use two main complementary information sources both provided to us by Regione Lombardia: a modeling of the road network of Lombardy and origin-destination (OD) matrices. The modeled road network is a spatial network made of about 37000 nodes and 82000 directional links, i.e. segments of road between two intersections, which model all types of roads of the real network with a major simplification for the municipal roads. For each directed edge of the network, the length (km), the typical velocity without traffic (km/hour) and the typical travel time (hour) are known. Moreover, for all the 290 bridges under examination the corresponding edge to which each bridge belongs is known. The OD matrices of Lombardy contain the number of trips between all the municipalities of the region, which is split in 1450 mobility areas, for each hour of a typical working day in the time span between February and May 2016. Since it is well known that the daily traffic profiles are characterised by a within-day variability, we model the OD trips making use of tools from Functional Data Analysis (FDA), the branch of statistics dealing with curves, surfaces or anything else varying over a continuum [7]. Specifically, we model each mobility flow between an origin and a destination during the 24 hours by means of a point belonging to a space of continuous functions defined on the time domain (0,24). For more details about the OD trips modelling see [6].

For the scope of our analyses, we first pass through a data fusion step aggregating our sources of information. Using the modeled road network as base network we assign each mobility area of the OD matrices, whose GPS coordinate is known, to the closest node of the modeled road network. In this way we are able to estimate how the OD trips move across the modeled road network by searching the shortest paths. Then, we asses the impact of each bridge according to its importance in maintaining a proper connectivity between all origin and destination couples of the OD matrices ([4], [8]). For each bridge, we remove from the road network the edge to which it belongs and we measure its impact in terms of total-trip cost variation on all the affected trips. The first step is to evaluate the cost for each OD trip caused by the removal of a edge of the network. In our case each cost is equivalent to the increase in terms of travel time. Then, to obtain a global index of impact for the closure of the bridge belonging to the removed edge, we weight this cost by the number of trips

it affects during the day and we sum over all the the OD trips. The unit measure of the estimated global index is man-hour, that is representative of the socio-economic impacts of the bridge closure. Applying this procedure on our sample of bridges, we obtain for each one of them a unique global index that can be used to obtain a clear ranking of the bridges, so to help the regional government in the prioritization of maintenance investments. In Figure 1 all the 290 analysed bridges are reported according to their global index. It appears that the most critical bridges are located in the north side of the region, which is mainly in a mountain area with a sparse road network made of few main roads. Moreover, these bridges are often over a river.

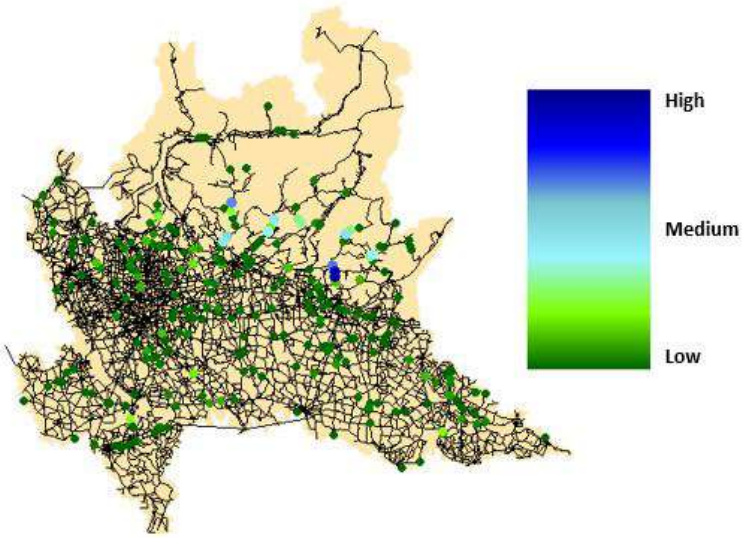

Fig. 1 Map of Lombardy highlighting the 290 analysed bridges according to their global index.

In addition to the just estimated global index, we provide a novel two-way spatio-temporal approach to explain how this impact spreads across the region and during the day. From a spatial perspective, we estimate how the impact of a bridge closure is distributed across the region, namely highlighting the most impacted areas of Lombardy. Hence, we apply again the same procedure used above for the construction of the global index, but now, when summing over all the the OD trips, we fix the origins or the destinations, respectively. For each origin we measure the cumulated impact of the closure of a bridge summing over all the trips starting from that origin. Analogously, for each destination we sum over all the trips directed to that destination. As result, for each bridge, we obtain a global index for each origin and for each destination. Obviously, summing up this spatial impact over all the origins or other all the destinations respectively we obtain the global index of the bridge closure. From a temporal perspective, we estimate how the impact of a bridge closure changes along time. To this end, we apply the same procedure used above

to estimate the global index but instead of weighting each OD cost by the total daily number of trips we weight it by the functional datum describing the number of trips from an origin to a destination at any time t of the day. These spatio-temporal analyses can be of great importance to better organize the road maintenance schedule. For example, the information about the most impacted origins or destinations by a bridge closure can be passed on to the affected travelers, with the aim of letting them optimize their trips. In addition, knowing the most impactful hours of the day for each bridge closure, road works can be planned by opening and closing the lanes of the road accordingly. Results related to this part are reported in [6].

3 Conclusions

In this work we discussed methodologies to evaluate the socio-economic impacts of the closure of critical infrastructures in a road network, stimulated by the analysis of a subset of bridges in the region of Lombardy in Italy. Specifically, we developed two different levels of impact assessment, both providing a unique global score for each bridge closure and investigating its spatio-temporal effects on mobility. The application of this methodology on the case of Lombardy revealed the most critical bridges of the region, which are mainly located in a mountain area, providing useful information to prioritize maintenance investments and for the correct allocation of available resources. The proposed approach is flexible and repeatable, thus ready to be applied to other realities in other countries.

Statistical Methods and Applications in Social Network Analysis

A clustering procedure for ego-network data: an application to Italian elders living in couple

Una procedura di clustering per l'analisi di reti ego-centrate: applicazione ai dati italiani sugli anziani che vivono in coppia

Elvira Pelle and Roberta Pappadà

Abstract The analysis of ego-network characteristics (especially size and composition) has become crucial in studying many aspects of everyday life. In this work, we propose a clustering procedure to find a partition of ego-networks into homogeneous groups according to their features. We use data from the "Family and Social Subjects" (FSS) survey conducted by the Italian National Statistical Institute in 2009, on elderly couples with both partners aged 65 years and more. Preliminary results show the suitability of our proposal to analyze this kind of ego-network data.

Abstract *L'analisi delle caratteristiche delle reti ego-centrate (in particolare dimensione e composizione) è diventata cruciale nello studio di molti aspetti della vita quotidiana. In questo lavoro, proponiamo una procedura di clustering per determinare una partizione di reti ego-centrate in gruppi omogenei in base alle loro caratteristiche. La procedura viene illustrata sui dati dell'indagine Istat su "Famiglia e soggetti sociali" (FSS, 2009), con riferimento alle coppie di anziani con entrambi i partner di età pari o superiore a 65 anni. I primi risultati mostrano come il metodo proposto possa essere utile ad analizzare questo tipo di dati di rete.*

shown the importance of network characteristics, especially size and composition, and of their effects on many aspect of everyday life (such as, social support [2, 7], health and well-being [10, 13]).

In this work we present a clustering procedure to identify homogeneous groups of ego-networks with specific characteristics. This problem has been addressed by some authors in recent literature (see [4, 1]). We use data from "Family and Social Subjects" (FSS) survey carried out by the Italian National Statistical Institute (ISTAT) in 2009. Focusing on Italian elders living in couples (married or unmarried) with both partners aged 65 years and more, we propose a clustering procedure to detect groups of ego-networks that are similar according to their features.

The remainder of the article is organised as follow: in Section 2 we present the characteristics of elderly Italian people and ego-network characteristics. In Section 3 we describe the clustering procedure and main results. Section 4 ends the paper with some concluding remarks.

2 Data description and ego-network of contact construction

We focus on Italian elders living in couples (married or unmarried) with both partners aged 65 years and more without other members (we consider 1722 couples, that is $n = 3444$ individuals, 7.8% of the total of respondents). Looking at the place of residence, 44.2% of elder partners live in Northern Italy, 19.5% lives in the Center and the remaining 36.4% in the South or Islands. According to the age, 60% of elders has a partner in the same age group, while in 37% of couples man is older than woman; on average, women are 73 years old while men are 76.2 years old. The mean number of children is 2.1 and almost 70% of elder partners has at most 2 children. No striking differences appear between the distribution of the health conditions for women and men: in both cases about 80% declares to perceive its own health as good or fair, while about 20% of partners perceives a bad health status. More than 18% of men presents a medium/high level of education (high school diploma or university degree), while about 87% of women has a low level of education (compulsory or none). For almost the totality of men in a couple (about 94%), pension is the principal source of income, while this percentage decreases to 71% for women, for which the second source of income is represented by allowance by partners (about 25%).

As well-known an ego-network can be derived "looking at relations from the orientation of a particular person" [5, p. 509], usually referred to as "ego", while the persons or institutions connected to the ego by some relations of interest are referred to as "alters". We use relational information on non-cohabitant persons in FSS 2009 edition to construct the ego-network of contacts for each elderly partner, as proposed in [2]. In particular, we use data about relation with non-cohabitant siblings, children, grandchildren, as well as information on the type and the number (if any) of other relatives and friends, and on the presence of neighbours. Thus, aggregating alters by their role relation with ego, we identify a maximum of 6 different alters'

role in the resulting ego-networks. Note that for each alter role data supply information about the presence and the number, except for neighbours, for which only the presence is available. The considered alter roles can be naturally classified into 4 network typologies: the "kin network" with alters from immediate family (children) and extended family (siblings, grandchildren and relatives), the "non-kin network" composed only by neighbours and/or friends, the "comprehensive network" with alters from both kin and non-kin network, and "other network" collecting network typologies not in the aforesaid categories (see Table 1). A small percentage of persons is not related to any of these types of alter (6.5% and 5.6% for men and women, respectively). Note that in the following section we will focus on those egos that are related with at least one of the considered types of alters, i.e. we consider $n = 3235$ individuals, 50.23% female and 49.77% male partners.

Table 1 Distribution of network typologies by gender (M=mean size, SD= standard deviation)

Gender	Isolated	Kin	Non-kin	Comprehensive	Other
Men	0.065	0.435 (M:4.4; SD:2.7)	0.042 (M:3.2; SD:3.0)	0.362 (M:9.9; SD:5.8)	0.096 (M:6.0; SD:4.2)
Women	0.056	0.437 (M:4.5; SD:2.8)	0.041 (M:3.2; SD:3.3)	0.367 (M:9.8; SD:5.8)	0.099 (M:6.1; SD:4.4)

3 Clustering methodology

In this section we develop a clustering procedure in order to identify groups of similar ego-networks with respect to their features. To this aim, for each ego E_i ($i \in \{1,\dots,n\}$) we collect the total number of individuals in the types of alters *siblings*, *children*, *grandchildren*, *relatives* and *friends*. In addition, we consider the availability of neighbours as a binary variable taking value 1 in case of presence of *neighbours* an ego "can count on if necessary", and 0 otherwise. The resulting data matrix that we use for clustering purposes is a $n \times p$ matrix, where $p = 6$ and the i-th row $x_i = (x_{i1},\dots,x_{ip})^T$, corresponding to the feature vector for ego E_i, is composed by five numeric attributes (the counts on each alter category) and one binary attribute (neighbours).

We now consider the problem of computing a $n \times n$ dissimilarity matrix for each pair $(x_i, x_{i'})$ of ego-networks for the female and male partners, separately. In general, let p_n and p_b be the number of numerical and binary variables, respectively ($p = p_n + p_b$). As it is common in clustering mixed data types, the distance between two units can be computed using partial dissimilarities with suitable weights (see, e.g., [11, 12]). We therefore introduce the following measure

$$d(x_i, x_{i'}) = \sum_{r=1}^{p_n} d_1(x_{ir}, x_{i'r}) + \gamma \sum_{s=1}^{p_b} d_2(x_{is}, x_{i's}) \quad (1)$$

where $d_1(x_{ir}, x_{i'r}) = 0$ if $x_{ir} = x_{i'r} = 0$, and $d_1(x_{ir}, x_{i'r}) = |x_{ir} - x_{i'r}|/(x_{ir} + x_{i'r})$, otherwise. In the latter case d_1 corresponds to the well-known Canberra metric. The dissimilarity measure on binary attributes is the number of mismatches, i.e., we set $d_2(x_{is}, x_{i's}) = 0$ for $x_{is} = x_{i's}$, and $d_2(x_{is}, x_{i's}) = 1$ otherwise. In this case, $p_n = 5$ and $p_b = 1$. In addition, γ is a weight for the binary part, introduced to avoid favouring either type of attribute. The resulting dissimilarity matrix $D = (d_{ii'})$ can then be input to a standard clustering algorithm (see, e.g., [8]). We adopt agglomerative hierarchical clustering, although different methods could be applied in this context (see [1] and the references therein). To specify a value for γ, we exploit the information available on the network typology described in Section 2 (Table 1) that yields a clustering $\mathscr{C}$ of the units into four groups. A different partition $\mathscr{C}'$ into four groups is obtained via standard agglomerative hierarchical techniques using the distance defined in (1) with different values of γ. Then, γ is chosen so that the *normalized mutual information* (NMI) [9] between $\mathscr{C}$ and $\mathscr{C}'$ is maximized (maximum index value is 1). For alternative approaches to the computation of weighted distances in clustering mixed-type data see [6]. Following the described method, we obtain the dissimilarity matrix of ego-network data using the estimated γ ($\gamma = 1.25$ and $\gamma = 1.5$ for women and men, respectively).

To obtain the final clustering we use the *minimax-linkage* hierarchical clustering method, implemented in the `R` package `protoclust`, where the distance between clusters is measured by the minimax radius of the resulting merged cluster. This method allows to identify the associated cluster prototypes, i.e. central units, chosen from the original datasets (for more details see [3]). The resulting *dendrograms* for female and male partners are shown in Figure 1. In both cases, the dendrogram structure seems suggesting a partition into $k = 4$ groups may be appropriate. This is not surprising, given that the starting point for our proposal is represented by the prior knowledge of individual network type used to calibrate the distance in 1. The final clustering can then be used to gain a more exhaustive description of the grouping structure in the data.

Table 2 can be useful for the interpretation of the clustering results. For instance, looking at female partners, the larger group (Cluster 1) shows strong separation with respect to non-kin groups, being characterized by a higher number of kin contacts (36% of alters are grandchildren). More than 30% of female partners belonging to Cluster 2 are aged 70-74 years (see Figure 2), and are connected to people across different kind of alters, including non-kin. The persons in Cluster 3 are individuals connected to a larger number of alters (the network mean size is 10), where we observe that the number of friends is prevalent. Female partners in Cluster 4 are assimilated since none of the previously distinguished groups dominates these networks, and most alters are relatives and non-kin members. The limited number of children and grandchildren suggests that this cluster is characterized by women with none or one son/daughter. Similar considerations can be drawn from the clustering of ego-networks of male partners (see Table 2).

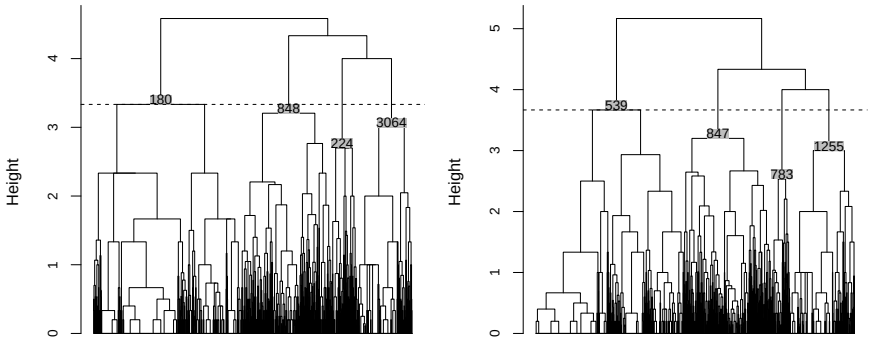

Fig. 1 The entire dendrogram of the ego-network dataset for females (*left*) and males (*right*) living in couple, with cut yielding the 4-cluster solution and prototypes displayed.

Table 2 Cluster size ($|C_i|$), mean size (MS) of ego-networks and relative frequency of alter types in the 4-cluster solution.

	$\|C_i\|$	MS	*siblings*(%)	*children*(%)	*grandchild.*(%)	*relatives*(%)	*friends*(%)	*neighb.*(%)
Female partner ($n = 1625$)								
1	753	4	14.65	34.69	35.79	14.87	0.00	0.00
2	276	5	1.28	22.20	19.65	19.36	17.94	19.57
3	465	10	7.19	17.04	19.08	20.80	26.36	9.53

4 Conclusions and future work

In this paper the ego-network of contacts of Italian elders living in couple (FSS Survey, 2009) is analysed at individual level. Agglomerative hierarchical clustering is adopted, based on a suitable dissimilarity in role structures, in order to find subgroups of similar networks. The influence of the weights adopted in the computation of the dissimilarity will be subject of further analyses. Preliminary results on the analysis of male and female partners show how the proposed procedure can be used to investigate the existing patterns in ego-networks data, especially in cases where the data are defined over heterogeneous attributes. Further challenges arise from modelling specific features of network data, as in the case of zero-inflated counts. As an extension of the presented work, the latest FSS Survey data collected in 2016 will be analysed. Future work will also explore consensus functions in order to improve the robustness of clustering by combining the output of multiple algorithms.

Analysing the mediating role of a network: a Bayesian latent space approach

Analisi di un network come mediatore: un approccio Bayesiano latent space

Chiara Di Maria, Antonino Abbruzzo and Gianfranco Lovison

Abstract The use of network analysis for the investigation of social structures has recently seen a rise, due both to the high availability of data and to the numerous insights it can provide into different fields. Most analyses focus on the topological characteristics of networks and the estimation of relationships between the nodes. We adopt a different point of view, by considering the whole network as a random variable conveying the effect of an exposure on a response. This point of view represents a classical mediation setting, where the interest lies in the estimation of the indirect effect, that is, the effect propagated through the mediating variable. We introduce a latent space model mapping the network into a space of smaller dimension by considering the hidden positions of the units in the network. Furthermore, the mediation analysis is extended by using generalised linear models. A Bayesian approach allows to obtain the entire distribution of the indirect effect, generally unknown, and to compute highest density intervals, which give accurate and interpretable bounds for the mediated effect. Finally, an application to social interactions among a group of adolescents and their attitude toward smoking is presented.

Abstract *Di recente si è assistito a un aumento nell'uso della network analysis per analizzare le strutture sociali, grazie sia alla notevole disponibilità di dati sia ai numerosi contributi che essa può apportare in diversi campi. La maggior parte delle analisi si concentra sulle caratteristiche topologiche dei network e sulla stima delle relazioni tra i nodi. In questo lavoro gli autori adottano un punto di vista differente, considerando il network nella sua interezza come variabile casuale che ve-*

icola l'effetto di un'esposizione su una variabile risposta. Questo è il classico caso di mediazione, in cui si è interessati alla stima dell'effetto indiretto, ovvero l'effetto che si propaga attraverso il mediatore. In particolare, si introduce un modello latent space che proietta il network in uno spazio di dimensione inferiore, considerando le posizioni latenti dei soggetti nel network. Inoltre, l'analisi di mediazione viene estesa a modelli lineari generalizzati. Un approccio Bayesiano consente di ottenere l'intera distribuzione dell'effetto indiretto, generalmente ignoto, e di calcolare gli intervalli di credibilità di massima densità, che forniscono valori soglia per l'effetto mediato accurati e interpretabili. Infine, viene presentata un'applicazione relativa alle interazioni sociali tra un gruppo di adolescenti e il loro atteggiamento nei confronti del fumo.

Key words: Network analysis, Bayesian methods, mediation analysis, longitudinal data, latent space model

1 Introduction

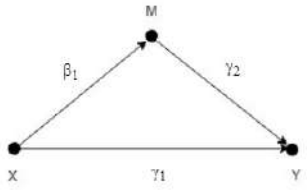
Network data consist of a set of n units and a relation tie m_{ij}, measured on each ordered pair of units $i, j = 1, \ldots, n$. Recently, there has been an explosion of network data in all corners of science [4]. Accordingly, several techniques have been proposed for the task of analysing network data. Graph theory is used to examine the network structure; fast and efficient algorithms are used to detect network communities; statistical models are adopted to understand the formation of connections between units. A review of statistical networks models, algorithms and software can be found in [8].

In this work, we view the network as a random variable M having a role in the mechanism through which an explanatory variable X affects a response Y. The aim is to decompose the total effect of X on Y into a direct and an indirect effect. Mediation analysis is a statistical technique widely used for this purpose [6]. The intermediate variable conveying the indirect effect is called *mediator*. For example, we consider an empirical analysis in which the social network of a sample of adolescents is regarded as a mediator in the relationship between sex and smoking status, and between the amount of pocket money each participant had per month and smoking status. The aim is to understand how social interactions can affect the propensity to smoke.

A major issue is related to the mismatch of dimensions between the network and the other variables. To deal with this evident mismatch, we do not use the network directly, instead we reduce its dimension through the latent space model proposed by [3]. This model projects the network in a space of smaller dimension, where each unit in the network is assumed to have an unknown position. These latent positions are estimated by modelling the presence of a link between two units in the network as dependent on their distance and possibly on additional covariates which may contribute to explaining the relationship. More details are provided in the next section.

2 Model specification: combining mediation analysis and latent space models

In the most straightforward setting, a mediation model includes three variables (see Fig. 1). If the mediator M and the outcome Y are assumed to be Normally distributed and to have linear relationships, the regression equations can be specified by:



$$\mathbb{E}[Y|X] = \tau_0 + \tau_1 X \tag{1}$$

$$\mathbb{E}[M|X] = \beta_0 + \beta_1 X \tag{2}$$

$$\mathbb{E}[Y|X,M] = \gamma_0 + \gamma_1 X + \gamma_2 M. \tag{3}$$

Fig. 1: Mediation model with three variables.

The equation (1) is the marginal model for the outcome; therefore, τ_1 represents the total effect of X on Y. The equation (2) is the mediator model, while in the last equation, the outcome model conditional on both the mediator and the exposure is specified. In the general associational framework, the indirect effect can be computed via the product method by multiplying β_1 and γ_2, that is, the coefficients corresponding to the arrows lying on the path connecting X to Y through the mediator M [1, 6]. In our analysis, the mediator is a network conveniently represented in a more parsimonious way through the latent space model, as described in [3]. This approach assumes the existence of a latent space where each unit in the network has a concealed position and relative distances predict the formation of a tie among units. Formally, a network with n nodes can be represented by an $n \times n$ matrix M, where each entry m_{ij} denotes a relationship between the units i and j. We focus on boolean relationships and, as a consequence, on adjacency matrices, but other kinds of relationships can be modelled as well. The probability that a link between i and j exists, denoted by p_{ij}, is assumed independent of all other ties in the network conditionally on the latent positions $\mathbf{z}$, and is modeled via a logistic regression

$$\text{logit}(p_{ij}|\mathbf{z}_i, \mathbf{z}_j, \alpha) = \alpha - \|\mathbf{z}_i - \mathbf{z}_j\|, \tag{4}$$

where $\mathbf{z}_i = (z_{i1}, \ldots, z_{iD})^\intercal$ and $\mathbf{z}_j = (z_{j1}, \ldots, z_{jD})^\intercal$ are the latent positions of units i and j and $\|\cdot\|$ is the Euclidean distance. The main advantage of this approach is that most networks can be represented in a space of dimension $D \ll n$. Moreover, the coordinates are orthogonal. Having established the setting, similar to [5], the idea is to use the components of the D-dimensional vector representing the position of each unit in the network as mediators in the relationship between an exposure and a response in order to estimate the indirect effect. If $D = 1$ we have a single mediator model, as in Figure 1. If $D > 1$ we have a multiple mediator model, as shown in Figure 2. The coordinates are mutually independent: joint mediation can then be addressed by performing separate mediation analyses considering one coordinate at a time and then combining the estimates of the indirect effects. Note that the

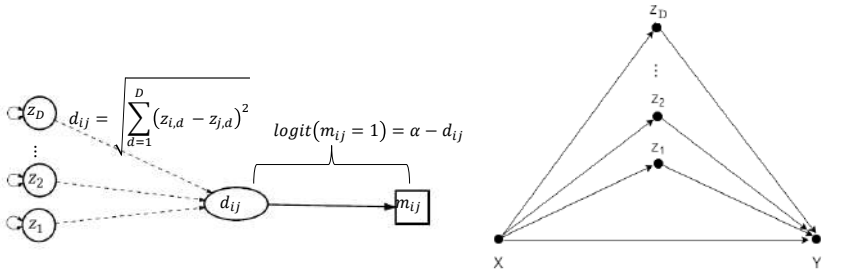


Fig. 2: Graphical representation of coordinates of a unit as mediators. The mediator for subject i is summarized by the latent position $z_{id}, d = 1, \ldots, D$ (see [5]).

assumption of linearity linking the mediator to the exposure, and the outcome to the exposure and the mediator is crucial since it ensures that the indirect effect can be obtained as a product of coefficients. For this reason, [5] used linear models for both the mediator and the outcome. We extend the model proposed in [5] by allowing the outcome to belong to the exponential family distribution, and to depend non linearly on its predictors. These extensions build on the works of [9] and [2]. [9] noticed that indirect effects could be seen as products of derivatives, the one with respect to the exposure in the mediator model and the one with respect to the mediator in the outcome model. For example, differentiating Equations (2) and (3) with respect to X and M, respectively, yields β_1 and γ_2, whose product is exactly the indirect effect in the classical Normal linear case. Formulas for the indirect effect when at least one between the mediator and the outcome model is nonlinear are more complex and depend on the values of X and (or) M: this is the reason why [2] suggest to call these effects *conditional*. The authors also point out that interpreting these effects as the increment in Y due to a unitary increment in X, mediated by M, is incorrect and that they should rather be commented in terms of increments of standard deviation, i.e. taking their magnitude into account.

Making inference on the indirect effect is not straightforward even in the linear case, since, even assuming that the two regression coefficients estimators are Normally distributed, generally their product is not. The distribution of the product may be highly skewed and, most importantly, unknown, and this complicates the estimation of confidence intervals for the mediated effect [7]. So, in this paper, inference is carried out within a Bayesian framework via Monte Carlo Markov Chain (MCMC) approach. The details of the inferential approach are omitted for the sake of brevity.

3 Data analysis

The data used in the analysis are a subsample of the 160 adolescents enrolled in the *Teenage Friends and Lifestyle Study*, a cohort study carried out in a secondary school of Glasgow between 1995 and 1997 intending to investigate how smoking behaviours change over time and the extent to which social interactions influence

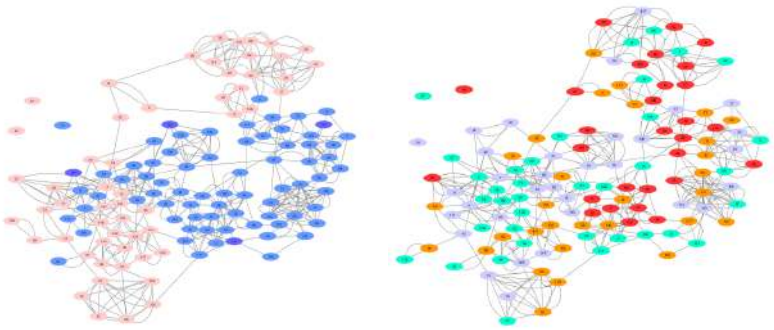

Fig. 3: Graphical representation of networks with nodes coloured according *Sex* and categories of *Money*: on the left, ■ = male and ■ = female, on the right ■ = 1 (0-7£), ■ = 2 (7-12£), ■ = 3 (12-20£), ■ = 4 (20-70£).

them. Except for participants' sex and age, which were recorded at baseline, other variables were collected at three different time occasions. Information on substance use (tobacco, alcohol, cannabis), leisure time activities, music taste, romantic relationships and several others are available. Moreover, social matrices representing friendship relationships among participants are included in the dataset. We conduct a cross-sectional analysis, choosing just variables relative to the last measurement occasion. Our interest lies on the way two exposures (*Sex*, participant's gender, and *Money*, the amount of pocket money each participant had per month) affect substance use through the relationship network. *Sex* is a binary variable, 0 denotes male and 1 female, *Money* is a continuous variable ranging from 0 to 70 pounds. We use the variable as it is and a categorical version obtained through its quarterlies so that we have four categories.

First, we fitted model in Equation (4) for different values of the latent space dimension D, and we compared the adjacency matrix corresponding to the actual network to the one obtained from the relative distances between the estimated latent positions in terms of F1-score. We obtained the highest F1-score for $D = 5$, and we noticed that increasing the dimension did not lead to a substantial improvement. Then, we used the estimated positions as mediators and estimated conditional indirect effects for each subject. We fit nine models, obtained combining the three exposure mentioned above with the three outcome variables *Smoke, Cannabis*, and *Alcohol*, binary variables where 0 indicates rare or no use of the correspondent substance and 1 moderate or high use.

We compute the direct effect of exposures on responses and individual conditional indirect effects and relative highest density intervals. The direct effect turns out to be significant in almost all analyses: in particular, *Sex* has a negative direct effect on *Smoke* and *Cannabis*, so the odds to make ample use of tobacco and cannabis is smaller for girls. In contrast, *Sex* has a positive direct effect on alcohol. Thus girls

seem to drink more than boys. The same pattern holds for *Money* in its categorical version. Indirect effects are non-significant for each subject and in each analysis.

4 Conclusions

We have addressed the issue of estimating the indirect effect in a mediational setting where the mediator is a network. We have used a latent space approach to reduce the dimensionality of the network, and the concept of conditional indirect effect to extend the estimation of the indirect effect on non-linear models. A Bayesian MCMC provides inferential results on the indirect effect. Finally, a dataset on adolescents shows that gender and the amount of pocket money available per month have a negative direct effect on smoking attitudes and cannabis use and a positive effect on alcohol consumption. Friendship relationships seem not to have any mediating role since indirect effects are non-significant in each analysis.

There are several directions this work can be developed on. It is necessary to carry out more research on how to extend latent space and mediation models to GLMs. Moreover, further extensions to the causal framework and longitudinal data to capture the dynamics of change would be promising.

Network-time autoregressive models for valued network panel data

Modelli autoregressivi per dati panel di network pesati

Viviana Amati

Abstract We propose and discuss the application of network-time autoregressive models to analyse the evolution of valued networks over time. Compared with more traditional network models explicitly modelling the network dependence structures, those models incorporate tie dependence using covariates and correlated random terms. The models are an extension of the classical space-time autoregressive models. We illustrate the applicability of the models by using data on networks of international migration flows.

Abstract Proponiamo e discutiamo l'uso di modelli autoregressivi di network per analizzare i cambiamenti nel tempo di network pesati. A differenza di tradizionali modelli che descrivono esplicitamente la struttura di dipendenza tra i legami, i modelli che proponiamo incorporano questa struttura mediante l'uso di covariate. I modelli autoregressivi di network estendono l'applicazione dei classici modelli autoregressivi spazio-temporali alla network analysis. L'utilizzo e l'interpretazione dei modelli proposti è illustrato con l'analisi di reti di flussi migratori internazionali.

1 Introduction

A network is a set of entities and the relations among them. In some cases, binary information, indicating the presence or absence of a relationship among pairs of entities is collected. In other cases, information on the intensity of the relationships is also recorded. For instance, friendship can be ranked according to its strength, trade can be measured by the volume of materials that are exchanged, interactions can be timed, and migration flows can be quantified by the number of people moving. A

Viviana Amati
Chair of Social Networks, Department of Humanities, Social and Political Sciences, ETH Zurich, Weinbergstrasse 109, 8092, Zurich, Switzerland e-mail: viviana.amati@gess.ethz.ch

network in which the relationships are characterized by intensity is referred to as a valued network.

Due to the complex dependence structure between the ties, many of the models applied to make inference on an observed network have to date been limited to binary networks. Thus, the modelling of valued networks has often required a dichotomization of ties. Ties with a value greater than a specified threshold are assumed to be present and ties with a value lower than that threshold to be absent. The dichotomization leads to a loss of information and introduces biases.

While many of the descriptive statistics have been easily extended to valued networks, there is a paucity of models that have been developed to model valued ties. Examples of these models are multiple regression quadratic assignment procedures [3, 2], exponential random graph models [4] for count data and stochastic actor-oriented models [9] for ordinal data.

In this contribution, we extend space-time autoregressive models to valued networks. The spatial component accounts for tie dependence and the covariates incorporate the network structure. Hereafter, we refer to the proposed model as the network-time autoregressive model. We discuss and illustrate the applicability of the model by analysing the evolution of the network of international migration flows.

2 Network time autoregressive models

2.1 Notation

Let $\mathscr{N} = \{1, \ldots, n\}$ be a set of entities over which a relation $\mathscr{R} : \mathscr{N} \times \mathscr{N} \to \mathbb{R}$ is defined. This relation can be regarded as a digraph on the set $\mathscr{N}$, and will be called the network. We represent the network as an adjacency matrix $Y_{n\times n}$, whose cell Y_{ij} takes the value $\mathscr{R}(i,j) \in \mathbb{R}$. The relation is assumed to be non-reflexive, implying that $Y_{ii} = 0$ and directed, i.e. $y_{ij} = c$ does not imply that $y_{ji} = c$, with $c \in \mathbb{R}$.

We assume that the network Y is subject to change over time. The dependence on time t is denoted by Y_t. Networks are observed at $M > 1$ distinct time points $t_1, \ldots, t_M$ in a panel design. Observations are denoted by y_{t_m}, $m = 1, \ldots, M$.

Entity- and dyadic-level variables might also be collected besides network variables. Entity-level variables describe constant or time-dependent characteristics of the entities and are denoted by the array $v = (v_1, \ldots, v_M)$ where $v_m \in \mathbb{R}^{n\times p}$ is the standard data table at time t_m. Dyadic-level variables describe constant or time-dependent characteristics of dyads and therefore are recorded for each pair of actors. Dyadic variables are represented by the sequence of arrays $z = (z_1, \ldots, z_M)$ where $z_m \in \mathbb{R}^{n\times n\times q}$ is an $n \times n \times q$ array whose element z_{ijq} is the value of the $q-th$ dyadic covariate over the pair (i, j) at time t_m.

The time series of networks $Y = \{Y_{t_1}, \ldots, Y_{t_M}\}$ together with monadic and dyadic covariates v and w constitute the valued network panel data.

2.2 Model formulation

Space-time autoregressive (STAR) models [7, 5] apply to the study of the dynamics of a variable recorded at the same locations and distinct time points. Variations of the variable over time and space are explained by both spatial and temporal correlation, as well as characteristics of the locations. Since valued networks panel data can be thought of as the collection of relational intensities over ties and time, we can extend the framework of the STAR model by replacing the spatial component with the network component to capture tie dependence. Thus, the network-time autoregressive (NTAR) models belong to the class of models that incorporate the network structure through covariates [8]. Compared with previous models belonging to this class, the NTAR model relaxes the standard assumption of independent residuals.

The vectorial form of the NTAR model is defined by the equation:

$$Y_t = v'\beta + z \odot \gamma + \sum_k \delta_k W_k f_k(Y) + \varepsilon_t \quad , \tag{1}$$

with β, γ and δ statistical parameters that need to be estimated from the data, the symbols $'$ (prime) the transpose of a matrix and $\odot$ the Hadamard product.

The first two terms on the right side of Eq. (1) capture the dependence of the value of Y_t on an entity's characteristics v and dyadic attributes v, respectively. For instance, entities with certain characteristics might be more prone to send or receive ties with high values. The third term models time and network dependencies through the row-normalized matrices of weights W_k whose generic element w_k represents tie dependencies at different times and network lags as defined by the function $f_k : Y \to \mathbb{R}$. The subscript k indexes the diverse forms of dependence that are in the data as described by the following examples. The last term ε_t is the error term accounting for the network correlation between the ties at time t. We assume that $\varepsilon_t = \rho W \varepsilon_t$ with ρ the network correlation coefficient at time t and ε a random variable normally distributed with mean 0 and variance-covariance matrix ρW.

We describe a few NTAR models to clarify the role and the structure of the matrix of weights W_k and the function f_k. We consider that the time lag is equal to 1 without loss of generality.

When tie independence is assumed, i.e. $W_k = I_k$ is an identity matrix, the NTAR model reduces to a regular autoregressive model in which the tie value Y_{ijt} is explained only by its previous value $Y_{ij(t-1)}$ and by the entity and dyadic covariates.

When dyadic dependence is assumed, ties within the same dyad are considered to be dependent. This implies that the value of Y_{ijt} depends on the values of $Y_{ij(t-1)}$, $Y_{ji(t-1)}$ and Y_{jit} due to the time lag 1. The dependence is mathematically expressed by using two weighted matrices. The identity matrix $W_1 = I$ captures the dependence of Y_{ijt} on $Y_{ij(t-1)}$. The matrix W_2 is a block diagonal matrix describing the dependence of $Y_{ij(t-1)}$ on $Y_{ji(t-1)}$ when the matrix is used jointly with $f_k(Y_{ij(t-1)}, Y_{ji(t-1)})$. For instance, if $\mathscr{N} = \{1,2,3\}$, we obtain the matrix

$$W_2 = \begin{array}{c} \\ (1,2) \\ (2,1) \\ \\ (1,3) \\ (3,1) \\ \\ (2,3) \\ (3,2) \end{array} \begin{array}{c} \begin{array}{cccccc} (1,2) & (2,1) & | & (1,3) & (3,1) & \quad (2,3) \quad (3,2) \end{array} \\ \left[\begin{array}{cccccc} 0 & 1 & | & 0 & 0 & 0 \quad 0 \\ 1 & 0 & | & 0 & 0 & 0 \quad 0 \\ - & - & - & - & - & - \\ 0 & 0 & | & 0 & 1 & | \; 0 \quad 0 \\ 0 & 0 & | & 1 & 0 & | \; 0 \quad 0 \\ 0 & 0 & - & - & - & - \quad - \\ 0 & 0 & & 0 & 0 & | \; 0 \quad 1 \\ 0 & 0 & & 0 & 0 & | \; 1 \quad 0 \end{array}\right] \end{array}$$

The matrix W_2 can be used, for instance, to model the effect of past reciprocity at time $t-1$ on Y_{ijt}. One way to express reciprocity in valued networks is to use the difference between tie values, i.e. $f_k(Y_{ij(t-1)}, Y_{ji(t-1)}) = Y_{ij(t-1)} - Y_{ji(t-1)}$. The closer this difference to 0 is, the higher the level of reciprocity. Alternatives are averages or the maximum and the minimum between $Y_{ij(t-1)}$ and $Y_{ji(t-1)}$. The choice depends on the relation that defines the network.

According to this specification, the NTAR model takes the form

$$Y_t = v'\beta + z \odot \gamma + \delta_1 W_1 Y_{ij(t-1)} + \delta_2 W_2 (Y_{t-1} - Y'_{t-1}) + \rho W_2 \varepsilon_t \quad . \tag{2}$$

The inclusion of W_2 in the error term accounts for the dependence of Y_{ij} on Y_{ji} at time t.

Similarly, we can extend the model to account for the Markov dependence assumption. Markov-dependence implies that two ties are dependent if they share a vertex. A third matrix W_3 can be added to the terms on the right side of Eq. (3), e.g., to model the effect of clustering of ties with particular values. This effect is the valued counterpart of the transitivity effect that is often observed and included in standard network models. As for reciprocity, the challenge of the model specification is to define the mechanisms that we think foster the changes in the tie values and the corresponding functions $f_k(Y)$.

Once the model is specified, several methods can be implemented to estimate the parameters of the NTAR model, among them the general least squares estimation, as in regular STAR model [7], or generalised estimating equation [6] abbreviated as GEE.

The model defined in Eq. (1) can be extended in several ways. The introduction of random effects and time-dependent parameters allows relaxing the assumptions of constant parameters over time and including time lags with order higher than 1, respectively. This modification should be implemented with caution since the increased number of parameters might lead to over-parametrized models.

The NTAR model can also be generalized to the evolution of valued networks where the values are determined by count data as the STAR models have been defined also for discrete variables. Like in standard generalized linear models, the valued tie variables, are related to the linear predictor using a link function and a different distributional assumption is assumed for the random error ε. In the next paragraph, we illustrate the use of NTAR model for modelling network of migration flows, where the values of ties are defined as a count.

3 Application

We illustrate the applicability of the NTAR models by analysing the network of migration flows between world countries. The United Nations website provides data on the international migrant stocks by country of origin and destination. A migrant is a person who is not born in the respective country of residence. This data allows estimating the network of international migration flows according to the demographic accounting pseudo-Bayesian approach described in [1]. Data are available for the years 1990, 1995, 2000, 2005, 2010 and 2015. Due to the illustrative purpose of this section, we consider only the last two observations. Information on religion and human development index (HDI) for countries were also collected from UNDP and the CIA World Fact Book websites.

To model the evolution of the international migration network between 2010 and 2015, we consider the following log-linear NTAR model [6] based on time lag 1 and dyadic dependence:

$$\log(E[Y_t]) = \beta_1 v_i + \beta_2 v_j + z \odot \gamma + \delta_1 W_1 Y_{ij(t-1)} + \delta_2 W_2 (Y_{t-1} - Y'_{t-1}) + \rho W_2 \varepsilon_t \quad , \quad (3)$$

with v_i and v_j representing the value of the human development index of the sender and the receiver countries of the tie, z the matrix containing the Jaccard index measuring similarity in religion, W_1 and W_2 as described in Sec. 2.2 and ε assumed to follow a Negative Binomial distribution.

Table 1 reports the results obtained using the GEE method. The parameters of the HDI sender and receiver indicate that the migration flow from low HDI to high HDI countries is larger than the flow from high HDI to low HDI countries. The similarity in religion is not significant, indicating that similar religious beliefs are not determinants of the migration flows. The time lag 1 parameter δ_1 is significant and positive, suggesting that flows between countries tend to consolidate over time. The coefficient of reciprocity, measured as differences of tie values in opposite directions, is also significant and positive. Thus, flows from country i to country j increase as the difference in the flows from i to j and from j to i increases. This indicates that flows are not reciprocated in values at time $t-1$ and this asymmetry foster the flows towards the direction of the largest flow. The parameter ρ is negative underlying that there is a negative network dependence in reciprocity even at time t. The results suggest that the network flows are directed to countries with more favourable living conditions as already suggested by the application of simpler models (e.g. gravity model).

The example is only used to illustrate the model specification and interpretation. More complex specifications, including, for instance, clustering effects, provide more information concerning the mechanisms that explain the evolution of the network of international migration compared with traditional models. However, the definition and inclusion of additional effects require particular caution in NTAR models since different functions $f(Y)$ might represent multiple mechanisms and the number of explanatory variables and parameters can quickly increase.

Table 1 Network time autoregressive model for the migration flow networks.

	Est.	s.e.

4 Conclusion

In this paper, we proposed network time autoregressive models to analyse the evolution of valued networks over time. Compared with more traditional network models explicitly modelling the network dependence structures, those models incorporate tie dependence using covariates and correlated random terms. We illustrated the applicability and the parameter interpretation by using data on networks of migration flows.

The NTAR models we presented are quite simple in their structure. More complex time and network dependence assumptions can be implemented in the model, e.g., by using random effects or relaxing homogeneity assumptions. This increase in complexity results in a greater number of parameters which might make the estimation of the model problematic. How to address model complexity, by introducing parameter constraints or using dynamic structural equation models for multiple time-series data, is the object of future work.

University student mobility flows and related network data structures

La mobilità studentesca universitaria e la definizione di strutture di dati di rete

Vitale Maria Prosperina, Giuseppe Giordano, Giancarlo Ragozini

Abstract The Italian student mobility in higher education represents a relevant issue for the academic system, especially for the regions located in Southern Italy. The aim of the contribution is to provide a first exploration of the structural patterns of student mobility flows among Italian geographical areas, focusing on South-North student migration routes and discovering the main destinations in the higher education migration phenomenon. A network perspective is considered by exploiting multimode network data structure. Data on cohorts of students enrolled at the Italian universities are considered.

Abstract *La mobilità studentesca rappresenta un tema di interesse per il sistema accademico soprattutto per le regioni del Sud Italia. L'obiettivo del presente contributo è fornire una prima esplorazione della struttura dei flussi degli spostamenti di studenti durante la carriera universitaria tra le regioni italiane, focalizzandosi sulla traiettoria Sud-Nord di tale catena migratoria. La prospettiva metodologica dell'Analisi delle Reti Sociali è utilizzata per individuare strutture di dati di reti multimodali. I dati su coorti di studenti iscritti ai vari corsi di laurea istituiti nelle università italiane sono oggetto di studio.*

1 Introduction

The Italian student mobility in higher education represents a relevant issue for the academic system [1, 14], especially for the regions located in Southern Italy. Such mobility generates massive student flows from the South to the North of the country [8, 13]. The choice to move from the place of residence is a complex decision that people often make to improve their quality of life, and economic drivers are only one of the motivation for people to migrate [13]. Several factors have been proposed in the literature as determinants of student mobility taking into account differences in socio-economic conditions of the origin and destination areas [10], cultural, institutional and organizational aspects. Students could move from their province of residence to find degrees in specific topics not available nearby, to enroll at Universities perceived as higher quality for research and teaching [6], and to join regions with better quality of life and/or with better job opportunities after graduation.

The university student mobility flows follow the traditional *South-to-North* migration chain. Indeed, considering the data provided by the National Student Archive (NSA) and related to the student enrollment at the first year of a Bachelor degree in the academic year (a.y.) 2018-2019, around 22% of students living in a region in Southern Italy and 24% of freshmen resident in the two main islands are enrolled in universities located in the Center and the North of Italy. Indeed, there are strong regional inequalities. For example, freshmen resident in the Basilicata region are enrolled in a university outside the region in 78% of the cases, among them 44% of students move to Center or North of Italy. On the contrary, students resident in the Campania region mainly stay in their own region and only around 11% of cases moves abroad the regional boundaries, showing an increasing power of the regional university system in retaining students. Considering one of the main Italian islands, Sicily shows the highest intellectual migration rate with 34% of students that enroll in universities outside the region. This phenomenon could yield some negative effects in terms of imbalance in government funding to universities, relevant brain drain on regional human capital accumulation [6], and demographic imbalance. Hence, the analysis of the factors explaining this phenomenon could help policy makers in promoting actions to counterbalance these negative effects of student migration in higher education.

Motivated by this framework, we aim at exploring the structural patterns of student mobility flows among Italian geographical areas, focusing on South-North student mobility route and discovering the destinations in the higher education migration phenomenon. A network perspective is considered in which regions as well as provinces or universities could be described as the set of nodes and student exchanges between units represent the set of links between them. The data on cohorts of students enrolled at the Italian universities are provided by the NSA archive. These data give rise to the definition of complex network data structures analyzed by considering community detection techniques in order to discover the presence of homogeneous territorial sub-areas in the student mobility phenomenon.

The contribution is organized as follows. Section 2 briefly describes the data on student mobility, while Section 3 introduces the methodological approach for ex-

ploring university student mobility data structure. Section 4 reports the first findings on the students' cohort under analysis.

2 Student Mobility Data

The NSA archive is considered to gather data on students enrolled in the Italian university system. Through this portal, the Ministry of University and Research offers the opportunity to consult, in an aggregate form, the information on student enrollments and careers of all registered universities. Here, data have been directly downloaded with information at individual level in anonymized form.[1]

Traditional data matrices could be defined by considering students' attributes (e.g., *sex*, *age*, *province of residence*, *type of secondary school*, *college grade*, *bachelor and master degree enrollment at university*, *type of bachelor and master degree*). These data can be analyzed as contingency tables in a classical statistical framework. Co-occurrence data might give rise to the definition of network data structures [4] in which frequencies weight the links connecting different sets of nodes, such as provinces of residence (province), universities of enrollment (university), and types of educational programs (educational program). Indeed, we can interpret frequencies as the number of student exchanges among geographical territories. The following network structures could be derived: *i) weighted one-mode networks* in which, for example, provinces are the nodes, and students' flows represent the edges' weights; *ii) weighted two-mode networks* in which the *province*×*university* or the *province*×*educational program* represent the two set of nodes, and students' flows represent the edges' weights; *iii) multimode* networks with different (three or more) modes (e.g., *province*×*university*×*educational program*; *iv) multiplex* networks with *province*×*university*, and the types of educational programs representing layers; *v) multilevel* networks with *province/university*×*educational program*, and regions representing nested level.

3 Multimode networks

In the following, the focus is on multimode networks to analyze complex network data structures derived from student mobility flows. Few papers are devoted to the study of multimode networks. A generalization of the conceptual basis and the matrix formalism of bipartite to tripartite graphs is described in the seminal paper of Fararo and Doreian [9], in which three types of nodes are defined and ties are present only between nodes of distinct types. The logic of this structure can be extended to

[1] The data at student level are available by the NSA archive for the universities involved in the project PRIN 2017 "From high school to job placement: micro-data life course analysis of university student mobility and its impact on the Italian North-South divide". Principal Investigator Massimo Attanasio, n. 2017HBTK5P, CUP: B78D19000180001.

any number of modes in a network. An extension on the use of regular and structural equivalence to multimode data is proposed in Borgatti and Everett [3]. The combination of the logic of multimode networks with Newman's spectral partitioning of graphs into communities is discussed in Melamed et al. [12]. Recently, Everett and Borgatti [5] suggest to examine the collection of all two-mode networks in case of multimode data.

Formally, a multimode network $\mathscr{M}$ can be conceived as consisting of a pair $(\mathscr{V},\mathscr{E})$, being $\mathscr{V} = \{V_i\}_{i=1,\ldots,K}$ the collection of K set of nodes, one for each mode i, $V_i \cap V_j = \emptyset$, $\forall i \neq j$, and being $\mathscr{E} = \{E_{ij}\}_{(i,j=1,\ldots,K)}$, $E_{ij} \subseteq V_i \times V_j$, $\forall i \neq j$ $E_{ii} = \emptyset$, $\forall i$, the collection of edges existing among the nodes belonging to the i-th and j-th mode. As said, the multimode network can be seen as the collection of all possible two-mode networks $\mathscr{G}_{ij} = (V_i, V_j, E_{ij})$ among the K set of nodes. Following the original idea of tripartite graphs [9], given the multimode network $\mathscr{M}$, we define a unique adjacency matrix $\mathbb{A}$ given by the combination in a block matrix of the sociomatrix $\mathbf{A}_{ij}$ corresponding to the two-mode networks $\mathscr{G}_{ij}$.

In the present contribution, as first step, a three-mode network is considered in which V_1 is the set of province of residence of Italian students enrolled at the first year of any Italian Bachelor degree in a given a.y., V_2 the set of public and private Italian universities (excluding the distance learning universities), and V_3 the set of types of educational programs as coded by the Italian law. In this network data structure, the links are the number of students enrolled, and the corresponding two-mode networks are weighted. Thus, the related adjacency matrix is defined as follow:

$$\mathbb{A} = \begin{bmatrix} \mathbf{0} & \mathbf{A}_{12} & \mathbf{A}_{13} \\ \mathbf{A}_{12}^T & \mathbf{0} & \mathbf{A}_{23} \\ \mathbf{A}_{13}^T & \mathbf{A}_{23}^T & \mathbf{0} \end{bmatrix}.$$

Note that the matrix $\mathbb{A}$ looks like the Burt matrix[11] (apart from the diagonal elements) used in the Multiple Correspondence Analysis. On the matrix A, we carry out the usual methods for weighted one-mode networks.

4 First results

The results on 223,908 students enrolled in a Bachelor degree of the Italian universities at the a.y. 2011-2012 are reported following their careers until the a.y. 2017-2018. 85.4% of the students were enrolled at the second year in the a.y. 2012-2013. 72.3% of the students confirmed their university choice, while the others moved in a different university and/or changed the educational program. About half of the students obtained the graduation in three years. This percentage increases to 60% considering the graduation after one year with respect to the regular duration of a study program.

To discover the presence of homogeneous territorial sub-areas in the student mobility phenomenon, we propose to use community detection algorithms [2] on two-

mode and three-mode networks: in the first step, we consider the two-mode network of *province*×*university*; in the second step, we analyze the full three-mode network ($\mathbb{A}$) *province*×*university*×*educational program*. In both cases, the edges with weight lower than 10 (i.e., pairs of entities sharing lower than a fixed threshold value) are removed. The interregional routes of student mobility, disregarding exchanges among the universities located within the same region, are taken into account.

Figures 1a and 1b report the visualization of two-mode and three-mode student mobility networks, respectively. In Figure 1a, on the top right, the group of the more attractive universities located in the North of Italy appears with the University of Bologna, the Polytechnic of Milan, and the Bocconi University emerging over the others; in the center of the network, the University of Turin and the University of Pisa attract students from Sicily and Sardinia; while the larger group, on the bottom, highlights the student mobility among Southern and Central provinces towards universities mainly located in the Center of Italy. On the left side, a small community emerges given by the link between Messina and Reggio Calabria exchanging students over the strait. In Figure 1b the information about the *type of educational program* is also considered. We note that the network structure of universities and provinces is rearranged in groups around specific topics. For example, in the bottom, business programs attract toward the Bocconi and the Luiss Guido Carli universities; on the top left, Engineering programs are linked to the Polytechnics and to the University of Pisa. Finally, in the center, Political Sciences and Foreign Languages programs are clustered with the University of Bologna and the University of Florence.

These first findings show that the network approach on multimode data structures provides interesting insights for the phenomenon under analysis. Besides the well-known South-to-North route, other interregional systems appear. However, we believe that specific tools for such complex network structures should be designed combining network analysis and multidimensional factorial techniques.

Statistical Methods in Psychometrics

A simple probabilistic model to evaluate questionable interim analysis strategies

Un nuovo modello probabilistico per valutare strategie di analisi intermedie

Francesca Freuli and Luigi Lombardi

Abstract Similar to other *"Researcher degree of freedom"*, the running of questionable "*Interim Analysis*" strategies may lead to an increase in the likelihood of observing a false positive rejection of the null hypothesis. This work aims to present a new probabilistic model to characterize the evidence that a statistically significant result is actually caused by the application of a questionable interim analyses (which does not correct the p-value as a function of multiple analyses). In particular, it is described the context in which two one sample t tests are carried out on an incremental data set composed of two consecutive blocks of independent observations for which only the second analysis results statistically significant. The application of the model to the literature could lead to greater control regarding the reliability of reported (already published) results.

Abstract *Cosi come altri "gradi di libertà dei ricercatori" la conduzione di strategie di analisi intermedie portano a un aumento della probabilità (non più imputabile quindi al teorico 5%) che il risultato ottenuto rappresenti un falso positivo. Obiettivo del presente lavoro è quello di descrivere un nuovo modello di stima della probabilità che un risultato statisticamente significativo sia stato ottenuto mediante l'applicazione di analisi intermedie. In particolare, viene descritto il contesto inerente lo svolgimento di due t test a campione unico (definita n la numerosità campionaria finale e $n = n_1 + n_2$, la prima analisi viene svolta a n_1 mentre la seconda a n) e viene assunto che solo i risultati della seconda analisi siano significativi. Qualora venga applicato alla letteratura, il modello proposto può rappresentare un utile strumento di controllo dell'affidabilità dei risultati osservati.*

1 Introduction

Uncontrolled interim analysis strategy represents one of the many questionable behaviors that researchers can adopt to force the publication of scientific results [3]. This strategy usually consists in carrying out multiple statistical analysis during the data collection phase, by adding, between the analysis sessions, a variable number of new observations. This recruiting and analysis "cycle" stops as soon as a significant result is observed.

Because a statistical control of the Type I error is lacking in this sort of practice, the observed results may easily lead to a 20% increment of false positives [7]. Several approaches have been proposed in the statistical literature to model rational interim analysis strategies to control for false positive rates [10]. For instance, the R package *GroupSeq* R [6] and another method [4] related to the Likelihood Ratio framework can be used to run interim analysis without incurring in statistical bias. Since, these approaches make it possible to plan a priori interim analysis while still preserving reliable results, they are frequently used in situations in which the recruitment process may be difficult, such as, for example, in clinical trials [2].

Another line of research regards the development of statistical procedures to estimate the reliability of the published statistical results. For instance, the method implemented in the R package *statcheck* makes it possible to replicate a paper's statistical analysis by comparing the model results against those reported in the published papers [5].

The present work aims to describe a new model to estimate the likelihood that a published statistical result was actually obtained via a questionable interim analysis. It is based on a transformed t-type density calculated by the convolution between a truncated t-density function linked to the first set of observations and the t-density function associated with the new set of observations in a two-step interim analysis. Importantly, this method is applied without having access to the original data (it only requires the final statistical test).Therefore, the proposed procedure can play a relevant role whenever a posteriori-analysis is required as a consequence of suspicious or alleged manipulations of the observed data or data analysis strategy. In the next sections, the procedure will be described together with a very simple application (one sample t test) in order to better highlight the underlying core logic of the novel proposal.

2 Model

2.1 Preliminary notation

Let $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ be a random sample of n independent and identically distributed (i.i.d.) observations sampled from a normal distribution $N(\mu_X, \sigma_X^2)$ with unknown mean (μ_X) and variance (σ_X^2). Moreover, let t_o^n be the observed one-sample

t-test statistic computed on $\mathbf{x}$. In particular:

$$t_o^n = \frac{\bar{x} - \mu_0}{s/\sqrt{n}}$$

with $\bar{x}$, s, and μ_0 being the sample mean, sample standard deviation, and population mean under H_0, respectively. It is straightforward to verify that t_o^n is also equivalent to $\bar{z}/(1/\sqrt{n})$ where $\bar{z}$ is the mean of the standardized array $\mathbf{z}$ with elements $z_i = (x_i - \mu_0)/s$ (with $i = 1, \ldots, n$) such that z_i are distributed according to the standardized normal $N(0,1)$. In what follows, we will limit our representation (without loss of generality) on the derived standardized array $\mathbf{z}$, only.

Now, suppose that 2 one-sample t-test sequential analyses are performed on the concatenated random samples $(\mathbf{y}_1, \mathbf{y}_2)$ such that

$$\begin{aligned} \mathbf{y}_1 &= \mathbf{z}_1 \\ \mathbf{y}_2 &= \mathbf{z} = (\mathbf{z}_1, \mathbf{z}_2) \end{aligned}$$

where $(\mathbf{z}_1, \mathbf{z}_2)$ is a concatenation of 2 sequential sub-samples of $\mathbf{z}$ (here simply called *blocks*) with the 1-th block $\mathbf{z}_1$ having n_1 observations and the 2-nd block $\mathbf{z}_2$ with $n_2 = n - n_1$ observations. Note that performing the interim analyses according to the former scheme corresponds to set a sequential data analysis strategy S which specifies the positions in the sequence $1, 2, \ldots, n$ where to split the original sample $\mathbf{z}$ and therefore how to create the 2 sequential blocks. More formally, we define an interim analysis strategy as

$$S_2 = \langle (n_1, n_2), 2 \rangle \tag{1}$$

Finally, let $B = \{0,1\} \times \{0,1\}$ be the binary space of the final decisions for the 2 sequential analyses. An element $b \in B$ is a Boolean pair (b_1, b_2) where $b_h = 1$, if the result of the analysis on the concatenated sample $\mathbf{y}_h$ (with $h = 1, 2$) turns out to be statistically significant (on the basis of a fixed Type I error probability α). Here we assume that no correction for the p-values is applied on the interim analyses. In our context, we are interested in that very particular case, denoted as $b^* = (0,1)$. The latter corresponds to that situation where the first interim analysis boils down to a non-significant result, whereas the analysis on the complete sample $\mathbf{z}$ allows to reject the null hypothesis. This mimics the result of a cheating analyst who stops collecting new data as soon as the analysis turns out to be (apparently) statistically significant (without correcting the p-values). In our context, to simplify the description, we assume that this event occurs after one single additional data collection $\mathbf{z}_2$.

2.2 Model representation

Here we introduce the simplest model representation which set a fixed strategy for a two-step interim analyses. In the discussion section, we will illustrate how a more

general representation can be straightforwardly derived from this basic simple instance. We assume that the following elements are observable or known:

1. the output, t_o^n, of the final statistical analysis (one-sample t-test) applied on the complete sample $\mathbf{z}$ (which results statistically significant: $p < \alpha$),
2. the specific hypothetical interim analysis strategy S_2 is also known.

Note that, in this representation we do not have direct access to the observations of $\mathbf{z}$, we only have access to the observed statistic t_o^n. This mimics that particular situation where we get access to an already published statistically significant result without having access to the original data. It is known (e.g., [1]) that the adoption of an interim analysis strategy certainly increases the chance to incorrectly reject the null hypothesis. Therefore, we are interested in computing the likelihood that the observed statistic, t_o^n, is actually the result of an interim analysis strategy S_2 conditioned that the null hypothesis H_0 is true ($\mu_X = \mu_0$) and consequently the observed statistically significant result is a false positive. Of course, the computation of this likelihood only represents a first step for computing other relevant information such as, for example, the posterior probability of the strategy S_2 given t_o^n and H_0 or the ratio between the posterior probability of the strategy S_2 and the posterior probability of a standard analysis S_1 with no interim analyses.

Under the assumption that H_0 is true we have that the unknown means $\bar{y}_1$ is distributed according to $N(0,\delta_1)$ with δ_1 being the standard error, $1/\sqrt{n_1}$, for the mean of the first block. Moreover, b^* entails the following constraints:

$$\bar{y}_1 \in D_1 = [-|t_c^{n_1}|\sqrt{1/n_1}, |t_c^{n_1}|\sqrt{1/n_1}] = [d_1^-, d_1^+], \tag{2}$$

where $t_c^{n_1}$ denotes the critical value of the t-distribution with $n_1 - 1$ df. By contrast,

$$\bar{y}_2 \in D_2 =]-\infty, -|t_c^n|\sqrt{1/n}[\cup]|t_c^n|\sqrt{1/n}, \infty[\tag{3}$$

We recall the following simple identity:

$$\bar{y}_2 = \frac{n_1}{n}\bar{y}_1 + \frac{n_2}{n}\bar{z}_2 \tag{4}$$

where $\bar{z}_2 \sim N(0,\delta_2)$ with δ_2 being the standard error $1/\sqrt{n_2}$ for the mean of the second block. Now, let the two transformed random variables $\bar{y}_1^* = \frac{n_1}{n}\,\bar{y}_1$ and $\bar{z}_2^* = \frac{n_2}{n}\,\bar{z}_2$. Clearly,

$$\bar{y}_1^* \sim N\big(0, \delta_1^2\big(n_1/n\big)^2\big) \qquad \bar{z}_2^* \sim N\big(0, \delta_2^2\big(n_2/n\big)^2\big).$$

Since $\bar{y}_1 \in D_1$, the density distribution of $\bar{y}_2$ can be defined as the convolution of the truncated normal distribution of $\bar{y}_1^*$ and the distribution of $\bar{z}_2^*$ [9]

$$f(\bar{y}_2) = \gamma \exp\left(-\frac{(\bar{y}_2)^2}{2(s_2^2+s_1^2)}\right)\left[\Phi\left(\frac{\bar{y}_2 - d_1^- - \alpha}{\beta}\right) - \Phi\left(\frac{\bar{y}_2 - d_1^+ - \alpha}{\beta}\right)\right] \tag{5}$$

where $s_1^2 = \delta_1^2\big(\frac{n_1}{n}\big)^2$ and $s_2^2 = \delta_2^2\big(\frac{n_2}{n}\big)^2$ and

$$\alpha = \frac{s_2^2 \bar{y}_2}{s_2^2 + s_1^2}, \quad \beta^2 = \frac{s_2^2 s_1^2}{s_2^2 + s_1^2}, \quad \gamma = \frac{\sqrt{2\pi}\beta}{2\pi s_2 s_1 (\Phi(e) - \Phi(c))},$$

and where

$$c = \frac{0 - d_1^+}{s_1} \quad \text{and} \quad e = \frac{0 - d_1^-}{s_1}.$$

Figure 1 shows the behaviour of the density function derived in Eq. (5) and compares it against the density function of the strategy $S_1 = \langle n, 1 \rangle$ representing the H_0 distribution (t distribution with 389 df) for a basic t-test analysis. Density points were calculated considering the left tail of the curve ($\alpha < 0.025$). Due to the symmetry of the distributions, results can be replied also for the right tail. From a quick inspection of Figure 1, we may observe a higher densities for S_2 for t values closer to the critical t. This result supports the expectation that questionable interim analysis increases the chance to invalidly reject the null hypothesis for observed t values with very close proximity with the uncorrected critical value.

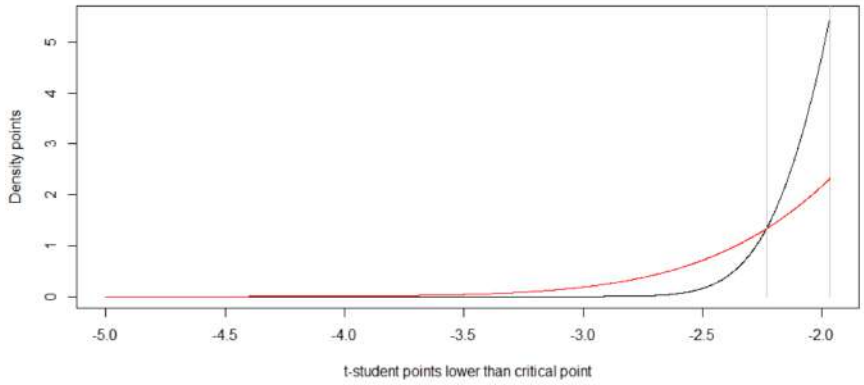

Fig. 1 Density function for the strategy S_2 (black line) and strategy S_1 (red line) model. In this representative example $n_1 = 360$ and $n_2 = 30$. The first grey line indicates the intersection point between two density function, the second one corresponds to the t critical point.

As stated earlier, the computation of the density function to represent the distribution of the test statistic under a questionable interim analysis strategy, constitutes only the first step to provide a full analysis about the evaluation of observed (and already published) statistical results. A subsequent step would require to combine or transform the derived densities to obtain useful information. For example, an analyst would be interested in computing the posterior probability of the strategy S_2 (resp. the strategy S_1) given the already published statistic t_o^n and H_0. Of course, the latter computation would require to set the prior probabilities for the two strategies, S_1 and S_2, on the basis of either speculative knowledge or previous empirical evidences which could naturally depend on the specific context of application.

3 Conclusions

In this short contribution, we presented a new model to estimate the density of a simple target statistic, the one-sample t-test, in case of a questionable interim analysis strategy. The ratio between these density values and the corresponding density values obtained under the "not questionable research practice" condition reflects the odds that a t value was obtained under the two conditions. For instance, for the condition described in figure 1, a t value of -2.1 is 1.65 times more likely to be associated with a questionable research practice than a not questionable one. Our approach can be useful to evaluate if an already published results may be consistent with questionable data analysis strategies, the so called researcher degree of freedom, which may drastically inflate the chance to erroneously reject a null hypothesis. By contrast, if an observed statistical result shows a very low evidence under the strategy, then this would indicate that rejection of the null is probably correct and not the result of a strategic manipulation adopted by the researcher to raise the chance to publish h(is/er) results.

Incorporating Expert Knowledge in Structural Equation Models: Applications in Psychological Research

Integrare il Parere degli Esperti con i Modelli di Equazioni Strutturali: Applicazioni nella Ricerca Psicologica

Gianmarco Altoè, Claudio Zandonella Callegher, Enrico Toffalini and Massimiliano Pastore

Abstract Structural Equation Modeling (SEM) is used in psychology to model complex structures of data. However, sample sizes often cannot be as large as ideal for SEM, leading to a problem of insufficient power. Bayesian estimation with informed priors can be beneficial in this context. Our simulation study examines this issue over a real case of a mediation model. Parameter recovery, power and coverage were considered. The advantage of a Bayesian approach was evident for the smallest effects. The correct formalization of the theoretical expectations is crucial, and it allows for increased collaboration among researchers in Psychology and Statistics.
Abstract *I Modelli di Equazioni Strutturali (SEM) sono spesso utilizzati in psicologia. Tuttavia, campioni limitati portano ad un problema di insufficiente potenza. Il nostro studio di simulazione esamina i vantaggi dell'approccio bayesiano con prior informative nel caso di un modello di mediazione. Sono state considerate la stima dei parametri, il coverage e la potenza. Il vantaggio dell'approccio Bayesiano è risultato evidente per gli effetti minori. La formalizzazione delle aspettative teoriche è cruciale e favorisce una fruttuosa collaborazione tra i ricercatori.*

1 Introduction

Structural Equation Modeling (SEM) encompasses a range of multivariate statistical techniques. SEMs are composed of two parts: a *measurement model* and a *structural model* (see Fig. 1). The measurement model defines unobserved constructs (*latent variables*, circles in Fig. 1) according to a set of measured outcomes (*observed variables*, squares in Fig. 1), whereas the structural model describes the relationships between latent variables. SEMs are widely used in psychology to model complex relations between different latent psychological constructs. However, as the complexity of the model increases, more data are required to obtain accurate parameter estimates and model fit statistics [10]. Nevertheless, in many research settings, the number of participants may be limited and appropriate statistical techniques are required to enhance the reliability of the results.

Often in the literature, the Bayesian approach is suggested over frequentist estimation when limited data are available [1]. The inclusion of prior information can help in the parameter estimation, but researchers have to carefully consider priors choice. However, most of the studies rely on default software prior settings. A recent review, underlined that the use of diffuse default priors can result in severely biased estimates, and this bias can be decreased only by incorporating informative priors [8].

Informative priors allow researchers to include in the analysis relevant knowledge in the field. Researchers could also consider to include opinions of experts. On the base of their experience in the field, experts can evaluate relevant information and help researchers in the definition of a plausible range of values and priors choice. *Elicitation* is a structured procedure that allows experts to express their knowledge and uncertainty about quantities of interest in the form of probability distributions [4, 3]. Elicitation can be used to define priors according to experts' judgement.

The remainder of this article is structured as follows. In Sec. 2, we present a simulation study to evaluate the influence of different prior specifications in the case of SEM with small sample size. For the sake of simplicity (but without losing generalizability) we present a mediation model in which the measurement model is not considered. Following common procedures, all variables were standardized (i.e., mean = 0 and a standard deviation = 1) before fitting all models. In Sec. 3, we discuss the obtained results.

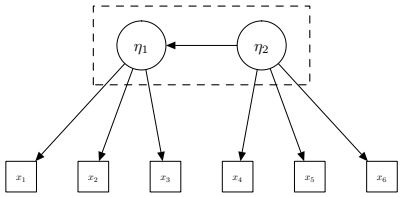

Fig. 1 A structural equation model. Within the dashed box is the structural model, outside is the measurement model. Circles for latent variables; rectangles for observed variables.

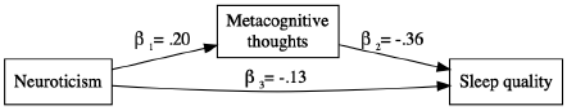

Fig. 2 Mediation model from [7]. The relation between Neuroticism and sleep quality is mediated by metacognitive thoughts.

2 Simulation

We considered a mediation model from [7] presented in Fig. 2. The study evaluated the relationship between participants' self-reported sleep quality (*Sleep quality*), participants' tendency to become anxious (*Neuroticism*), and negative beliefs about sleeping problems (*Metacognitive thoughts*). In particular, the association between *Neuroticism* and *Sleep quality* ($\beta_3 = -.13$) is mediated by *Metacognitive thoughts*. In other words, people with higher levels of distress and anxiety tend to have dysfunctional beliefs and attitudes about sleep ($\beta_1 = .20$) that, in turns, induce them to perceive and report a worse-quality sleep ($\beta_2 = -.36$).

2.1 Simulation details

The simulation was carried in `R` version 3.6.2 [5] using R-packages `lavaan` [6] and `blavaan` [2]. In the simulation, we considered as parameters of interest the regression coefficients ($\beta_1,\ \beta_2,\ \beta_3$). We compared the performance of Maximum Likelihood (ML) estimation and Bayesian estimation under four different sample size conditions (i.e., 20, 50, 100, 500).

Three different prior distribution specifications were used (see Fig. 3):

1. *Default prior* - $\beta_i \sim N(0, 10)$. These are intended to be non-informative.
2. *Reasonable prior* - $\beta_1 \sim N(.20,\ .50)$, and $\beta_{2;3} \sim N(-.20,\ .50)$. These are moderately informative to exclude excessively large values that are not reasonable within psychology research. Moreover, the mean of each prior is set to reflect the direction of the main results in the literature.
3. *Experts prior* - $\beta_1 \sim N(.20,\ .20)$, $\beta_2 \sim N(-.40,\ .20)$, and $\beta_3 \sim N(-.20,\ .20)$. These are intended to be highly informative representing experts' judgement.

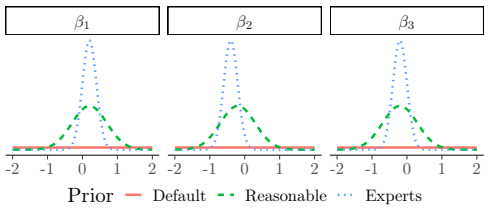

Fig. 3 Prior distribution in the three different settings. Default priors are intended to be non-informative. Reasonable priors are intended to exclude implausible values. Experts priors represent experts' judgement.

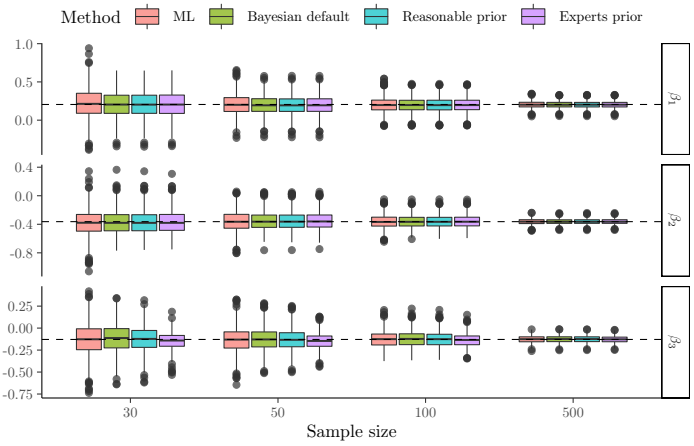

Fig. 4 Estimates distribution for each parameter across the different condition. Dashed lines represent the true population values.

Relative mean bias, relative median bias, mean square error (MSE), coverage and power were considered [9]. The relative mean bias (or median bias) evaluates the relative difference between mean estimate ($\bar{\theta}$; or median estimate $\widetilde{\theta}$) across replications and the population value (θ). Relative bias included between -.10 and .10 are considered acceptable [9]. MSE takes into account variability as well as bias of the estimates: $MSE = \sigma^2 + (\bar{\theta} - \theta)^2$, where σ is the standard deviation of the estimates across replications and $\bar{\theta}$ is the mean. Coverage is the proportion of replications in which the population value is included in the 95% confidence interval (CI; for the ML estimation) or 95% highest posterior density interval (HPD; for the Bayesian estimation). Instead, power is the proportion of replications in which the value zero is not included in the 95% CI or 95% HPD. Analyses were conducted considering the standardized parameters and for each condition 1000 replications were considered.

2.2 Results

The tables with detailed results for each parameter and condition are available at `https://osf.io/hwj8d/`. To interpret the results of relative mean and median bias, we considered the distribution of the estimated parameters (see Fig. 4). Only with very small sample sizes ($n = 30$) it is possible to observe some differences between estimation methods: Maximum likelihood approach produces the widest distributions, whereas Bayesian approach with experts prior has narrower distributions. However, differences between methods are noticeable for the parameter β_3 (i.e., the parameter with the smallest population value) but are less evident for the other parameters and, as the sample size increases, estimation methods perform similar to each other.

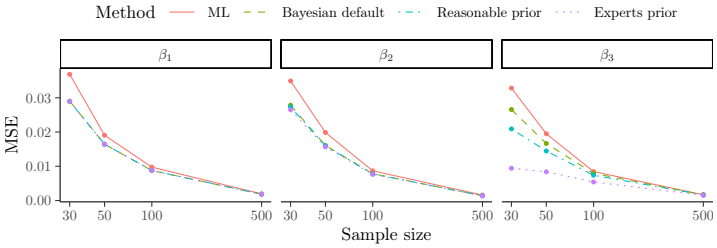

Fig. 5 Mean Squared Error (MSE) values for each parameter across the different conditions.

Considering the MSE (see Fig.5), we have the same results pattern. Differences between methods are bigger in the case of very small samples ($n = 30$), where Bayesian approach with experts prior performs better. However, differences between prior specification are noticeable only for the parameter β_3.

Finally, the result of coverage and power are presented in Fig. 6. Coverage reaches adequate levels in all conditions with sample size equal to or greater than 100. With smaller sample sizes, Bayesian approach with experts prior showed excessive coverage in the case of the parameter β_3. Power is extremely low when sample sizes are small. ML estimation performs slightly better in terms of power across all conditions, except for the parameter β_3 where is outperformed by Bayesian approach with experts prior. However, adequate levels of power are reached for all parameters only with large sample sizes ($n = 500$).

3 Discussion and conclusions

In the simulation, we evaluated the different estimation methods in the case of SEMs with small sample size. Overall, results indicate that informative priors are useful in

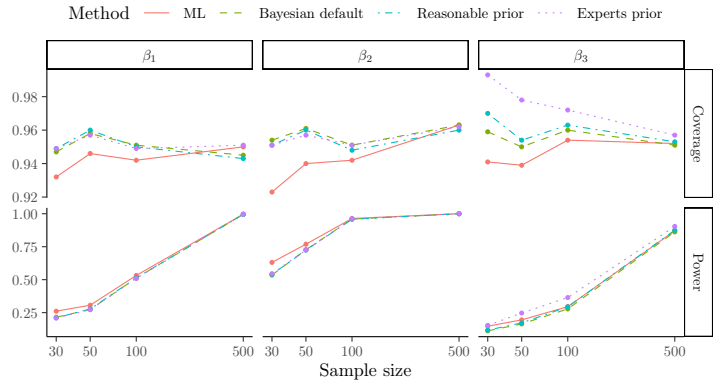

Fig. 6 Coverage and power values for each parameter across the different conditions.

the case of limited sample sizes and when the true population values are small. Parameter estimates were more stable across replications and extreme values were less likely. When the sample size increases the difference between estimation methods becomes less evident.

However, results are not consistent for all the parameters. In most conditions, Bayesian approach performs better than ML but results are very similar between the different prior specifications. Only in the case of small true population parameter values the Bayesian approach with expert priors performs much better than the other prior specifications. Future studies should focus on the role of prior definition in SEMs with different levels of complexity (e.g., also taking the measurement part into account) and in which the effect sizes vary on a larger range. Another important aspect that future studies should evaluate is the impact of prior knowledge misspecification, in particular in situations with small sample sizes.

Finally, we want to highlight that expert knowledge elicitation is not only useful to inform prior distributions but it can help also in other aspects of the analysis. Experts can help and inform researchers in the design of the experiments, definition of the models, interpretation of the results and make reasonable and informed choices along all the research process. Thus, the collaboration between different experts is a crucial point that should be encouraged in any applied research field.

Predicting social media addiction from Instagram profiles: A data mining approach

Uso del data mining per predire la dipendenza da Instagram in un campione italiano di studenti

Antonio Calcagnì, Veronica Cortellazzo, Francesca Guizzo, Paolo Girardi, Natale Canale

Abstract In this short paper, we describe an application of data mining techniques to predict Instagram users' addiction from a set of features related to (i) Instagram captions extracted from photos, videos, comments, and stories, and Instagram indicators such as number of followers and following, blocked and closed friends, and frequency of use. We first applied text mining to explore and describe the main contents of Instagram captions. Next, we used a set of non parametric models and ensemble methods to predict Instagram addiction as measured by the Instagram addiction scale [1]. Models were compared via cross-validation using test and training (random) sets from the original dataset. Results showed that Instagram addiction is mainly predicted by the overall time spent on Instagram, writing stories and comments, and number of followers. Moreover, the results suggest that Instagram users made use of photos/videos and stories/comments differently, with the latter being mostly related to emoticons, experiences, and relationships with other users.

Abstract *Questo lavoro presenta alcuni risultati di una ricerca più ampia condotta su un campione di giovani donne italiane circa l'utilizzo di Instagram come facilitatore dell'oggetivizzazione sessuale. In questo lavoro si presentano i risultati relativi allo studio circa il modo con cui attività di Instagram come pubblicazioni di foto, video, commenti e realizzazione di storie possano predire la dipendenza dal social media, come misurato dall'apposita scala di Instagram addiction. analisi è stata realizzata mediante data mining, utilizzando una serie di modelli non parametrici e metodi di ensemble. La validazione e la scelta del modello migliore è stata effettuata via validazione incrociata. I risultati mettono in evidenza il ruolo del tempo trascorso su Instagram, del numero di storie, commenti e followers come elementi di predizione della dipendenza dal social network. I risultati, inoltre, hanno altresì evidenziato come gli utenti tendano ad utilizzare video e foto in maniera diversa da commenti e storie: questi ultimi, infatti, sembrano maggiormente connessi a esperienze, emozioni e relazioni rispetto ai primi.

Key words: data mining, text mining, Instagram, social media addiction

1 Introduction

Instagram is a well-known social platform commonly used for personal reasons as well as business activities. Over the last years, it has gained wide popularity across the globe, becoming one of the most popular photo-sharing applications on the Facebook platform [2]. In particular, recent trends show that Instagram is the most important network being used among adolescents [3]. Recently, a number of research have shown the role of Instagram in several psychological processes, such as women objectification (e.g., see [4]). In this respect, appearance-related comments on women's bodies accompanying Instagram images seem to play a role in body dissatisfaction as well as women self-objectification [7]. This and other results suggest the importance of investigating the interplay between social media behaviors and social media addiction, especially in young users [5].

In this short paper we will focus on Instagram addiction in a sample of Italian students. In particular, we will investigate the predictive role of Instagram contents such as text (comments, hashtags, photo captions/descriptions), indicators (number of followers/followings, blocked users, closed friends), and activity frequency on social media addiction, as measured by the *Instagram Addiction Scale* [1]. Data mining techniques have been used to analyse the data. Particularly, text mining was applied to textual components of the dataset (comments, emoticons, captions) whereas a set of non parametric models and ensemble methods has been used to choose the best model and predictors for the response variable *Instagram addiction* [6]. The results suggest that the latter is mainly predicted by activities like interactions with other users of the social networking system via messages, comments, and likes.

2 Data and Methods

2.1 Data

The *Instagram Addiction Scale* [1] was administered to $N = 97$ female participants, all of them using Instagram on a daily basis. Data were collected by using an online survey.[1] Subjects were between 18 and 31 years old with an average age of 23.64 years (standard deviation 2.23). They were asked to answer fifteen items grouped into two sub-scales (i.e., Social effect, Compulsion) using an ordinal scale with six anchors. As scales were standardized, final scores were computed by summing the items corresponding to each sub-scale. Thus, the aggregated variable *addiction* was then defined, with higher scores being indicative of higher levels of Instagram addiction. For each participant, all Instagram data were also available in compressed format (up to six months before). They consisted in *comments* to other posts, *connections* with other users (followers, following, friends, blocked users), *likes* given to media (photos and videos) as well as *comments*, *media* (photo, stories, videos), *searchers* (texts, hashtags), and *stories*. For all these data, temporal information regarding the use of the social network (time, day) were also available. The final dataset comprises 94 subjects and 95 variables, including the response variable regarding Instagram addiction. Before running the analyses, 3 subjects were excluded as they included missing observations (row-wise exclusion) whereas 36 variables were left out from the analyses because of multicollinearity (as indicated by the threshold $r \geq 0.9$).

2.2 Methods

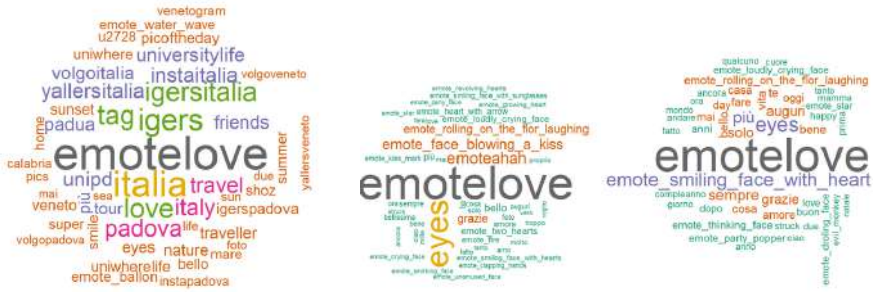
Data were analysed by means of data mining methods. With regards to the textual part of the data (photo captions, comments, hashtags), text mining descriptive techniques (i.e., most frequent terms, bigrams, graphical analyses, sentiment analysis) were used as implemented by the `R` library `TextWiller` [8] and `tidytext` [9]. All texts from Instagram were pre-processed according to standard text-mining pre-processing procedure (i.e., text-normalization, stopwords elimination, tokenization) [10]. In order to predict Instagram addiction with respect to 95 features of Instagram use, the following non-parametric and ensemble methods were instead adopted: (i) Principal component regression (tuning: number of variables), (ii) Partial least squares regression (tuning: number of variables), (iii) Lasso regression (tuning: λ penalty parameter), (iv) Regression trees (tuning: α complexity parameter), (v) Random forest (tuning: number of variables), (vi) Boosting (tuning: number

[1] The institutional review board at the University of Padova gave ethical approval for the study (protocol number: 2956)

and depth of trees), (vii) Bagging. They were compared via 10-fold cross validation, with prediction errors being computed via Out Of Bag (OOB) approach.[2]

3 Results and Discussion

Figure 1 shows wordclouds of the most frequent terms as extracted from captions of Instagram photos, videos, comments, and stories. Results indicate how distributions of photos/videos' comments were different from those of stories: indeed, words used in the first category were essentially descriptive (i.e., they just described photos/videos in terms of reference to places or experiences like traveling) whereas words used in stories/comments contained mainly emoticons and tag to users. Therefore, Instagram users made use of stories/comments and photos/videos differently. In general, sentiment analyses of captions revealed the presence of neutral sentiments more frequently than negative and positive sentiments. In particular, comments and stories showed a positive sentiment when compared to photos and videos, which suggest that users tended to use photos/videos and comments/stories with a different strategy.



(a) Photos and videos (b) Comments (c) Stories

Fig. 1: Wordcloud for captions of Photos, videos, comments, and stories.

In order to select the best subset of predictors of Instagram addiction from the large set containing 95 features, we proceeded by running a set of non-parametric models and ensemble methods as describe in section 2.2. Table 1 show the results of model comparison on training and test sets, respectively. Among others, Random

[2] More in details, ten train/test sets were created by bootstrapping the original dataset row-wise. Then, models were estimated for each training data using a 10-fold cross validation; cv-errors were computed and used to select the optimal tuned model. The best model was then chosen among those having minimum RMSE, which was computed on the test sets using the out-of-bag observations. Finally, the prediction error of the model was obtained as average of the ten RMSEs. Note that cross-validation was used as implemented in the `caret` library [11].

forest achieved lower MAE and RMSE w.r.t. parameters estimation (training set) and, in a similar way, it showed lower RMSE in the set as well. Thus, Random forest was selected as the best predictive model of Instagram addiction.

	RMSE	Test set error
PCA regression	0.7769	0.8715
PLS regression	0.663	1.0411
LASSO regression	0.7189	1.0016
Regression Tree	0.7387	0.8615
Bagging	0.6017	0.7631
Random Forest	0.6403	0.7324
Boosting	0.6749	0.7909

Table 1: Model comparison on test set. Note that Test set error is computed via bootstrap prediction error using 10 samples whereas the best model is represented in gray tones.

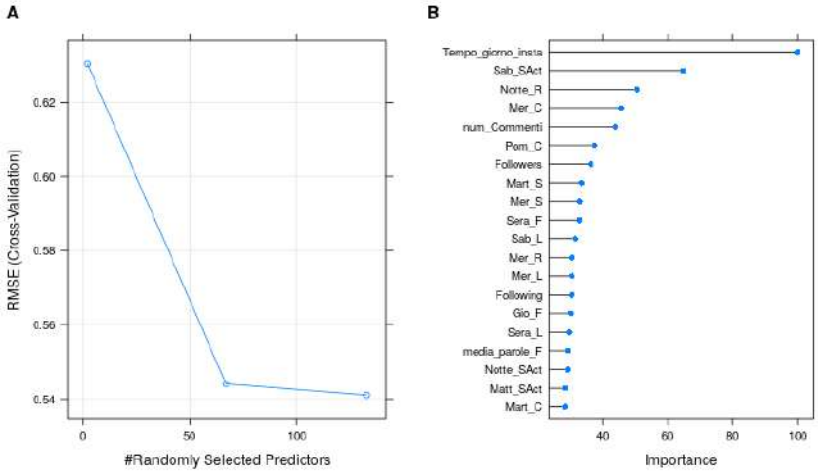


Fig. 2: Random forest to predict Instagram addiction: (A) RMSE as a function of the best number of predictors, (B) Variable importance plot for the final model. Note that variable importance measures are computed via the `importance()` function as implemented in the `randomforests` library [12].

The Random forest model was built on 500 trees which selected a final set of 67 predictors. Figure 2 shows the results of the final model. Overall, they suggested the following main predictors for Instagram addiction (in order of importance): Overall time spent on Instagram (`Tempo_giorno_insta`), replies to users' stories on Saturday (`Sab_SAct`), content searches during the night (`Notte_R`), writing com-

ments overall (`num_Commenti`) or in a specific temporal window, namely on afternoon (`Pom_cC`) and on Wednesday (`Mer_C`), number of followers (`Followers`).

4 Conclusion

We investigated the role of Instagram user's data (captions, photos, comments, likes, stories, hashtags, following and followers) in predicting social media addiction as measured by *Instagram Addiction Scale* [1] in a sample of Italian students. We used data mining techniques in order to (i) describe the use of Instagram commonly made by users and (ii) find predictors of Instagram addiction from a large database containing 95 features. The results suggested the importance of some variables, such as time spent on Instagram, writing stories, comments, and number of followers, as predictors of Instagram addiction. Moreover, the results also showed that users tend to use photos/videos and stories/comments differently: the first were mainly adopted for describing the objects they are related to. By contrast, the latter are more than simple descriptions, as they include emoticons, reference to places and experiences, tags to other users. Further studies need to be conducted to establish insights into the various mechanisms of Instagram addiction. For instance, text mining results (e.g., emoticons, sentiments) may be used to define new predictors of social media addiction, which would shed light on the role played by *typed emotions* on this emerging phenomena.

Structural entropy based modeling for psychological measurement

Modeling Strutturale basato sull'entropia per le misure in Psicologia

Enrico Ciavolino, Mario Angelelli, Paola Pasca and Omar Carlo Gioacchino Gelo

Abstract The contribution introduces the Entropy Based Structural Models and their dynamical evolution: the *Streaming entropy*. The new variant is described and tested on a typical clinical psychology scenario, that is, the psychotherapy process, as no previous work made us of behavioral data to study the psychotherapeutic relationship. Textual data consist of a psychotherapy transcript, whose word blocks have been processed and classified according to their valence: positive, negative and abstract. At first, the Stre-GCE algorithm computes one model parameter for each interaction components, then parameters get updated in an alternate way (therapist-patient, patient-therapist and so forth). Results show that Stre-GCE accounts for the fluctuating nature of the psychotherapy interaction.

Abstract *Il contributo introduce i Modelli Strutturali basati sull'Entropia ed una loro evoluzione dinamica: la Streaming Entropy. La nuova variante viene descritta e testata in uno scenario tipico della psicologia clinica, il processo psicoterapeutico, in quanto non esiste ancora un lavoro che utilizzi dati comportamentali per esaminare la relazione psicoterapeutica. I dati testuali consistono nel trascritto di un'intera psicoterapia, i cui blocchi di parole sono stati classificati in categorie: positive, negative, astratte. Inizialmente, l'algoritmo Stre-GCE stima i parametri di un modello per ciascuno dei componenti dell'interazione terapeutica, per poi aggiornarli in modo alterno con riferimento all'interlocutore precedente (terapeuta-paziente, paziente-terapeuta, ecc..). I risultati riflettono le fluttuazioni tipiche dell'interazione psicoterapeutica.*

Key words: Entropy Measures, Streaming Data, Structural Models, psychotherapy process

1 Introduction

The maximum entropy principle can be employed to quantify, keep track or estimate the information content in a system. Among the various applications of this principle, the Generalized Cross Entropy (GCE) proved to be useful in the estimation of model parameters subject to different forms of uncertainty (randomness, fuzziness). In this work, we examine the information content from a dynamical perspective through the Streaming Generalized Cross Entropy (Stre-GCE) method. As the Stre-GCE performed well in several simulations (see [2]), this work considers a real-life scenario in the clinical psychology context. In particular, we examine how the patient-therapist relationship unfolds over the psychotherapeutic process. Starting from an initial prior, we estimate the parameters evolution of an underlying statistical model through the Stre-GCE algorithm. This allows one to quantify the response to the stimuli and to evaluate the effects of the therapy in terms of the mutual actions in the patient /therapist pair.

2 Entropy models

In the following sections GCE theoretical framework and the Streaming version are introduced.

2.1 Generalized Cross Entropy (GCE)

Golan et al. [8] proposed by GCE as a generalization of the Maximum Entropy principle (MEP) developed by E.T. Jaynes [11, 12]. The GCE is based on the reformulation of regression parameters as expected values. Let us consider the i^{th} unit of the following regression model (n observations and m variables) by omitting the intercept:

$$y_i = \sum_j^m x_{ij}\beta_j + \varepsilon_i \tag{1}$$

the parameters (β_j, ε_i) are re-formulated as follows:

$$\beta_j = \sum_k^K z_{jk}^{\beta} p_{jk}^{\beta} \qquad \forall j, \qquad \varepsilon_i = \sum_h^H z_{ih}^{\varepsilon} p_{ih}^{\varepsilon} \qquad \forall i$$

where z^{β}_{jk} and z^{ε}_{ih} are the elements, called fixed points, of the support vectors $\mathbf{z}^{\beta}_{j}$ and $\mathbf{z}^{\varepsilon}_{i}$ equally spaced, uniformly and symmetrically chosen around zero. For the definition of these vectors see ([4, 8]). The associated vectors $\mathbf{p}^{\beta}_{j}$ and $\mathbf{p}^{\varepsilon}_{i}$ are the probability distributions of the unknown parameters β_j, ε_i, estimated by the minimization of the following cross-entropy function:

$$\begin{cases} \text{Minimize :} & \sum_j \sum_k p^{\beta}_{jk} \log p^{\beta}_{jk}/q^{\beta}_{jk} + \sum_i \sum_h p^{\varepsilon}_{ih} \log p^{\varepsilon}_{ih}/q^{\varepsilon}_{ih} \\ \text{Subjectto :} & \sum_k p^{\beta}_{jk} = 1, \quad \forall j \\ & \sum_h p^{\varepsilon}_{ih} = 1, \quad \forall i \\ & \sum_j x_{ij} \sum_k z^{\beta}_{jk} p^{\beta}_{jk} + \sum_h z^{\varepsilon}_{ih} p^{\varepsilon}_{ih} = y_i, \quad \forall i \end{cases} . \tag{2}$$

The key features and the main advantages of the GCE are the flexibility to introduce prior information in the model, defined by the two vectors $\mathbf{q}^{\beta}_{j}$ and $\mathbf{q}^{\varepsilon}_{i}$.

Entropy-based models do not require any distributional assumption, for instance they may be extended to cases where errors are correlated. In addition, contrary to other methods such as OLS, GCE can be applied without special algebraic requirements, e.g. when multicollinearity among covariates occurs. Finally, it is worth remarking that GCE works well in the case of small sample size too [8, 4, 5, 6, 9].

2.2 Streaming GCE

The choice of the criterion to update probability distributions starting from data may depend on the specific situation and on data characteristics. In several contexts, there is a temporal dimension associated with data. In particular, modern ICT systems involve *streams* of data, which are captured in different moments.

In order to explore the GCE approach in a dynamic context and extend it with adaptive aspects, we introduced the Streaming Generalized Cross Entropy algorithm in [2]. The algorithm involves two phases: the *batch* phase and the *streaming* phase.

2.2.1 The Batch phase

The *batch* is represented by m data samples to be used to assess the initial estimates. The Stre-GCE process continues until n data samples are collected. Formally, these n samples provide consistency constraints and $m < n$ distinguished samples represent the batch. They are processed using (2) with uniform prior:

$$\begin{cases} \text{Maximize:} & \left(-\sum_{j=1}^{J} \sum_{k=1}^{K} p^{\beta}_{j,k} \cdot \ln p^{\beta}_{j,k} - \sum_{h=1}^{H} \sum_{i=1}^{m} p^{\varepsilon}_{i,h} \cdot \ln p^{\varepsilon}_{i,h}\right) \\ \text{Subject to:} & \sum_{k=1}^{K} p^{\beta}_{j,k} = 1, \quad \forall j \\ & \sum_{h=1}^{H} p^{\varepsilon}_{i,h} = 1, \quad \forall i \\ & y_i = \sum_{j=1}^{J} \sum_{k=1}^{K} p^{\beta}_{j,k} \cdot z^{\beta}_{j,k} \cdot x_{i,j} + \sum_{h=1}^{H} p^{\varepsilon}_{i,h} z^{\varepsilon}_{i,h}, \quad \forall i \end{cases} . \tag{3}$$

The output $(\hat{\mathbf{P}}^{\beta(m)}, \hat{\mathbf{p}}_1^{\varepsilon}, \ldots, \hat{\mathbf{p}}_m^{\varepsilon})$ constitutes initial estimates:

$$\begin{aligned} \hat{\beta}_j^{(m)} &:= \sum_{k=1}^{K} \hat{p}_{j,k}^{\beta(m)} \cdot z_{j,k}^{\beta}, \quad j \in \{1,\ldots,J\}, \\ \hat{\varepsilon}_i &:= \sum_{h=1}^{H} \hat{p}_{i,h}^{\varepsilon} \cdot z_{i,h}^{\varepsilon}, \quad i \in \{1,\ldots,m\} \end{aligned} \tag{4}$$

2.2.2 The Streaming phase

In the update process, the upcoming information follows to the already present one (that is, the actual probability distribution used to compute the model estimates). Formally, the new estimates will be produced through the minimization of the cross entropy

$$\mathrm{D_{KL}}(\mathbf{P}^{\beta} || \hat{\mathbf{P}}_i^{\beta}) - H(\mathbf{p}^{\varepsilon}). \tag{5}$$

So we find the new distribution as the solution to the following constrained optimization problem:

$$\begin{cases} \text{Minimize :} & \left(\sum_{j=1}^{J}\sum_{k=1}^{K} p_{j,k}^{\beta} \ln p_{j,k}^{\beta} - \sum_{j=1}^{J}\sum_{k=1}^{K} p_{j,k}^{\beta} \ln \hat{p}_{j,k}^{\beta(i)} + \sum_{h=1}^{H} p_{i+1,h}^{\varepsilon} \ln p_{i+1,h}^{\varepsilon}\right) \\ \text{Subjectto :} & \sum_{k=1}^{K} p_{j,k}^{\beta} = 1, \qquad \forall j \\ & \sum_{h=1}^{H} p_{i+1,h}^{\varepsilon} = 1, \qquad \forall i \\ & y_{i+1} = \sum_{j=1}^{J}\sum_{k=1}^{K} p_{j,k}^{\beta} \cdot z_{j,k}^{\beta} \cdot x_{j,i+1} + \sum_{h=1}^{H} p_{i+1,h}^{\varepsilon} z_{i+1,h}^{\varepsilon}, \qquad \forall i \end{cases} \tag{6}$$

It is noted that the difference between signal and error is described in terms of effects of the temporal dimension, (i.e. note the different priors in 5: at the $(i+1)$th step, the probability distributions selected are chosen as prior $\hat{\mathbf{P}}_i^{\beta}$ for the signal, while the uniform prior is chosen for errors.

3 Theoretical model for synchronization in Psychotherapy

The flow of the psychotherapeutic interaction has been traditionally studied and located in the theoretical framework of the self-organization theory [7]: according to this view, a transition from a behavioral pattern to another occurs as a consequence of a temporary destabilization of a relatively stable system. So far, self-report measures were the primary source of information about instability/discontinuity moments [10]. Thus, the use of behavioral data to investigate the therapeutic interaction is still an unexplored territory.

Our textual data comprise a whole psychotherapy transcript from the York I Depression Study. It consists of a number N_S of sessions, and a number w_t of word

blocks for the t-th session. Words in each block are partitioned into three classes, i.e. positive words, negative words, and abstract words. This partition provides each block i with two probability distributions, i.e. the relative frequencies of each class compared to the total number of words in the i-th block. Therefore, we also get two entropies $h_i^{(T)}$ and $h_i^{(P)}$ associated with the therapist's and the patient's frequencies in the i-th block, respectively.

Two simultaneous models are provided to describe the effects of the patient's (respectively, the therapist's) word block: for the i-th word block , we consider the following pair of relations describing the mutual influence of the two actors:

$$h_i^{(T)} = \beta^{P\to T} \cdot h_i^{(P)} + \varepsilon_i^{P\to T}, \tag{7}$$

$$h_i^{(P)} = \beta^{T\to P} \cdot h_i^{(T)} + \varepsilon_i^{T\to P}. \tag{8}$$

The number of session is used as an index to switch between the updates of the patient's and the therapist's estimates, while the word-blocks within a given session represent the block stream that feeds the block Stre-GCE algorithm.

In principle, the two parameters $\beta_s^{P\to T}$ and $\beta_s^{P\to T}$ are distinct. In the models (7-8) $\beta_s^{P\to T}$ and $\beta_s^{P\to T}$ are uni-dimensional (i.e., scalars), but they can be extended to a multi-dimensional case when more synchronization "measures" are considered. We also stress that the present model envisages two different entropies: the pair of entropies $\left(h_i^{(P)}, h_i^{(T)}\right)$ associated with the individual i-th word block, and the cross entropy representing the objective function in (6) to get the estimates for parameters. It is worth remarking that the relation among entropies at different scales has been explored in a different framework in [1].

We will assume that the models alternately update: (7) is updated when s is odd, while (8) is updated when s is even. For each session s, we focus on the corresponding word blocks indexed by $i \in \{1,\dots,w_s\}$. Each such block contains the data for a single update. Therefore, the Stre-GCE algorithm discussed in this work is an adaptation of the Stre-GCE algorithm already discussed in [2]. A different approach is to run the Stre-GCE algorithm on the individual data within a given block. The output of this process is the update of the therapist's (respectively, the patient's) response model estimate. In particular, the updated distribution represents the prior distribution in the subsequent update. As for the Stre-GCE algorithm, only the distributions $\mathbf{p}_s^{\beta,P\to T}$ and $\mathbf{p}_s^{\beta,P\to T}$ associated with parameters $\beta_{P\to T}$ and $\beta T \to P$ are updated, while the distributions associated with errors are not.

4 Stre-GCE in the psycho-therapeutic context: Results and Discussion

We consider each session as a domain in which the actors affect one another in a specific way. At the considered domain of the interaction, we assume that only one of the actors influences the other one. Specifically, this means that sessions labelled

by odd integers preserve one of the models, say (8) while updating the other one (7). Conversely, sessions labelled by even integers preserve (7) and update (8).

The Stre-GCE algorithm described in previous sections gives the estimates shown in Table 1: they represent a quantitative response of the patient to the psychotherapist and vice-versa.

	1	2	3	4	5	6	7	8	9	10
$\hat{\beta}_{P\to T}$	0,803		1,030		0,741		0,602		0,844	
$\hat{\beta}_{T\to P}$		0,643		0,719		0,952		0,991		0,746
	11	12	13	14	15	16	17	18	19	20
$\hat{\beta}_{P\to T}$	0,867		0,850		0,772		0,977		0,921	
$\hat{\beta}_{T\to P}$		0,979		1,066		0,661		0,884		0,722

Table 1 Stre-GCE estimates of model parameters β_{PT} and β_{TP} in (7)-(8).

Results show fluctuations between the two interactans. As the psychotherapeutic relationship comprises moments of engagement and disengagement, these findings are not surprising [7, 10]. In summary, the Stre-GCE algorithms proves to be a viable means to further explore the psychotherapy interaction via behavioral data.

Statistical modelling in environmental epidemiology

A Time Varying Coefficient Model to Estimate the Short-Term Effects of Air Pollution on Human Health

Un Modello con Coefficienti Variabili nel Tempo per la Stima degli Effetti di Breve Periodo dell'Inquinamento Atmosferico sulla Salute Umana

Valentini Pasquale, Ippoliti Luigi and Grazian Clara

Abstract Misspecification in regression models can lead to biased coefficients and, in turn, to incorrect inference. In this paper we consider the problem of omitted variable bias in a regression framework where we estimate the relationship between air pollution and health data. In this context, we show that the problem of the omitted variable bias of OLS estimators can be overcome by using a time-varying coefficient model. By relying on a state-space representation, some different model specifications are presented.

Abstract *Alcuni casi di errata specificazione dei modelli di regressione possono portare a coefficienti distorti e, a sua volta, a un'inferenza errata. In questo lavoro consideriamo il problema della distorsione derivante dall'omissione di una o più variabili in un contesto di regressione in cui si vuole stimare la relazione tra inquinamento atmosferico e salute umana. In particolare, si dimostra che il problema può essere affrontato usando un modello state-space a coefficienti variabili nel tempo. Per il modello proposto vengono presentate alcune parametrizzazioni corrispondenti a specifici interventi correttivi della distorsione.*

Key words: Hierarchical model, spatio-temporal model, time varying coefficients

1 Introduction

A rich literature on health care research has provided substantial statistical evidence of the adverse health effects associated with air pollution. Most of the studies are

usually based on time series models, developed both in single and multi-sites frameworks (see, for example, [1]).

Time series studies allow to estimate associations between day-to-day variations in air pollution concentrations and day-to-day variations in adverse health outcomes. In this context, the nature of the data make risk estimation challenging, requiring complex statistical methods sufficiently sensitive to detect effects that can be small relative to the combined effect of other time-varying covariates. It is also common for researchers to be confronted with situations where unobservability of variables, or unavailability of data, force them to omit relevant variables correlated with both pollutants and the outcome (e.g. measured confounders). Confounding by unmeasured variables ([1]) also remains a large concern in this framework. Influenza and respiratory infections, for example, may produce seasonal and long-term trends in health data and not accounting for these potential confounders can lead biased conclusions on the effect of exposure on health.

Though the omitted variable bias (OVB) is well known and has been discussed for decades, the mechanics of OVB are not yet fully understood. In the next Section, we discuss the use of time-varying coefficient (TVC) models which results useful to improve inference in the presence of omitted variables. The theoretical framework considers the possibility of using a set of *driving* variables as well as a state-space representation of the model. Some model specifications are presented.

2 Model Specification

Assume that Y is a spatio-temporal process observed at temporal instants $t = 1,2,\ldots,T$ and generic sites, $\mathbf{s}$, located within a fixed region $\mathscr{D}_y$. Usually, health data (Y) are collected over time in a fixed study region with N locations typically in the form of mortality and morbidity counts or hospital admissions, coded according to the type of disease (e.g. cardiovascular, acute respiratory, etc).

The model is based on Poisson conditional distribution

$$Y(\mathbf{s},t)|Y^*(\mathbf{s},t) \overset{ind}{\sim} Poi[\exp(Y^*(\mathbf{s},t)]$$

with the logarithm of the conditional mean given by

$$Y^*(\mathbf{s},t) = \beta_0 + \beta_1 X(\mathbf{s},t) + \sum_{p=1}^{P} \alpha_p Z_p(\mathbf{s},t) + \varepsilon(\mathbf{s},t) \tag{1}$$

where $X(\mathbf{s},t)$ is the pollutant, $Z_p(\mathbf{s},t)$ are time-varying covariates to control for measured and unmesaured confounders, and $\varepsilon(\mathbf{s},t)$ is assumed to be Gaussian with zero-mean and variance σ_y^2 constant over space and time. Of course, it is also possible to introduce a spatial dependence in $\varepsilon(\mathbf{s},t)$.

Without loss of generality, assume $P = 1$ so that

$$Y^*(\mathbf{s},t) = \beta_0 + \beta_1 X(\mathbf{s},t) + \alpha_1 Z(\mathbf{s},t) + \varepsilon(\mathbf{s},t). \tag{2}$$

Our interest lies in the estimation of the linear exposure-outcome relationship β_1, conditional on Z.

By using only predictor X it is known that the OLS estimator b_1 of β_1 is biased:

$$E(b_1) = \beta_1 + \alpha_1 \frac{\sum_{i=1}^{N}\sum_{t=1}^{T}(X(\mathbf{s}_i,t)-\bar{X})(Z(\mathbf{s}_i,t)-\bar{Z})}{\sum_{i=1}^{N}\sum_{t=1}^{T}(X(\mathbf{s}_i,t)-\bar{X})^2} \tag{3}$$

that is, it is equal to β_1 in expectation only if $\sum_{i=1}^{N}\sum_{t=1}^{T}(X(\mathbf{s}_i,t)-\bar{X})(Z(\mathbf{s}_i,t)-\bar{Z}) = 0$ (the omitted variable is uncorrelated with X), or if $\alpha_1 = 0$. In any other case we have to face with the OVB problem. In epidemiolologic-based time-series studies, various covariates, such as temperature, humidity, or ozone, are likely to be confounders because they do co-vary with pollution. Therefore, if the model is specified incorrectly (either because the confounding variables are unknown or because the data do not exist) we can lead to wrong conclusions on the effect of exposure on hospital admissions.

Swamy and Metha ([2]) and, subsequently, Granger ([3]) state that any misspecification problem can be solved by relying on a model which is linear in variables, but with time varying coefficients. The implication of this result is that, even if we do not know the correct specification form of a relationship, we can always represent this relationship as the following TVC model

$$Y^*(\mathbf{s},t) = \beta_0(t) + X(\mathbf{s},t)\beta_1(t) + \varepsilon(\mathbf{s},t). \tag{4}$$

To make TVC estimation fully operational, we specify the following state equation for the time varying coefficients:

$$\beta(t) = \Phi\beta(t-1) + \Gamma\mathbf{C}(t) + \omega(t) \tag{5}$$

where $\beta(t) = [\beta_0(t)\ \ \beta_1(t)]'$, Φ denotes a state-transition matrix for the unobserved components, $\mathbf{C}$ is a vector $(r \times 1)$ containing a set of *driving variables* which are correlated with the omitted variable $Z(\mathbf{s},t)$, Γ is a $(2 \times r)$ coefficient matrix, and $\omega(t)$ represents the (2×1) vector of temporally uncorrelated error terms with distribution $N(\mathbf{0},\mathbf{Q})$.

Equations (4) and (5) may be rewritten as

$$Y^*(\mathbf{s},t) = \beta_0 + \delta_0(t) + X(\mathbf{s},t)\beta_1 + X(\mathbf{s},t)\delta_1(t) + \varepsilon(\mathbf{s},t) \tag{6}$$

$$\delta(t) = \Phi\delta(t-1) + \Gamma\mathbf{C}(t) + \omega(t) \tag{7}$$

where $\delta(t) = [\delta_0(t) \;\; \delta_1(t)]'$, $\delta_0(t) = \beta_0(t) - \beta_0$ and $\delta_1(t) = \beta_1(t) - \beta_1$.

Considering equations (6) and (7), we note that imposing some restrictions on the parameters it is possible to obtain three nested models. In particular, imposing $\mathbf{Q} = \mathbf{0}$, $\Phi = \mathbf{I}$, $\Gamma = \mathbf{0}$ and the initial state $\delta(0) \sim N(\mathbf{0}, \mathbf{0})$, the regression coefficients remain constant for all periods, and accordingly we have the traditional OLS solution.

The second specification, known as the Random Coefficient (RC) models, is obtained by setting $\Phi = \mathbf{0}$ and $\Gamma = \mathbf{0}$.

Finally, fixing $\mathbf{Q} = diag(0, q_{2,2})$, $q_{2,2} > 0$, , $\Phi = \mathbf{I}$, $\Gamma = \mathbf{0}$ and the initial state $\delta(0) \sim N(\mathbf{0}, \mathbf{0})$, the Time Varying Parameters (TVP) model is obtained.

The general model given in equations (6) and (7) is developed specifying the prior distributions of all hyperparameters within a state-space framework. The full probabilistic inference for the parameters is facilitated by a Markov chain Monte Carlo (MCMC) scheme for multivariate dynamic systems.

The performance in terms of bias reduction for the general and the nested models will be tested trough both an extensive simulation study and real data in an extended version of this paper.

Joint Analysis of Short and Long-Term Effects of Air Pollution

Analisi congiunta degli effetti a breve ed a lungo termine dell'inquinamento dell'aria

Annibale Biggeri[1], Dolores Catelan[1], Giorgia Stoppa[1], Corrado Lagazio[2]

Abstract We present a bivariate Bayesian space-time geostatistical model for exposure assessment and disease risk estimation. We use data from a panel study of 113 children on respiratory health in the high risk area of Valle del Mela (Sicily, IT). Data and gaseous pollutants were collected on 12 weeks in 21 locations 2007–2008. The model consists in an exposure model to predict pollutant concentrations at children's residential addresses; a bivariate disease model. The original features are the joint specification of a spatial long-term effect and a spatiotemporal short-term effect of the pollutant concentrations and uncertainty propagation.

Abstract *Presentiamo un modello geostatistico bayesiano spazio-temporale bivariato per la predizione dell'esposizione e la stima del rischio di malattia, applicato ai dati di uno studio longitudinale sulla salute respiratoria di 113 bambini dell'area a rischio Milazzo-Valle del Mela. Dati sanitari e inquinanti gassosi furono misurati su 12 settimane in 21 postazioni tra 2007-2008. Il modello include un modello predittivo dell'esposizione e un modello bivariato per lo stato di salute. L'originalità sta nella specificazione congiunta di un effetto a breve ed un effetto a lungo termine dell'inquinante e nella corretta propagazione dell'incertezza.*

1 Introduction

In Environmental Epidemiology exposure to pollutants may affect disease risk on a short or very short time lag. The exposure is acting as a precipitating event and some cases are simply anticipated of few days. If the exposure dose is high enough we can observe acute toxicological effects. In the case of chronic degenerative diseases like cardiovascular diseases or cancer, we cannot observe an acute effect because the pathogenesis requires several steps to be completed before the disease become clinically detectable. In this case, to measure a change in disease risk a potentially life-long observation period is needed.

Short-term effects are measured by longitudinal designs with average daily concentration of pollutants as exposure metrics. Long-term effects are measured by population cohort studies in which individuals at different baseline levels of exposure are followed-up over decades. The exposure metrics are annual averages.

Few studies attempted to joint model short and long-term effects of air pollution on the occurrence of health outcomes (Kloog (2013)). The methodological approach was to specify a generalized linear mixed model including in the linear predictor the two exposure metrics – daily and annual averages – and enrolling several population cohorts over a wide geographical region. Currently, most efforts are devoted to create huge datasets covering millions of people over long calendar periods. Exposures is obtained as daily averages predicted at a fine geographical resolution by integrating remote sensing data via machine learning and ensemble modelling (Shtein (2019)). We expect that joint modelling be soon a data science hot topic.

In this paper we present a joint Bayesian space-time geostatistical model for exposure assessment and disease risk estimation. The originality of this modelling is the joint specification of a spatial long-term effect and a spatiotemporal short-term effect of the pollutant concentrations and an appropriate uncertainty propagation.

2 Motivating example

The data came from an epidemiological project on the National Remediation Site of Milazzo-Valle del Mela funded by WHO and Regione Siciliana (Biggeri (2014)). Main sources of pollution were oil refinery, petrochemical plant, oil-powered energy plant, foundries, seaport and traffic. In this paper we used a panel study on 113 susceptible children (compliance rate 73%) selected from all 2506 children attending the primary schools of the area. We analysed for the present study inflammatory symptoms (persistent cough). In the study period 21 passive monitors for gaseous pollutants were located in the backyard of each primary school. We will concentrate on Nitrogen Dioxide weekly averages ($\mu g/m^3$) monitored on 12 weeks between November 2007 and April 2008. Baseline information on demographics, respiratory health, lifestyles and risk factors were collected by parents' questionnaires. Weekly diaries were collected during the study period as well as lung function examinations.

3 Methods

We develop a joint bivariate disease and exposure model, within model-based spatio-temporal geostatistics (Diggle and Giorgi (2019)). Below, we introduce the disease, the exposure, the bivariate model and the Cronbach model.

3.1 Disease model

Let assume that $s \in R^d$ be a location – residential address - in *d*-dimensional space and $Y_t(s)$ be a data response variable observed at location *s* on time *t* for subject *i*

$$\{\mathbf{Y}_{it}(s): s \in D\},\ D \subset R^d$$

the disease model can be expressed as

$$\boldsymbol{Y}_{it}(s) = g\left(\beta_0 + \beta_1 \tilde{X}_{it}(s) + \gamma W_{it}(s) + S(s,t) + Z_i(s) + Z_{it}(s)\right)$$

where $g(\cdot)$ is the link function, $\tilde{X}_{it}(s)$; $W_{it}(s)$ are predicted exposure and observed fixed confounder(s), β; γ regression coefficients, S(s,t) a continuous spatio-temporal process and $Z_i(s)$, $Z_{it}(s)$ random error terms.

3.2 Exposure model

Let assume now that $s' \in R^d$ be a location - ambient monitoring site - in *d*-dimensional space and $X_t(s')$ be a data exposure value observed at s' on time *t*

$$\{X_t(s'): s' \in D\},\ D \subset R^d$$

the **exposure model** can be expressed as

$$X_t(s') = g\left(\beta_0' + \gamma W_t'(s') + S'(s',t) + Z_t'(s')\right)$$

where $X_t(s')$; $W'_t(s')$ are exposure and confounder(s), γ' regression coefficients, S'(s',t) a continuous spatio-temporal process and $Z'_t(s')$ a random error term.

The disease and the exposure models are linked by the predictive distribution. To obtain $\tilde{X}_{it}(s)$ - the exposure value at location *s* on time *t* – we use the known covariate vector $W'_{it}(s)$ and the predictive distribution from a Bayesian Gaussian Spatio-temporal Exponential model. MCMC methods are used taking advantage of the posterior samples and the conditional normal distributions arising from the joint multivariate distribution of $X_{it}(s')$ and $X_{it}(s)$ (Banerjee, Carlin and Gelfand (2014)).

3.3 Short and Long-term effects modelling

The regression coefficient of interest are respectively short-term – associated to the exposure at time *t* and location *s* - and long-term – associated to the average exposure at location *s*.

The disease model could be expressed in two alternative forms, the Firebaugh model (not shown) and the Cronbach model:

$$Y_{it}(s) = g\left(\beta_0 + \beta_1\left(\tilde{X}_{it}(s) - \tilde{X}_i(s)\right) + \beta'_2\tilde{X}_i(s) + \gamma W_{it}(s) + S(s,t) + Z_i(s) + Z_{it}(s)\right)$$

In the Cronbach model under specific assumptions on confounders, the regression coefficient β'_2 is equal to the coefficient of the model on the aggregated data:

$$Y_i(s) = g\left(\beta''_0 + \beta'_2\bar{X}_i(s) + \gamma'' W_i(s) + S''(s) + Z_i(s)\right)$$

This equality can be used to specify a computationally more robust bivariate model which takes the form - $\eta_{2i}(s)$ denoting the linear predictor of $Y_{2i}(s)$:

$$\begin{Bmatrix} Y_{1it}(s) \\ Y_{2i}(s) \end{Bmatrix} = \begin{Bmatrix} g\left(\beta_{0,i} + \beta_1\left(\tilde{X}_{it}(s) - \bar{X}_i(s)\right) + \gamma W_{it}(s) + S(s,t) + Z_{it}(s)\right) \\ g\left(\beta''_0 + \beta'_2\bar{X}_i(s) + \gamma'' W_i(s) + S''(s) + Z_i(s)\right) \end{Bmatrix}$$

$$\beta_{0,i} = \left(\eta_{2i}(s) + Z_i(s)\right)$$

where we can recognize the Cronbach model specification and the specification of a model on the aggregate data – i.e. averaged over time.

4 Results

We fitted a hierarchical Bayesian model. The exposure model was:

$$X_t(s') = exp\left(\beta'_0 + \gamma W'_t(s') + S'(s',t) + Z'_t(s')\right)$$

$$S'(s',t) = \pi(s') + \pi(t) + \psi(s',t)$$

$$\pi(s') \sim GP\left(\mu(s'),\ {}^{s}\sigma^2, \rho(d)\right)$$

$$\pi(t) \sim G\left(\bar{\pi},\ {}^{t}\lambda\ \ n_t\right)$$

$$\psi(s',t) \sim GP\left(\mu(s',t),\ {}^{st}\sigma^2, \rho(d)\right)$$

where $\pi(s')$ is a Gaussian process (GP) with covariance matrix $\Sigma_{ij} = {}^{s}\sigma^2 \cdot \rho(d)$ induced by the correlation function $\rho(d) = exp(-\varphi \cdot d)$ that depends on the distance d between pairs of points and by the spatial variance parameter ${}^{s}\sigma^2$; φ is chosen to get almost zero correlation at the maximum distance (9.32 Km) and almost one at the minimum distance (0.103 Km); $\pi(t)$ is a conditional autoregressive term of order 1; $\bar{\pi}$ is the mean of the (t-1)-th and (t+1)-th terms, ${}^{t}\lambda$ is the precision and n_t the number of adjacencies; $\psi(s',t)$ is a Gaussian process with time-dependent mean $\mu(s',t) \sim G\left(\bar{\mu},\ {}^{\mu.st}\lambda\ \ n_t\right)$ and covariance matrix according to the specification of the spatial main effect $\pi(s')$. A GIS for the study area was developed using as data-layers: digital elevation, slope and aspect of the study area (spatial resolution = 40 m); land use (Corinne Land Cover), population density (LandScan 2010) and road map (TeleAtlas). The selection of the covariates to be included in the model was done outside the Bayesian model through both an automatic stepwise regression and information from the literature. The selected covariates $W'_t(s')$ were: altitude above the sea level, distance to the main roads, population density and land use covariates calculated as the proportion of surface area with the characteristic over a buffer of 500 meters radius (industrial, urban and

suburban land cover). Information of all these covariates was obtained for each residential address and pollution monitor location (Vicedo-Cabrera (2013)).
The multivariate disease model takes the form:

$$\begin{Bmatrix} Y_{1,it}(s) \\ Y_{2,i}(s) \end{Bmatrix} = \begin{Bmatrix} logit\left(\beta_{0,i} + \beta_1\left(X_{it}(s) - \bar{X}_i(s)\right) + \gamma W_{it}(s)\right) \\ logit\left(\beta''_0 + \beta'_2 \bar{X}_i(s) + \gamma'' W_i(s)\right) \end{Bmatrix}$$

$$\beta_{0,i} = \left(\eta_{2,i}(s) + Z_i(s)\right)$$

We consider inflammatory symptoms as bivariate 0-1 responses ($Y_{1,it}(s)$cough or phlegma outside common cold in the *t*-th measurement week; $Y_{2,i}(s)$ cough or phlegma outside common cold for more than three months in the last 12 months - as defined in the ISAAC study). As time-dependent confounder $W_{it}(s)$ we include use of β_2 agonist in the *t*-th measurement week, and as subject specific confounders $W_i(s)$ we include age, sex, parents education, mother smoking, mould or dampness in the children bedroom, familiarity for asthma. The hierarchical Bayesian model specification includes two joint Bernoulli likelihoods for the two responses, weakly informative priors for all regression coefficients, $Z_i(s)$ as a Gaussian noise. The joint exposure and disease model provides uncertainty propagation and potentially adjust for the measurement error bias in the regression coefficients. In figure 1 we report as example the average predicted Nitrogen Dioxide concentration surface. In figure 2 we show the posterior density for the long-term coefficient (log Odds Ratio) of inflammatory symptoms for a 10 μg/m^3 increase in the annual average of Nitrogen Dioxide. In light yellow we show for comparison the posterior density if we do not consider uncertainty in the predicted exposures.

Figure 1: Average Nitrogen Dioxide concentration surface. Results of the exposure model (see text). Milazzo – Valle del Mela study (Biggeri et al. 2014).

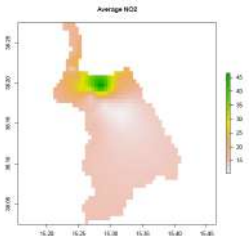

Figure 2: Posterior density of mean NO2 coefficient (green). In light yellow the posterior density of a model which does not consider the uncertainty in the exposure model (see text).

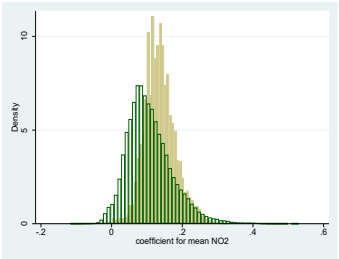

Discussion and Conclusions

Alternatively to our modelling choice, a Firebaugh multilevel model could have been specified. Fitting it on our data gave very unstable results on estimating variance components, multimodality of posterior distributions and correlation among model parameters which affect proper mixing in MCMC algorithm. A multinomial model, reparametrizing the bivariate response in a trinomial response could also have been considered. Fitting this model results in effect estimates which may partially explain the bimodality in the posterior distributions of the multilevel model. Different space-time interaction specification can be considered in the exposure model, but it was not the case in our data, which shows a very stable time pattern (see figure 1). The effect estimates are consistent with the literature. In conclusion we stress that accounting for prediction uncertainty provided a more accurate effect estimate. Short-term and long-term effects are difficult to jointly model and we present a robust approach which take advantage of aggregate data. This modelling can be connected with the literature on hybrid designs in environmental epidemiology (e.g. Smoot (2015)).

Statistical Modelling of Scientific Evidence for Forensic Investigation and Interpretation

DNA mixtures with related contributors

Misture di DNA con contributori correlati parentalmente

Peter J. Green and Julia Mortera

Abstract In both criminal cases and civil cases there is an increasing demand for the analysis of DNA mixtures where relatives are involved. The goal might be to identify the contributors to a mixture where the donors may or may not be related, or to determine the relationship between individuals based on a DNA mixture. Here we present examples that might occur in forensic casework, where we wish to determine which among a group of relatives involved in criminal activity left a mixed DNA trace at the crime scene.

Abstract *Sia nei processi penali che civili vi è una crescente domanda per l'analisi di misture di DNA in cui vi siano tra i potenziali contributori dei parenti. L'obiettivo potrebbe essere quello di identificare se i contributori alla mistura possono o meno essere correlati parentalmente, o di determinare la relazione di parentela tra individui sulla base di una mistura di DNA. In questo lavoro presentiamo due esempi che potrebbero verificarsi in casistica forense reale, dove si vuole determinare quali tra un gruppo di parenti coinvolti in attività criminali abbiano lasciato una traccia mista di DNA sulla scena del crimine.*

Key words: coancestry, deconvolution, disputed relationship, identity by descent, kinship, DNA mixtures, likelihood ratio

1 Introduction

DNA is now routinely used in criminal and civil investigations. DNA samples are of varying quality and therefore present complex problems for their interpretation.

The identification of the DNA composition of mixed samples gives rise to a wide range of challenging statistical questions, some associated with uncertainties and artefacts in the measurement processes and some associated with population genetic variations. In both criminal cases and civil cases based on relationship inference there is an increasing demand for the analysis of DNA mixtures where relatives are involved. The goal might be to identify the contributors to a mixture where the donors may or may not be related, or to determine the relationship between individuals based on a mixture. Here we use probabilistic genotyping methods for DNA mixtures, under hypotheses about the relationships among contributors to the mixture and to other individuals whose genotype is available.

The basis for any model-based DNA mixture analysis is a joint model for the peak heights $\mathbf{z}$ in the electropherogram and genotypes represented as allele counts $\mathbf{n}$ $p(\mathbf{n},\mathbf{z}|\psi) = p(\mathbf{n}) \times p(\mathbf{z}|\mathbf{n},\psi)$, having parameters $\psi = (\phi,\rho,\xi,\eta)$. Given a hypothesis on the DNA mixture contributors, the database allele frequencies, the parameters ψ, the DNA mixture model consists of two components: (a) the joint distribution $p(\mathbf{n})$ of the contributors' genotypes; (b) the conditional distribution $p(\mathbf{z}|\mathbf{n},\psi)$ of the peak heights as observed in the electropherogram, given the genotypes. We base the analysis of the DNA mixture on the model described in [1]. This model takes fully into account the peak heights and the possible artefacts, like stutter and dropout, that might occur in the DNA amplification process. We refer to the review on DNA mixtures by [8] for further details.

In the standard case, unknown contributors to the mixture are assumed drawn i.i.d. from the gene pool – multinomial sampling. When contributors are related, there is positive association between their genotypes. [6] extend the peak height model above to allow for inference about the relationships between contributors to a DNA mixture with unknown genotype and other individuals of known genotype: a simple example would be testing whether a contributor to a mixture is the father of a child of known genotype. The evidence for these relationships is presented as the likelihood ratio LR for a hypothesis H_p about the specified relationship versus the null hypothesis H_0, that there is no relationship, so the person of interest is taken to be a random member of the population.

Here we extend the analysis to different scenarios where:

(i) we have the genotypes of some of the actors, the others being contributors to a mixture;
(ii) we do not have the genotypes of the actors but they are contributors to one or more mixtures;
(iii) a combination of (i) and (ii).

In all cases were one unknown contributor to the mixture is higher up the relationship pedigree than the other contributor we need to test whether the major unknown contributor U_1 is a descendant or an ancestor of U_2 – the minor unknown contributor. Examples 1 and 2 in Section 2 illustrate scenarios of type (ii) and (iii), where we make inference about the two-way relationships between two mixture contributors with and without information on relatives' genotypes.

We also present an example where a group of relatives are involved in criminal activity. This case can occur when a family is engaged in a joint criminal activity and a DNA mixture might be found on, *e.g.* a getaway car, a balaclava, banknotes, a crowbar, a gun *etc.* that might have been handled by some members of the family.

Software used to analyse the examples is the new `KinMix R` package [4] that generalises the `DNAmixtures R` package [2] to allow for modelling DNA mixtures with related contributors.

2 Relationships among contributors

In both civil and criminal cases, we sometimes need to allow for dependence between genotypes of contributors. This possibility will obviously affect the evidential value of the mixture. We distinguish two cases: populations with high relatedness, due to inbreeding, and specific close relationships, *e.g.* father and son, or brothers engaged in a joint criminal activity. In both cases, the genotypes of two or more actors will be positively associated through identity by descent (IBD), the phenomenon that two genes may be identical because they are copies of the same ancestor gene, rather than being independent draws from the 'gene pool'. The phenomenon is the same in both cases, but they require different modelling approaches.

(a): Populations with high relatedness – ambient IBD

As observed in [5] the same probabilistic model for the joint distribution of multiple genes arises in a simple model for uncertainty in allele frequencies, in which the true allele frequencies are treated as unknowns with a Dirichlet distribution and the database used for calculation regarded as a multinomial sample from these true frequencies.

In discussion of [1], [3] observes that when genotypes are represented by allele counts arrays $(n_{ia})_{a=1}^{A}$, the number of alleles a of individual i, the conditional distributions over allele counts have Beta–Binomial conditional distributions:

$$n_{ia}|(n_{j.})_{j=1}^{i-1}, \{n_{ib}, b<a\} \sim \mathtt{BB}((2-n_{i,<a}),(q_a+n_{<i,a}),(q_{>a}+n_{<i,>a})),$$

where q_a are the database allele frequencies. The new `KinMix` software contains code to implement this model.

(b): Specific close relationships

Two non-inbred actors, can either share none, one or both of their genes IBD with probabilities $\kappa = (\kappa_0, \kappa_1, \kappa_2)$, $\sum_i \kappa_i = 1 \;\; i = 0, \cdots, 2$ determined by the pedigree [9]. Table 1 gives the values of κ for various pairwise relationships between non-inbred

individuals. For example, half-sibs have $(\kappa_0, \kappa_1, \kappa_2) = (0.5, 0.5, 0)$ and quadruple half-first cousins have $(\kappa_0, \kappa_1, \kappa_2) = (7/32, 7/16, 1/32)$. The IBD probabilities are used in the new `KinMix` to implement inference about DNA mixtures with related contributors. `KinMix` also handles situations where more than two contributors are related, and allows them to be inbred.

Example 1: Testing relationships among DNA mixture contributors

In this example, we test whether two contributors to a mixture U_1 and U_2 have a specific relationship, with respect to the hypothesis that all contributors are unrelated, *i.e.* H_p*: U_1 has relationship R to U_2 versus* H_0*: U_1 is unrelated to U_2*. Table 2 shows the results for a group of relationships $R = \{$parent-child; half-sibs; cousins; quadruple-half-cousins$\}$.

We first simulate several DNA mixtures using `pcrsim` [7], which simulates the DNA amplification process. Each DNA mixture is simulated from the pedigrees in R where the two actors have a specified "true" relationship. Table 2 gives the $\log_{10}$LR for testing H_p *versus* H_0.

Table 1 Values of κ for various relationships between two non-inbred individuals.

Pairwise relationships	κ_0	κ_1	κ_2
unrelated	1	0	0
parent-child	0	1	0
sibs	0.25	0.5	0.25
quadruple-half-cousins	0.5312	0.4375	0.0312
half-sibs	0.5	0.5	0
cousins	0.75	0.25	0

Table 2 Median $\log_{10}$LR over 4 replicates for H_p: U_1 and U_2 have relationship R versus H_0: U_1 and U_2 are unrelated.

	"True" relationship				
Relationship of U_1 to U_2 under H_p	parent-child	sibs	half-sibs	cousins	quadruple half-cousins
parent-child	3.76	2.01	-Inf	-60.56	-79.93
sibs	2.16	6.50	3.05	-2.33	0.37
half-sibs	2.54	3.65	1.91	-0.54	0.44
cousins	1.60	2.69	1.28	-0.12	0.44
quadruple-half-cousins	2.31	4.38	2.12	-0.57	0.62

The highest median $\log_{10}$LR's are attained along the diagonal for close relationships, like parent-child, $\log_{10}\text{LR} = 3.76$ and sibs $\log_{10}\text{LR} = 6.5$, showing that these are correctly identified. However, more distant relationships among contributors to a mixture are harder to distinguish. When there is additional information, like the

genotypes of some individuals potentially related to mixture contributors the evidence becomes much stronger, as we will see in Example 2.

Example 2: Family involved in a joint criminal activity

This case concerns a family with 6 male children (some having a different mother) hypothesised as being engaged in a joint criminal activity. A two-person DNA mixture was found on the door handle of a getaway car abandoned after a crime. DNA samples were taken from two brothers B1 and B2, the other 4 children having escaped the country. A first analysis excluded that B1 or B2 were contributors to the mixture. The question then was to test which if any of the escaped brothers or half brothers were contributors to the incriminating mixture. Table 3 gives the $\log_{10}$LR for various different hypotheses, such as, H_p: the major contributor U_1 is the brother (half-brother) of B1 and B2 (or of B1, or B2 alone) against a defence hypothesis H_0: B1 and/or B2 are unrelated to U_1. Similarly for the second contributor U_2.

The results in Table 3 show that it is likely that the major contributor U_1 to the mixture was the brother of B1 and the half-brother of B2. The $\log_{10}$LR for testing this was 9.86, whereas it seems plausible that the second contributor to the mixture is the brother of B2.

Table 3 The $\log_{10}$LR for testing different hypotheses H_p on the potential relationship between the contributors to a two-person DNA mixture and the typed individuals B1 and B2 versus H_0 the null hypotheses of no relationship.

	$\log_{10}$LR for H_p vs. H_0	
Relationship in H_p	U_1	U_2
brother of both B1 and B2	7.65	10.64
brother of B1	6.86	2.73
brother of B2	1.71	8.77
half-brother both B1 and B2	6.02	7.33
half-brother of B1	1.10	2.22
half-brother of B2	5.37	5.38
brother of B1 and half brother of B2	9.86	–

3 Conclusions

We have shown a wide range of relationship inference problems, where one or more actors appear as contributors to a DNA mixture, can be handled coherently. We handle relationships among contributors, and between contributors and typed individuals. This approach provides a toolkit for new problems of this kind that can arise in forensic casework.

Forensic Statistics: How to estimate life expectancy after injury

Statistiche forensi: come stimare l'aspettativa di vita dopo un infortunio

Jane L Hutton

Abstract People who are injured in a traffic, industrial or medical accident, or contract a disease or cancer through negligence of an employer, doctor or local authority, can bring a civil case for compensation. Approaches to establishing causation differ between medical and legal professionals. If responsibility is assigned, the value of compensation will often depend on how long the person is expected to live. In the UK, for common injuries, there are life tables known as the Ogden Tables. For some particular injuries, such as spinal cord or brain injuries, an expert witness might be instructed to provide individual report. Such a report might also take into account other factors, such as alcohol consumption or medical history of diabetes or depression. I will compare the approaches used by actuaries, statisticians and medical doctors to estimating an individual person's life expectancy. The underlying assumptions of independence of different factors, or additive or multiplicative modifiers of mortality rates differ substantially.

Abstract *Le persone che sono vittime di incidenti stradali, industriali o di errori medici, o che contraggono una malattia o un cancro per negligenza del datore di lavoro, di un medico o di un'autorità locale, possono intentare una causa civile al fine di ottenere un risarcimento. Gli approcci utilizzati per stabilire il possibile nesso causale differiscono tra professionisti operanti in campo medico o giuridico. Nel caso di attribuzione di responsabilità, l'ammontare del risarcimento è spesso legato all'aspettativa di vita della persona coinvolta. Nel Regno Unito, per gli infortuni più comuni, si fa ricorso a delle tavole di mortalità note con il nome di 'Ogden Tables'. Per lesioni di una certa gravità, ad esempio lesioni del midollo spinale o lesioni cerebrali, un esperto potrebbe essere incaricato di redigere una perizia individuale. Quest'ultima potrebbe tenere conto di diversi fattori, incluso il consumo di alcol, o di altri elementi caratterizzanti la storia clinica della persona, ad esempio patologie quali il diabete o la depressione. In questo lavoro, verranno messi a confronto i diversi approcci utilizzati da attuari, statistici e medici per stimare l'aspettativa di vita di una persona. Ne emergerà una differenza sostanziale, in merito sia alle*

ipotesi di indipendenza tra i diversi fattori, che di effetti additivi o moltiplicativi in termini di tassi di mortalità.

Key words: Compensation, injury, life expectancy, methods of estimation

1 Introduction

Accidents are part of life. A road traffic accident might leave a young woman tetraplegic, unable to use her limbs, but still able to learn and pass examinations. An industrial accident might result in a man losing several fingers. A mismanaged birth might leave a baby with cerebral palsy. A factory might expose workers to dangerous chemicals, which increase the risks of cancer. In such cases, if some person or company can be shown to be responsible, the injured person might be given financial compensation. The differences between professions in methods for establishing causation is not considered here (Hutton, 2018). In some countries and situations, compensation is almost automatic. In others, a civil case for damages will be lodged with a court. If adequate care is estimated to cost £100,000 in 2020, and the claimant is expected to live for 10 years, a total sum of £1 million is implied. Of course, this should be adjusted to take into account assumptions about the investment of the lump sum and inflation for the next 10 years.

This article considers how life expectancy is estimated. The two main challenges are finding reliable data or estimates of mortality risks (Hutton, 2018; Pharoah and Hutton, 2006), and deciding on a sensible method of estimation. General population estimates are considered, then smaller datasets which focus on particular populations. Medical doctors methods of estimation are considered before those used by statisticians.

2 Population life tables

In countries with adequate vital statistics registration, population life tables are estimated from age-specific death rates calculated from records of deaths and estimates of the numbers alive derived from censuses. There are some difficulties to address, such as the accuracy of population numbers between censuses and delays in death registration. However, population life tables are standard demographic resources.

National Statistics Offices publish period life tables and cohort life tables. The estimates which determine the tables are the observed central mortality rates at age x, $\hat{m}_x$, given by y_x/N_x, where y_x is the number of deaths of people aged x last birthday, and N_x is the number aged $[x, x+1)$ at the midpoint $x+0.5$. Period life tables use the current age-specific death rates with no changes for the future, so the observed mortality rate of 4.7/1000 per year for a 59 year old woman in 2013-15 would be used for a life expectancy estimate for woman aged 59 in 2020. Cohort life tables

use predictions of death rates. Using a simple 0.5% decrease per year, the mortality rate of 4.7/1000 in 2014 for a woman age 59 decreases by $1.005^6 = 1.0303$ to $4.0/1000$ in 2020. The older a person is, the more observed mortality rates rather than projected rates are used in the calculation of life expectancy.

In the UK, the size of lump sum compensation awarded in personal injury and fatal accident cases is usually informed by particular life tables, the Ogden tables (Government Actuary's Department, 2011). A prescribed discount rate is set by the government. The Ogden tables give multipliers for annual costs by adjusting 2008 cohort life expectancies for different rates of return. The UK has recently revised the methods used to project mortality rates (Dodd et al, 2018).

3 Medical doctor's life expectancy estimates

Lawyers for a claimant who lost several fingers might be content with general population tables, but those acting for parents of a child with severe disabilities due to cerebral palsy will usually seek an expert opinion on life expectancy. In the past, such opinions were sought from medical doctors. However, medical doctors generally lack the relevant statistical and epidemiological knowledge, and do not have resources to follow-up patients to death (Pharoah and Hutton, 2006). A pediatrician is asked to give a life expectancy estimate for a child will not know about adult life. I was called by lawyers already in court in Dublin because a pediatrician's report assumed that a ten year old boy was more likely than not to live to age 15. She then used a research article (Brooks et al, 2014, Table III) which gave estimated additional year life expectancy at age 15 of 18 to argue that the boy would live to age 30 'on balance of probability'. She therefore assumed he would be alive at age 30, again used life expectancy of 19, and gave her final estimate of expected age at death life expectancy of 59, 14 years from age 45 years. The judge had no difficulty in understanding that being likely to live to age 30 'on balance of probability' is not the same as certainty, and that the probability of death before age 30 must be taken into account in the estimate.

A rehabilitation specialist provided many expert witness reports on life expectancy for people who had had serious brain or spinal cord injuries. His approach was to review some of the research literature, and then decide how many years to substract from general population life expectancy for various factors. For an older person, such as a 70 year old man in 2000 with a life expectancy of 13.9 years, there was a possibility that subtracting some years for several factors would mean zero or negative life expectancy. This approach was described as a "top-down" approach. After a judge expressed his disapproval, the specialist changed his approach to deciding on a percentage of remaining life expectancy based on one or two research articles.

Another physician uses a method referred to as the "Rating of Substandard Lives", a widely accepted methodology for the assessment of life expectancy amongst medical insurance companies (Kita, 2006). He also selects factors which

might affect life expectancy, references some research articles and then chooses a mortality risk, such as 200% for smoking, 150% for obesity or 400% for brain injury. These risks are *added* together, and a look-up table used (Bowen-Jones et al, 2014). The natural method of combining percentages is multiplication, not addition. The incoherence of adding or subtracting mortality risks as a method can be seen by considering the effect of subtracting from a baseline mortality 100%, factors for being a non-smoker, say 40%, and for being fit with no family history of disease, say 60%. This gives 100% - 40% - 60% = 0%, so the person is immortal.

No indication is given of how interdependence of risk factors is assessed, or how such dependence should be used to reduce mortality rates. If rates for, say, obesity and diabetes and cholesterol are all included, then there will be double-counting, as increased mortality associated with obesity includes deaths from diabetes and cholesterol related causes.

In a 2018 joint report from medical doctors, estimates are given as feelings: "Dr X feels that there is a reasonable range of 7-12 years of further life expectaiton. Professor Y feels that Mrs A is likely to live around another 19 years (say a range of 18-20 years)."

4 Statistical approaches to individual life expectancy estimates

I use data from a geographically-based cohort of about people with cerebral palsy for estimates (Hutton and Pharoah, 2002). For the most severely affected children, it is possible to estimate the median survival using Kaplan-Meier estimates conditional on the severity of the person's impairments, and his current age. Lawyers often like large data sets, so assume that data on 12,709 clients of the California Department of Developmental Services labelled as having cerebral palsy (Strauss et al, 1998) must be more relevant than smaller data sets. However, the definition of cerebral palsy used to include people was incoherent. The distribution of impairments differed from geographical cohorts, as more severely impaired individuals are more likely to be clients of the state (Hutton et al, 2000). Even if there is a large, high quality patient cohort, it is unlikely that all deaths have been observed. Such cohorts will include people born, or injured, in past decades, we cannot assume there are no secular improvements in mortality rates. In general, there is limited access to good quality data on specific patient groups. Further, life expectancy before injury might need to allow for factors such as obesity or smoking.

An approach which does not modify the age-specific mortality rates, $\hat{m}_x$, is to "rate up," which means assuming that the effect of a medical condition is to increase a person's effective age by, say, 10 years, so that the population life expectancy at 70 years might be used to estimate the life expectancy of a 60 year old heavy smoker. Estimated death rates or relative risks inform the up-rated age.

Common statistical approaches begin with estimates of absolute mortality rates, or excess mortality rates or relative risks, either directly from available datasets, or from published research. These estimates are used to adjust the mortality rates

given in National Statistics Office life tables, and the adjusted mortality rates used to create a customised individual life tables. The choice between period and cohort life tables as baseline is debated. A Californian group claims that there have been no improvements in survival of people with spinal cord injury (Shavelle et al, 2015), therefore period life tables should be used to estimate compensation. The UK courts usually require the use of cohort life tables.

Let $\hat{d}$ be an estimated death rate, and $\hat{r}$ an estimated relative risk of death. The difference between two death rates is an excess death rate. If $\hat{d}$ is large, say $> 1\%$, the excess death rate will be close to the estimated death rate. Age-specific mortality rates, $\hat{m}_x$, can be modified by adding an excess death rate, and using $\hat{m}_x + \hat{d}$ to derived a new life table. Assuming a constant excess death rate, the risk of death *relative* to the general population rate will decrease towards one as age increases, as the general population death rate increases. Alternatively, the mortality rates can be multiplied by a relative risk, so that $\hat{m}_x \times \hat{r}$ determines the customised life table. There is debate as to whether either of these assumptions is appropriate, with Shavelle et al (2015) asserting that a constant relative risk is correct. However, observed relative risks tend to decrease with age (Middleton et al, 2012). Other proposals include log-linear declining relative risk, which requires a choice of age at which to apply the relative risk, and the age at which the log relative risk should reach zero (Strauss et al, 2005). A smooth function of relative risk which tends to an asymptote at unity might be more sensible. A further suggestion is to have proportional life expectancy constant: men might be assumed to have life expectancy 95% of women at all ages.

Medical statisticians have developed guidelines to assist in reporting research which aims to provide reliable predictions for individuals (Collins et al, 2015; Moons et al, 2015). Moons et al (2015) document different types of prediction model studies, and performance measures. An important distinction is made, between apparent performance of a model which is only validated on the data used to define the model, and the performance of that model in future use.

Within forensic practice, there are no common statistical approaches to deciding between different methods of predicting life expectancy for individual people. Shavelle et al (2015) used absolute errors, in years and percentages, for predictions at age 30 only, averaged across general and four patient populations to conclude that log-linear declining relative risk is the best approach.

5 Conclusion

The open issues for estimation of life expectancy to inform legal decisions are sources of reliable estimates of absolute and relative mortality rates, exploring methods for projecting life expectancy and determining which criteria to use to decide which methods are optimal.

The additional contribution of combining genetic evidence from multiple samples in a complex case[1]

Il contributo supplementare fornito dalla ridondanza di analisi genetiche da più campioni in un caso complesso

Giampietro Lago[2]

Abstract In an Italian well known case, indicated by the media as "Yara murder", supplementary information was obtained from mixed DNA profiles thanks to the application of statistical models. The analysis is based on an interpretation model for DNA mixtures that takes into account the heights of the peaks and possible artifacts, such as stutters or dropouts that could occur in the DNA amplification process. The proposed interpretation model illustrates how to compose tests of multiple samples and different marker systems. The combined evidence is used for deconvolution, where the focus is to find likely profiles for the donors to the sample. Furthermore, a mixture can be used to establish familial relationships between a reference profile and a donor to the mixed DNA sample. Results based on a single mixed DNA profile can be compared with combination of replicates, combinations of different samples and combinations of different kits.
The purpose of this contribution is to highlight, also in the context of judicial police investigations and that of a criminal trial such as the combination of different redundant data sets (different samples, different kits) works in itself an added value that provides to produce novel information unknowingly overlooked by investigators, investigators, prosecutors, lawyers and judges.
Abstract *In un caso italiano molto noto, indicato dai media come "omicidio di Yara", dai profili di DNA misti si sono potute ottenere informazioni suppletive grazie all'applicazione di modelli statistici. L'analisi si basa su un modello di interpretazione per misture di DNA che tiene conto delle altezze dei picchi e dei possibili artefatti, come gli stutter o il dropout che potrebbero verificarsi nel processo di amplificazione del DNA. Il modello di interpretazione proposto illustra come comporre prove di più campioni e di diversi sistemi di marcatori. La*

[1] This contribution is largely extracted from the paper The Yara Gambirasio case: Combining evidence in a complex DNA mixture case (2019) by T. Graversen, J. Mortera, G. Lago, Forensic Sci. Int. Genetics *40* 53-63).

[2] Giampietro Lago is forensic biologist, colonel of the Carabinieri Armed Force and commander of RIS Parma, the forensic department located in Parma for northern Italiy of the Raggruppamento Carabinieri Investigazioni Scientifiche.

combinazione dell'evidenza viene utilizzata per il miglioramento del processo di deconvoluzione in cui l'obiettivo è quello di trovare probabili profili per i contributori della traccia mista. Inoltre, una mistura può essere utilizzata per stabilire relazioni familiari tra un profilo di riferimento e un contributore al campione di DNA misto. La comparazione degli esiti basati sullo studio di un singolo profilo di DNA misto e su quello della concorrenza di replicati, di diversi campioni e diversi kit mostra l'efficacia del modello.
Lo scopo di questo contributo è quello di evidenziare, anche nell'ambito delle investigazioni giudiziarie e nei processi come la combinazione stessa di diversi set di dati ridondanti (diversi campioni, diversi kit) costituisce in sé un valore aggiunto che consente di produrre informazioni nuove altrimenti inconsapevolmente tralasciate dagli investigatori, pubblici ministeri, avvocati e giudici.

Key words: Combining evidence, DNA mixtures, forensic statistics, kinship, likelihood ratio, mixture deconvolution, probabilistic genotyping.

1 Introduction

The genetic data production on casework can support different purposes. These goals are generally obvious but in some cases, with the support of advanced statistical tools, the analysis of the data produce innovative information generally not considered by forensic geneticists and in criminal trials.
How statistical models can help extract information from mixed DNA profiles? (i) One common use of statistical models for mixtures focuses on computing a likelihood ratio that quantifies the evidence for the presence of DNA from a specific person of interest. (ii) A second use is for deconvolution. (iii) A third aspect is the possibility of studying a mixture to establish familial relationships between a reference profile and a donor to the sample.
All DNA analysis for forensic purposes can be based on different combinations of evidence. The simplest analyses are based on a single mixed DNA profile or possibly on a set of replicates thereof.
In this paper we focus on an unusual, more complex approach. We may wish to use a combination of mixed DNA profiles taken from different samples, or profiles that are typed using different kits.

1.1 The case

On Friday 26 November 2010 at 17:15 13-year-old Yara Gambirasio left home in Brembate di Sopra, a small town near Milan, Italy, to go to the gym. An hour and a half later she left the gym never to return home. Three months later her body was found in an abandoned field in an industrial area about 10 km away. She had suffered multiple injuries from a sharp weapon, which had pierced her clothing at various points. It seemed that she had been attacked and abandoned. She had died slowly from hemorrhage and hypothermia.
The DNA from the genetic material that was taken from the victim's clothes was analysed. The DNA extracted from the front and the waistband of her underpants showed the presence of male DNA. The analysis of these DNA profiles that we will show here, lead to the profile of an unknown contributor, referred to by the media as Ignoto 1 (U1[3]). It was assumed that this profile was from the murderer, who had left his DNA on the girl's underpants.

[3] U1: Unknown man #1

The profile of 'Ignoto 1' was compared to many thousands of individuals who were either local or known to have been in the area around the time of Yara's disapperance. Comparisons were previously also made with different criminal databases but had not given any leads.
Familial search showed that two brothers, who were visitors to a nearby nightclub and unrelated to the crime, shared many alleles with 'Ignoto 1' and could therefore potentially be related to the murderer. A DNA sample from their mother revealed that she shared no alleles with Ignoto 1. The brothers' father, GG, was a bus driver who had died in 1999, eleven years before the crime. A DNA profile was at first retrieved from a stamp he had licked, and in March 2013 DNA was extracted from his exhumed body. The resulting profile identified him as overwhelmingly likely to be the father of U1.
However, it was apparently totally unknown to anyone that GG had any other children, so it was hypothesized that GG had an illegitimate child. The investigators then decided to screen women who potentially could have borne him a child decades earlier. By combing through the population registers of the time they found a woman, EA. Before moving in other town she had, in fact, lived in the same village as GG and an analysis of EA's DNA showed that she was very likely to be the mother of Ignoto 1. Thus EA's son, MGB, became the chief suspect.
MGB was sentenced to life imprisonment on 1 July 2016 for the murder. On 18 July 2017 the appeal court upheld the life sentence. On 12 October 2018 the "Corte di Cassazione", the Italian Supreme Court, confirmed the sentence to life imprisonment.

1.2 Crime scene profiles

A thorough analysis of Yara's clothes revealed the presence of male biological material in an area on her underpants (exhibit #31). This area was further inspected through 24 virtual grid cells (G1 to G24). Each grid cell was split into two parts.
Serological analyses were made on one part of the grid cell, in order to determine the biological nature of the male contribution (e.g. blood, saliva, or sperm). The other part of each grid cell was used for DNA profiling with at least three different kits among NGM, Identifiler, PowerPlex ESI16, and PowerPlex ESX16. Some grid cells, e.g. G20, were also analysed with Argus X, Y-Filer, and PowerPlex 16 in order to obtain information about the X- and Y-chromosomes and the two Penta loci.
The forensic lab analyzed the following pieces of evidence pertaining to Yara's underpants, but emphasize that many more pieces of evidence played a part in resolving the case: (i) an NGM profile from each of the grid cells G13-G16 and G20; (ii) an ESX16 profile from grid cell G14; (iii) replicates (R1 and R2) of an Identifiler profile obtained from grid cell G20.
Genetic outputs show all the observed peaks above 150RFU. Some loci, e.g. D18 for sample G13, exhibit complete dropout at this level of detection (an excerpt of the profiles can be seen in Graversen et al. 2019).

2. Combining evidence from multiple samples or different marker systems

As detailed above there are multiple crime scene profiles available in the Yara case. These are either replicates or originate from different samples. Furthermore, the samples were also typed with different kits.

There are many reasons for combining evidence, one important being that it strengthens the information about the profiles of any shared contributors. The model presented and discussed by Graversen et al. (2019) readily allows a combined analysis of multiple crime scene profiles.
Combining the information in multiple profiles requires a slightly more complex analysis than that of single profiles, since it is necessary to make assumptions about which – if any – contributors may be in common. When combining replicates it is natural to make an assumption that contributors are the same, however when combining profiles from different samples one needs to carefully consider whether there is perhaps only a partial overlap. However, once a hypothesis describing the contributors is formulated, the mathematical details in extending a peak height model from one to multiple crime scene profiles are completely straightforward.
Imagine a pool of k persons, who are all (proposed) contributors to one or more of the profiles under analysis. The model then describes the DNA profiles of the set of k persons and the associated peak heights across the set of profiles. Each profile (EPG[4]) has an individual set of model parameters that determines the variability of the peaks that we may observe just for this profile.
We assume that, conditionally on the DNA profiles of the entire pool of contributors (and the model parameters), the peak heights in one EPG are independent of the peak heights in the other EPGs. The variability of the peak heights for each profile is then described by the gamma distribution as described in Cowell et al. (2015).
A pictorial representation of the combination of peak height information from four crime scene profiles can be seen in Fig.1. Ignoring the node R, the figure depicts how the peak-height information is conditionally independent across the four EPGs given the full DNA profiles of all the contributors to the mixture. Here the set of contributors is assumed to consist of the victim and two unknown contributors, U1 and U2.

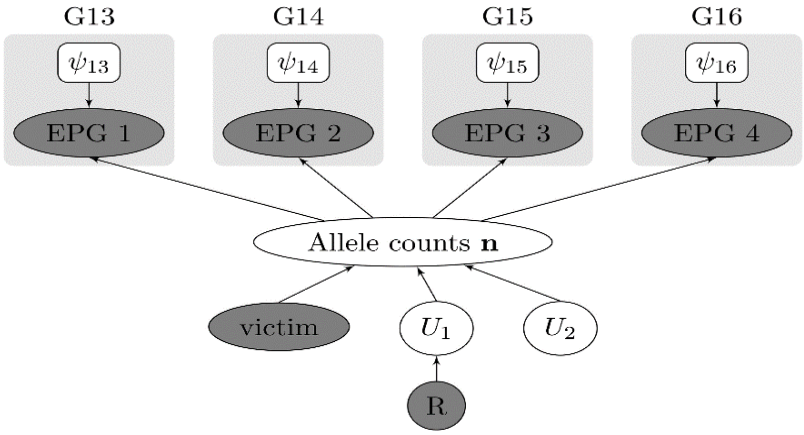

Fig. 1. Pictorial DAG representation of the combination of different types of evidence: four crime scene profiles (EPG 1–4) for samples G13-16 as well as the reference profiles of the victim and a putative parent of U1. The hypothesis under investigation here assumes a total of at most three contributors to the four samples. Each EPG has its own set of model parameters.

[4] EPG: ElectoPheroGram

3 Discussion

Model checking methods suggest that the model captures well the pattern of peaks for each profile, as described by the set of alleles observed in the profile. The set of model checking methods applied here to the statistical model in DNAmixtures (Graversen, 2015). Two model checking examples for samples G13-G16 of the Yara case are shown in Figs 2 and 3. The two figures each address different aspects of the modelling and jointly enable a thorough assessment of the joint analysis. From the probability plot in Fig.2, we see that the model adequately captures the overall variability of peak heights above the detection threshold of 150RFU. When the model fits well, the points should resemble the diagonal line as they do here. Fig.3 shows a prequential monitor plot (Seillier-Moiseiwitsch & Dawid, 1993), which assesses the ability of the model to predict whether or not a peak is observed at the next allelic position in the EPG. When the model fits well, the monitor should stay below the two upper prediction limits. We see that the model captures these aspects of the data very well.

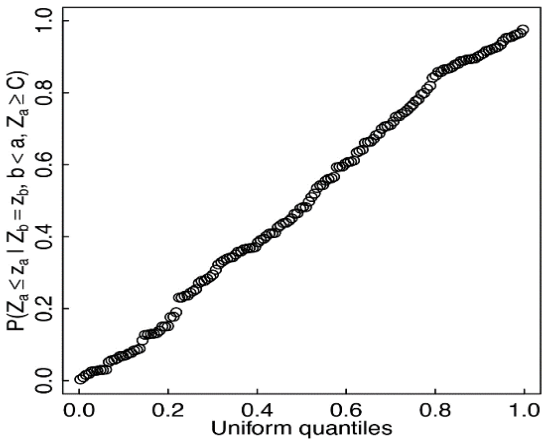

Fig. 2 Probability plot assessing the variability of peak heights for all peaks above the detection threshold of 150RFU. When the model fits well, the points should follow the diagonal as they do here.

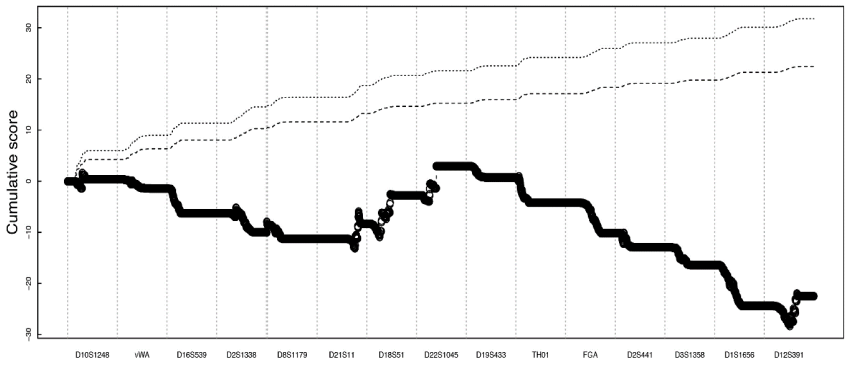

Fig.3 Prequential monitor plot confirming that the model is able to predict at which allelic positions a peak is observed. When the model fits well, the monitor should stay below the two upper prediction limits (dashed 95%, dotted 99%)

4 Final remarks

The author is not a statistician and the description and discussion of the interpretation model of the data presented is not an objective of this paper. The aim of this contribution is to highlight, also from the point of view of casework applications, how it is possible and of great interest to extract coherent and different information from a dataset of EPG profiles. The replication of analyses on a given area is a typical approach, used by forensic biologists point of view, on exhibits of particular complexity such as that described in the present paper. The reasons for this choice are substantially technical and of two types: (i) the search for the best possible outcome and (ii) the confirmation of the robustness of the outcome itself.
A novel lesson from this approach is useful for a forensic biologist. The redundancy of complex and heterogeneous results is not only a generic confirmation of the technical robustness of the same but is, in itself, a source of additional coherent information.
The redundancy of certain outcomes can therefore be translated into further scientific proof at the criminal trial. This is the challenge for the near future in which forensic biologists and statisticians will face in finding a common language capable of respecting the rigor of scientific methodology and the need for its entry into court.

The history of forensic inference and statistics: a thematic perspective

La storia dell'inferenza e della statistica in campo forense: una prospettiva tematica

Franco Taroni and Colin Aitken

Abstract In the last two decades, publications in judicial and scientific literature reveal that the trend among researchers in forensic science is to adopt a Bayesian approach to the evaluation of trace evidence, such as glass, fibres, fingerprints and biological evidence. In many areas of forensic science, however, such as those involving tool marks, shoe marks, gunshot residues and document examination, the Bayesian approach remains ignored or untrusted.
The presentation argues that it is time for Bayesian methods of evaluating evidence to be generalized. Such a broad use of the Bayesian perspective not only follows from the recent achievement of statistical arguments in forensic science, but also from the history of its earlier and effective use, at the turn of the nineteenth and twentieth centuries, in a great variety of cases and contexts. The historical development of forensic inference and statistics is presented through fifteen themes that are identified as important in the development of the ideas for reasoning in forensic science.

Abstract
Negli ultimi due decenni, pubblicazioni in riviste giuridiche e scientifiche rivelano che la tendenza tra i ricercatori in scienze forensi è quella di adottare un approccio bayesiano per la valutazione di 'prove' scientifiche, quali frammenti di vetro, fibre tessili, tracce digitali e materiali biologici. In molte aree della scienza forense, tuttavia, come quelle relative a residui di polvere da sparo ed esami di documenti, l'approccio bayesiano rimane ignorato o considerato come non applicabile.

Franco Taroni, School of Criminal Justice, The University of Lausanne, Switzerland; Franco.Taroni@unil.ch

Colin Aitken, School of Mathematics and the Maxwell Institute, The University of Edinburgh, United Kingdom; C.Aitken@ed.ac.uk

Lo scopo della presentazione è di sottolineare la necessità di estendere l'applicazione dell'approccio bayesiano alla valutazione di tutte le prove scientifiche.
Un più vasto ricorso alla prospettiva bayesiana è suffragato non solo dal recente sviluppo di argomenti statistici nella scienza forense, ma anche dalla storia che mette in evidenza il suo uso efficace, a cavallo tra il XIX e il XX secolo, in una grande varietà di casi e processi. Lo sviluppo storico dell'inferenza e della statistica forense è presentato attraverso quindici temi chiave nello sviluppo delle idee per il ragionamento nelle scienze forensi.

Key words: forensic science, forensic statistics, evidence evaluation, Bayesian framework

1 The choice of relevant themes describing the historical development of the area

The historical development of forensic inference and statistics is presented through fifteen important themes. The themes are identified as important in the development of the ideas for probabilistic and statistical reasoning in forensic science and have been chosen as the ones that created, and in some cases are still creating, important debates. The choice of themes is a personal choice of the authors and some readers may not agree. This form of presentation aims to clarify thinking around past and current problems in forensic statistics and suggests ways in which the subject may develop further.
It is only the role of statistics in the evaluation of evidence in criminal cases that is discussed.

The first theme is the recognition in the early 20th century of the need for the evaluation of scientific findings in the administration of criminal justice through the use of probability as a measure of uncertainty. Early examples are those of Bertillon (1893, 1898) and Locard (1920).

The next two themes (2 and 3) concern ideas for the integration of scientific information with other relevant information from a particular criminal case and the increasing support of judicial disciplines for the scientific presentation of evidence. From a theoretical point of view, we can refer back to 1897 when Mr Justice Holmes, then of the Supreme Judicial Court of Massachusetts and latterly of the Supreme Court of the United States (Holmes, 1897) wrote:

> For the rational study of the law the black-letter man may be the man of the present, but the man of the future is the man of statistics and the master of economics. (at p. 469)

From a practical point of view, with reference to the Dreyfus' military trial held in 1908, Henri Poincaré and others invoked the use of Bayes' Theorem as the only way in which the court ought to revise its opinion about the issue of forgery (Darboux et al., 1908).

These ideas led to recognition of the importance of the separation of the evidence from the propositions of prosecution and defence and the correct conditioning of one on the other depending on the role of the person making the judgement (theme 4). Such separation should help avoid confusion (as presented by Thompson and Schumann, 1987) between, on one side, a small probability of finding the evidence on a person who is innocent of a crime and, on the other side, a small probability that a person on whom the evidence is found is innocent of the crime.

Various attempts to quantify the value of the evidence before the general acceptance of the likelihood ratio as the best way to do this are described in theme 5, followed by a description of the discrediting of the idea of a match (theme 6). Procedures for the evaluation of evidence in forensic science were changed dramatically by a paper by Dennis Lindley in 1977 (Lindley, 1977) emphasizing the change from a so-called 'two-stage approach' to a continuous approach.

The advent of DNA profiling in the mid-1980's led to consideration of many new factors in the evaluation of evidence which are outlined in theme 7, for example, how to assess the value (a) for a result after a database selection, (b) by taking errors into account, and (c) by conditioning on a suspect's profile in a particular population.
One factor in particular, that of the possibility of extremely small probabilities for a DNA profile and correspondingly large values of the likelihood ratio, merits a theme on its own (8). The factor relates to the acceptance as accurate and reliable experts' testimony that quote astronomical figures such as 1 in ten billion or trillion (Kaye, 1993).

The concept of propositions was developed further in the late 1990's with the introduction of differing levels of propositions (theme 9), a so-called 'hierarchy of propositions' in a project called 'Case Assessment and Interpretation' (Cook et al., 1998).
The general use of the likelihood ratio and the difficulty jurists had with its interpretation led to attempts to summarise its numerical value verbally (theme 10). The translation of a numerical value into a verbal equivalent dated back to Jeffreys (1983) (first edition in 1939) and is still under discussion (Berger and Stoel, 2018).

Though the role of the likelihood ratio was generally accepted by forensic scientists in part of Europe, there could be several different values in a particular case arising

from the use of different assumptions and statistical models. Recognition of these differences led to consideration of methods for the assessment of the performance of different models (theme 11). Measures of performance are generic. They are applied to the general performance of the model with measures obtained from datasets where the correct answer is known. Earlier works dated back to the use of scoring rule used for evaluation of evidence (Good, 1950).

The role for the forensic scientist in the investigation of a crime (the investigative role) before they are asked to evaluate evidence in a trial (the evaluative role) was recognised in a separate development in the 1990's, a role that is described as theme 12.

Statistical research in the late 20th century led to probabilistic graphical networks for complicated problems of inference. These networks had an intuitively satisfying application in forensic science, in particular for the management of many different pieces of evidence, and this application is described in theme 13. The use of Bayesian networks to manage information dates back to Aitken and Gammerman (1989) with the charting method developed by Wigmore (1913) as a predecessor of this modern network approach to inference and decision analyses.
Ultimately a decision has to be reached by the jurist (jury or judge) concerning the outcome of a criminal trial. Scientists also have decisions to make, earlier in the process, for example concerning sample size or choice of analysis. The role of decision theory for the scientific process is described in theme 14; a description that is heavily inspired by the seminal chapter written by Kaye (1988).

Finally, the early years of the 21st century have seen the questioning of the presentation of a single value for evidential value with the likelihood ratio. The alternative suggestion is that the single value of the likelihood ratio should be replaced by an interval for, or a lower bound on, its value. A comment on this debate is given in the final theme 15. The debate is still continuing; some quarters are thinking about the existence, or otherwise, of a true value of the evidence.

Topological learning: interpretable representations of complex data

Comparing Neural Networks via Generalized Persistence

Persistenza generalizzata per la comparazione di reti neurali

Mattia G. Bergomi, Pietro Vertechi

Abstract Artificial neural networks are often used as black boxes to solve supervised tasks. At each layer, the network updates its representation of the dataset in order to minimize a given error function, which depends on the correct assignment of predetermined labels to each observed data point. On the other end of the spectrum, topological persistence is commonly used to compare hand-crafted low-dimensional data representations. Here, we provide an application of *rank-based persistence*, a generalized persistence framework that allows us to characterize the data representation generated by each layer of an artificial neural network, and compare different neural architectures.

Abstract *Le reti neurali artificiali sono spesso usate come scatole nere per risolvere task supervisionati. Durante il training la rete aggiorna la rappresentazione del dataset ad ogni layer, in modo da minimizzare una certa funzione errore che dipende dall'assegnamento di etichette predeterminate ad ogni sample analizzato. In maniera antipodale, la persistenza omologica è usata per comparare rapidamente dati, in base a caratteristiche specificate dall'utente. Proponiamo di utilizzare* rank-based persistence*, una generalizzazione della teoria della persistenza topologica, per caratterizzare la rappresentazione dei dati ottenuta ad ogni livello di una rete neurale e comparare architetture neurali differenti.*

Key words: Generalized persistence, rank-based persistence, interpretable neural networks.

1 Introduction

Topological persistence allows for swift quantitative comparison of topological spaces [1]. However, often data are not organized as, or easily mappable to such spaces. In [2], we generalize persistence to work with a broader set of categories and functors than topological spaces and homology.

Here, we exemplify one of the use cases discussed in [2], where persistent homology is used to characterize labeled point clouds, by working on the category of metric spaces and the poset induced by the inclusion on non-empty subsets of the label set. We focus on point clouds generated by each layer of an artificial neural network when solving a supervised classification task. We use the generalized persistence framework for both the evaluation of the layer-wise representation of different subsets of labels and to compare neural architectures.

In section 2, we give an intuition about the classical and generalized persistence frameworks. Section 3 shows how data represented at each layer of a feed-forward neural network can be summarized via *multicolored persistence diagrams*. Afterwards, two neural architectures are compared by computing the *multicolored bottleneck distance* between their diagrams.

2 From classical to generalized persistence

Classical persistent homology is based on three main ingredients: 1. A filtered topological space; 2. the homology functor H_k mapping topological spaces to finite vector spaces; 3. a notion of *rank*, such as the dimension of the vector space, or the cardinality in the category of sets [3]. See fig. 1 for an example and an intuitive introduction to persistent homology, and [4] for details.

In [2], we introduce a framework that extends classical persistence to new categories, functors and rank-like functions. We will not discuss the technical details of rank-based persistence here. See [2, Table 1] for an intuitive summary.

The main theoretical tool used in the following applications is what we called *multicolored persistence*. Multicolored persistence allows one to use persistence in semisimple categories (which can have more than one non-isomorphic indecomposable object), by preserving the fundamental properties of persistent homology: flexibility (dependence on the filtering function), stability [5], and resistance to occlusions [6]. In [2, Section 4] we discuss the stability conditions of such construction; we define multicolored persistence diagrams (MPD), and adapt the bottleneck distance to the semisimple case. These results allow us to use the classical Vietoris-Rips construction to study the interactions at the homological level of cycles generated by labeled points in a metric space.

Vietoris-Rips filtration with labeled data. Let us consider a metric space X, a finite set of points $d \subset X$ and a labeling function $l : X \to L = \{l_1, \dots, l_n\}$ associating each point with a label in the finite set L. Let $\{X_i = l^{-1}(l_i)\}_{i \in \{1,\dots,n\}}$ be the family of subdatasets corresponding to each label.

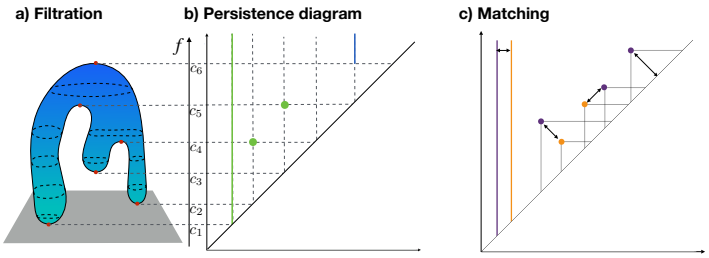

Fig. 1 Let (X, f) be a a topological space X and a continuous function $f : X \to \mathbb{R}$, respectively. The (homological) critical values $\{c_1, \ldots, c_6\}$ of f induce a sub-level set filtration of X, depicted in panel a. The change in number of generators of the kth homology groups is represented as a persistence diagram (panel b). Birth and death of homological classes are represented as points and half-lines, named cornerpoints and cornerlines, color coded depending on their associated degree: connected components in green, and the void obtained at the last sublevel set as the blue half-line. Two persistence diagrams can be compared by computing the optimal cornerpoints matching (panel c). Unmatched points are associated with their projection on the diagonal.

In the classical framework, it would be straightforward to build a filtration of X through the Vietoris-Rips construction and compute its persistent homology. However, this procedure cannot address the problem of quantifying how points belonging to different subdatasets contribute to the evolution of homological classes throughout the filtration. To do this we consider the poset $(P_n, \subseteq)$ of non-empty subsets of $\{1, \ldots, n\}$ ordered by inclusion, and the functor $F : P_n \to \mathbf{Met}$ mapping $\{1, \ldots, k\} \mapsto \sqcup_{i \in \{1,\ldots,k\}} X_i$, where **Met** is the category of metric spaces and $k \leq n$. The Vietoris-Rips construction allows us to build a $(P_n, \subseteq)$-indexed diagram (see [2, Remark 3.8]) and consequently a multicolored persistent diagram, i.e. a persistence diagram in which the information concerning the subset of labels contributing to a homological class is retained and color coded.

Implementation. Let $\mathscr{C} = \{c_1, \ldots, c_k\}$ be a neural network classifier composed of k layers, and (d, l_d) and (t, l_t) the training and test labeled datasets. We compute the Vietoris-Rips multicolored persistence as follows: 1. We train $\mathscr{C}$ on (d, l_d), by using the cross-entropy loss function and stochastic gradient descent. 2. We obtain the space $X = \sqcup_i X_i$ by considering the activation of the j-th layer on the samples belonging to the test dataset (250 randomly chosen samples per label). 3. We filter X with the classical Vietoris-Rips construction, labeling each simplex according to the labels associated to its vertices. 4. We sort the simplices of the filtration according first to their sublevel set, and then by considering the mode of their associated labels. 5. Finally, we compute the persistent homology of the sorted filtration and retrieve the labeling information associated to each homology class.

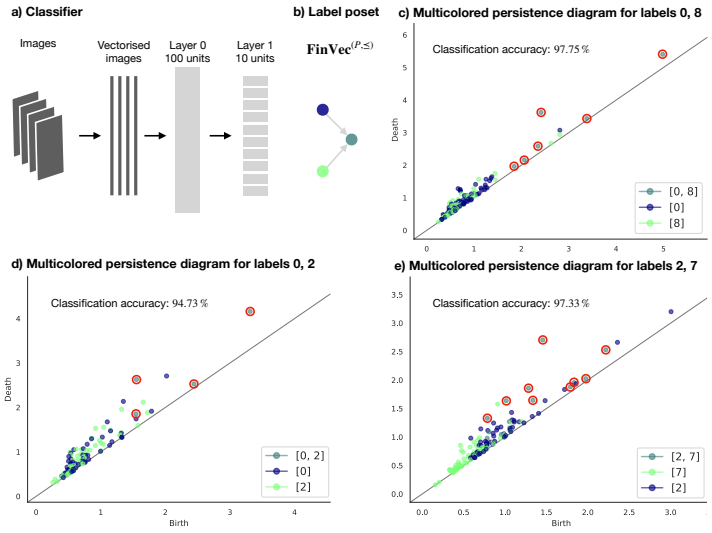

Fig. 2 Multicolored persistence. We encode the data representation obtained considering the activity pf a layer of an artificial neural network (panel *a*), by considering the multicolored persistence diagrams induced by the labeling defined on the dataset (panel *b*). In panels *c*,*d* and *e*, we show the multicolored persistence diagrams computed by considering the activation of the last layer of the trained network on the corresponding MNIST test samples. Cornerpoints originated by the interaction of simplices associated with multiple labels as highlighted (red circles).

3 Applications

In the following applications we use a shallow feed-forward neural network composed only by fully-connected layers, to classify the images of handwritten digits of MNIST [7]. The neural network is composed of two layers of 100 and 10 units, where the first layer is followed by a ReLU [8] nonlinear function.

Layer-wise embedding evaluation. As a first application we want to show how homological classes arising from the interaction of different labels carry information concerning the separability of those labels at a given layer. We consider samples belonging to pairs of labels in the MNIST dataset, train the neural network described above for 20 epochs, and evaluate it on the test set. We then consider the label poset of fig. 2, panel (b) and compute the multicolored persistence diagram by following the algorithm described in section 2.

The 1-multicolored persistence diagrams corresponding to the pairs of labels $(0,8),(0,2)$ and $(2,7)$ obtained considering the activity of the last layer of the network on the samples belonging to the test dataset are shown in panels (c, d, e) of fig. 2. An artificial neural network applies nonlinear transformations in order to separate samples belonging to different classes. Indeed, the cornerpoints associated with cycles generated by samples belonging to a single label appear overlapping and with low persistence. Observe how, although present in all the examples we

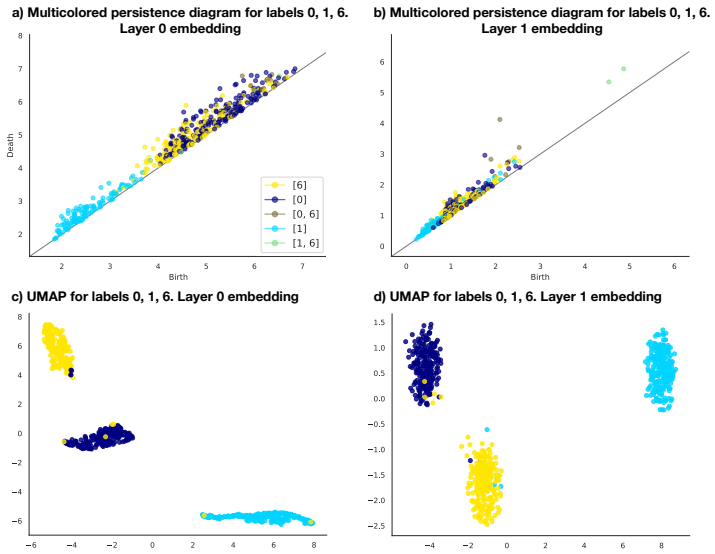

Fig. 3 Multicolored persistence diagrams obtained by considering the point clouds generated by the activation of the first (panel a) and last (panel b) layers of the neural network described in fig. 2, after training to distinguish the MNIST samples labeled with $0, 1$ and 6. Panels c and d are obtained by reducing the dimensionality of the same point clouds.

showcase, it modulates depending on the considered pair of labels, reflecting the validation accuracy of the classifier, it being $97.75\%, 94.73\%, 97.33\%$ for each of the considered pair of labels. However, cornerpoints associated with multiple classes are born later along the filtration (they are *larger holes*) and have larger persistence, again correlating with the classifier's score.

The same analysis for samples with labels $(0, 1, 6)$ are reported in fig. 3. There, however, we considered the point cloud generated by the first and second (last) layer of the network. The corresponding multicolored persistence diagrams are shown in panels (a) and (b) of fig. 3. As a comparison, we reduced the dimensionality of the point clouds by using UMAP [9].

A distance for neural architectures. One of the main advantages in using stable data representations such as multicolored persistence diagrams is that they can be compared through the multicolored bottleneck distance. This distance is essentially a color-wise version of the classical bottleneck distance used in persistent homology [10], i.e. it only admits matching between cornerpoints that respect their coloring (labeling).

As a proof of concept we compared the neural architecture and a second one, identical in its structure, but with 10 units in the first layer. The classification accuracy of the two models after 20 training epochs are 98.6% and 99%, respectively. Although the difference in accuracy is low, the multicolored bottleneck distance between the 1-MDPs computed by considering the activity of the last layer of the two trained architectures can be used to discriminate between them.

The values of the multicolored bottleneck distance (label-subset $\to$ distance) are: $\{0\} \to 0.6$, $\{1\} \to 0.2$, $\{6\} \to 0.3$, $\{1,6\} \to 0.5$, $\{0,6\} \to 1$. Coherently with our previous applications, cycles produced by multiple labels or associated with labels that are easily misclassified (0 and 6) have higher distances.

4 Discussion

After providing a short introduction to persistence homology and its rank-based generalization, we showed how this latter technique can be used to represent and compare in a robust and stable fashion the transformations learned by artificial neural networks in supervised classification tasks.

This work is intended as an exemplification of the theoretical framework described in [2], and in particular of the generalization of persistence to semisimple categories. In a forthcoming work, we plan to apply this technique to the evaluation and selection of more complex architectures (e.g. convolutional neural networks) and biological neural networks.

On the topological complexity of decision boundaries

Sulla complessita' topologica delle superfici di separazione

António Leitão and Giovanni Petri

Abstract Complex data requires complex models, or so the saying goes. However, the reason why classifying two concentric circles is challenging is not because they are circles, but because they are concentric. Our contribution aims at shifting the focus from data-driven to task-oriented models. To this aim, we study the topology of the decision boundary of a classification problem as a measure of its intrinsic complexity. We employ a topological approach to understand how the architecture of a model can limit its topological expressiveness and how complex data might not equate with difficult classification problems.

Abstract *I dati complessi richiedono modelli complessi, o almeno così si dice. Tuttavia, la ragione per la quale classificare due cerchi concentrici è difficile non è perché sono cerchi, ma perché sono concentrici. Il nostro contributo mira a spostare l'attenzione da modelli basati sui dati a quelli orientati ai compiti. A questo scopo, studiamo la topologia della superficie di separazione di un problema di classificazione come misura della sua complessità intrinseca. Utilizziamo un approccio topologico per comprendere come l'architettura di un modello possa limitare la sua espressività topologica e in che modo dati complessi possano non corrispondere a problemi di classificazione difficili.*

Key words: Neural Networks, persistent homology, topological complexity

1 Introduction

Neural Networks have taken over as one of the most popular methods in machine learning, due to both their versatility and power. However, in many domains, one of the major difficulties is how to select the optimal neural network architecture for a given task. While a large effort has been poured into developing effective

António Leitão

ISI Foundation, Turin, Italy e-mail: giovanni.petri@isi.it

architecture for computer vision tasks [Simonyan and Zisserman, 2014, Szegedy et al., 2014, He et al., 2015], it is still unclear what defines an optimal architecture for an arbitrary task. Although recent work [Bianchini and Scarselli, 2014, Raghu et al., 2016, Daniely et al., 2016] has shed some light on how the parameters of a neural network influence its effectiveness, the adequate complexity of the model must be known beforehand in order to find the optimal set of parameters for a problem.

We propose to bridge these two concepts by adopting a novel perspective on the problem. In particular, we propose a method to retrieve from data the minimal model complexity required to accurately generalize to an arbitrary classification problem. This is done by assessing the topological complexity of the decision boundary of the classification problem. Our contribution hinges on the fact that harder problems display more topologically complex decision boundaries and that neural networks learn by disentangling the representations of different classes from one another. We also provide some insight into how the architecture of a neural network is directly involved in how effective it is in disentangling classes.

If we consider neural networks as a set of transformations between spaces, topology becomes a natural lens through which to study them. For example, Guss and Salakhutdinov [2018] showed that persistent homology can be used to characterize the capacity of neural architectures in direct relation to their ability to generalize on data. Rieck et al. [2019] observed that the 0-dimensional homology class of the weights and their connections is an adequate indicator of a given Neural Network's learning performance. Finally, Bianchini and Scarselli [2014] adopt the total sum of Betti numbers as a measure of how the depth of feedforward networks affects their ability to implement high complexity functions. Other works [Olah, 2014, Brahma et al., 2015, Guss and Salakhutdinov, 2018] instead assume the complexity of the classification problem to be solely expressed by the complexity of the data. Ramamurthy et al. [2018] address this issue yet do not offer a solution that is scalable to multi-classification problems.

Our work differs from these because we base our analysis in the topology of the decision boundary and show evidence that in many cases the topological characterization of the data does not reflect the topological characterization of a given classification problem (Fig. 1a and b). Our contribution is threefold: (i) we introduce a topological characterization of neural networks in simple cases; (ii) we present a method to characterize classification problems by the topological complexity of their decision boundary; and, (iii) we provide empirical results pointing to how a neural network's data representation becomes less and less disentangled during training.

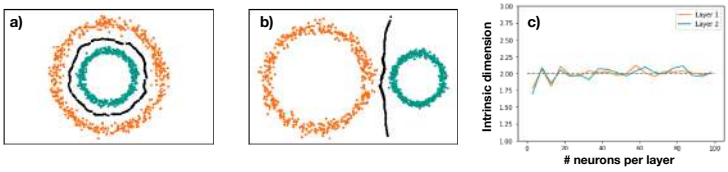

Fig. 1: Difference in the complexity of decision boundary for datasets with the same topological characteristics but different task structure. a) The boundary has non-trivial topology, while b) on the right is homologically trivial. c) The intrinsic dimension of the layers' representation of a dataset of 2 interlinked Tori for trained networks (in the conditions of theorem 1) with increasing number of neurons.

2 Neural Networks from a topological perpective

Definition 1 (Neural Network). A fully connected dense Neural Network of n-layers can be seen as a chain:

$$X_0 \xrightarrow{L_0} X_1 \xrightarrow{L_1} \dots X_{n-1} \xrightarrow{L_{n-1}} X_n \tag{1}$$

Where X_0 is called the *input* and X_n the *output*. Each L_i is in general defined to be the composition of an affine transformation with a non-linear continuous monotonous function, called *activation* function. $L_i(x) = a(W_i x + B_i)$.

The expressiveness of a neural network is then fully characterized by the nature of the chain of transformations $L_0 \dots L_{n-1}$. Interestingly, it is possible to show that there are situations in which these transformations do not alter the topological properties of the data: this is possible when a given L_i is a homeomorphism.

Theorem 1. *Let W_i be a $m \times n$ matrix such that $m \geq n$ and $rank(W_i) = n$, and let a be a continuous bijection with continuous inverse. If we consider: $L_i(X_i) = a(W_i x + B_i) \quad \forall x \in X_i$, then we have that X_i and $X_{i+1} = L_i(X_i)$ are homeomorphic.*

Proof. Let us first consider the case when $m = n$. In these conditions W_i is a linear function with a linear inverse. Since linear functions are continuous W_i is a homeomorphism. If a is a continuous bijection with a continuous inverse then L_i is a composition of homeomorphisms which is also a homeomorphism.

Let us take now $m > n$. Without loss of generality we only need to find a homeomorphism between X_i and $W_i X_i$. Since $rank(W_i) = n$, $dim(W_i x) = n$. Since $W_i x \subset \mathbb{R}^m$ there exist $m - n$ linearly independent vectors $\{e_1, \dots e_{m-n}\}$ such that the matrix $W_i' = \left[W_i |\ e_1\ \dots\ e_{m-n} \right]$ has $rank(W_i') = m$. We have then that:

$$W_i x = W_i' x' = \begin{bmatrix} & e_1^1 & \dots & e_{m-n}^1 \\ W_i & \vdots & & \\ & e_1^m & \dots & e_{m-n}^m \end{bmatrix} \begin{bmatrix} x_1 \\ \vdots \\ x_n \\ \hline 0 \\ \vdots \\ 0 \end{bmatrix} \begin{matrix} \Big\} \text{n} \\ \\ \\ \\ \Big\} \text{m-n} \end{matrix} \tag{2}$$

By construction W_i' is a linear function with a linear inverse such that

$$L_i(X_i) = a(W_i x + B_i) = a(W_i' x' + B_i) \quad \forall x \in X \tag{3}$$

Along with the first case we conclude that X_i and $X_{i+1} = L_i(X)$ are homeomorphic. □

We have then that if the number of neurons does not decrease from one layer to the next, neural networks will never be able to alter the topology of the data. These conditions are somewhat restrictive, but this result is important because it challenges a very common misunderstanding that a larger number of neurons directly translates into a more powerful model.

We show this in a simple example: consider a dataset of 2 interlinked Tori (a 2-dimensional manifold) given by a uniform sample of vectors in $\mathbb{R}^3$. Consider also

a neural network with two hidden layers and sigmoid activation functions, aimed at classifying in which Torus a given point lies on. Since, by construction, the layers of the neural network are homeomorphisms, no matter how much we increase the number of neurons in each layer, the intrinsic dimension (a topological property) of the representation of the dataset through the layers is unchanged (Figure 1c). The intrinsic dimension can be accurately estimated with a method presented by Facco et al. [2017].

This simple observation allows us to contextualize previous results. For example, Ansuini et al. [2019] showed that the first layers of a convolutional neural network dramatically increase the intrinsic dimension of the data representation, while the last ones steadily decrease it. In the light of Theorem 1, this is not surprising. In fact, the neural networks studied in [Ansuini et al., 2019] do not satisfy Theorem 1, and thus different results may appear. Interestingly, they also find that in the last few layers, which are fully connected layers with constant dimension, the intrinsic dimension does not change anymore, as predicted by Theorem 1.

3 Decision Boundaries

We now try to characterize the complexity of a task from a topological perspective.

We propose to shift the focus from the datasets to the tasks themselves. The complexity of the model should not be determined by the topological features of the data, but by that of the decision boundary. Here, we consider the boundary that maximizes the distance between each point of different classes, which corresponds to the edges of adjacent Voronoi cells corresponding to points of different classes.

Definition 2 (Voronoi Cell). For each point in a given set $S = \{s_1, ..., s_k\}$ we define a Voronoi cell as the set:

$$x \in V_{s_i} \quad \Leftrightarrow \quad d(x, s_i) \leq d(x, s_j) \quad \forall x \in \mathbb{R}^n \wedge i \neq j \tag{4}$$

Intuitively, the Voronoi cell of a point s_i is the set of all the points that are the closest to s_i than to any other datapoint. Given two points of different classes a_i, b_i, if they have adjacent Voronoi cells, their edge is the set:

$$DB_{a_i,b_i} = \{x \in \mathbb{R}^n \mid d(x, a_i) = d(x, b_i) \leq d(x, s_j)\} \tag{5}$$

We call *decision boundary* the collection of all these edges. Therefore, for a classification problem in $\mathbb{R}^n$ with c classes, the decision boundary is a $n-1$-manifold that divides the space in c sections.

Definition 3 (Decision Boundary). We call *Decision Boundary* to the union of the edges of adjacent Voronoi cells corresponding to points of different classes.

3.1 Finding the decision boundary

While they are fundamental structures, computing a Voronoi diagram on n points in $\mathbb{R}^d$ requires $O(nlogn + n^{\lceil d/2 \rceil})$[Aurenhammer and Klein, 1996] making it prohibitive in high dimensions. We introduce an algorithm to sample the decision

boundary that is computationally feasible and theoretically exact for high dimensions. The central idea is to sample randomly a point and then "push" it into the decision boundary, by iteratively projecting it to the hyperspace orthogonal to its closest points belonging to different classes.

Algorithm 1: Sample the decision boundary

```
Q ← Uniform cover of n points.;
for each epoch do
    for each point q in Q do
        A ← closest point of a class to q ;
        B ← closest point of a different class to q;
        O ← hyperplane orthogonal to A − B;
        do an affine projection of q onto O;
        q ← P_O(q) ;
    end
end
```

Theorem 2. *The algorithm converges to the edges of adjacent Voronoi cells corresponding to points of different classes.*

Proof. By definition the Voronoi cell associated with point $s_i \in S$ is the set $\{x \in \mathbb{R}^n \mid d(x,s_i) \leq d(x,s_j) \forall i \neq j\}$. Given a point a_i belonging to a class, and b_i belonging to another class, we have that the set of points in the common edge of their Voronoi cells is given by: $DB_{ab} = \{x \in \mathbb{R}^n \mid d(x,a_i) = d(x,b_i) \leq d(x,s_j)\}$.
Therefore, at a given iteration of the algorithm, if point P does not belong to the set DB_{ab} then, by definition of Voronoi cell, there has to exist a point a_j (or b_j) such that $d(P,a_j) < d(P,a_i) = d(P,b_i)$. And therefore this point is considered the new closest neighbor in the next iteration. It follows that the algorithm only stops when all points reach the decision boundary. □

3.2 Topological Complexity

It now becomes possible to characterize the complexity of a classification model by looking at the topology of the decision boundary. We consider a complex decision boundary to be the opposite direction of linear separability, meaning that we consider richer topological structures to be more complex. In this perspective, we would like to measure how far a decision boundary is from being a hyperplane. In practice, we do this by computing the persistent homology [Silva and Carlsson, 2004, Edelsbrunner and Harer, 2010] of the sampled decision boundary. We define *topological complexity* as the sum of the persistences of the generators of the persistent homology groups in each dimension.

We tracked this complexity through training of a neural network and found that –even in very simple cases– one can clearly see how the topological complexity decreases (the classes become less and less entangled) the deeper we go into the network, and the further we are in the training. In Figure 2 we show the results for a neural network with 2 hidden layers with ReLU activation functions and with variable number of neurons (10/20/100) for the MNIST, Fashion-MNIST and CIFAR-10 datasets respectively.

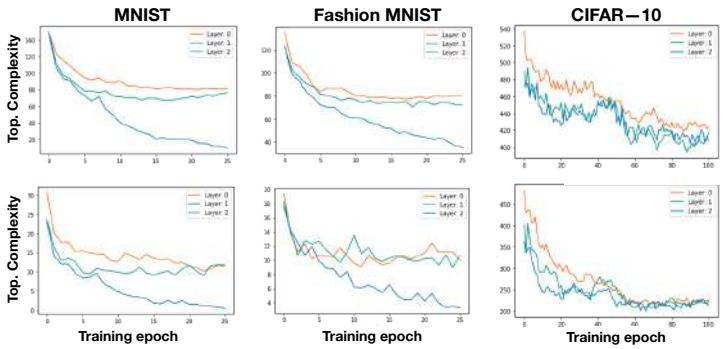

Fig. 2: Topological complexity of decision boundary. Results aree shown for H_0 (top row) and H_1 (bottom row). The studied datasets are MNIST, Fashion-MNIST and CIFAR-10.

Persistence-based Kernels for Data Classification

Kernel basati sulla Persistenza per la Classificazione di Dati

Ulderico Fugacci

Abstract In the last decades, topological data analysis and, specifically, persistent homology have widely proven their capabilities in extracting from large and unorganized datasets stable and discriminative information. Despite this, the retrieved topological descriptors need to further pass a "translation" process before being suitable for statistics and machine learning. In this paper, we will show how such a process can be achieved thanks to the introduction of persistence-based kernels aiming at endowing the space of persistent diagrams with an inner product. Moreover, we present a brief overview of the various definitions of a kernel for persistent and multi-parameter persistent homology given in the literature.

Abstract *Negli ultimi decenni, l'analisi topologica di dati e, in particolare, l'omologia persistente hanno ampiamente dimostrato la loro capacità nell'estrarre informazioni stabili e discriminanti da insiemi di dati non organizzati e di grandi dimensioni. Nonostante ciò, i descrittori topologici ottenuti necessitano di un ulteriore processo di "traduzione" prima di essere utilizzati in contesti statistici e di apprendimento automatico. In questo lavoro, mostreremo come tale passaggio possa essere realizzato grazie all'introduzione di kernel basati sulla persistenza che permettano di dotare lo spazio dei diagrammi di persistenza di un prodotto interno. Inoltre, presenteremo una breve panoramica delle varie definizioni di kernel per l'omologia persistente e l'omologia persistente multi-parametrica fornite in letteratura.*

1 Introduction

Nowadays, one of the most challenging problems with which researchers from all the scientific disciplines have to deal consists in extracting the core information

Ulderico Fugacci
Polytechnic University of Torino, Torino, Italy; e-mail: ulderico.fugacci@polito.it

from huge, high-dimensional, and noisy datasets. *Topological data analysis (TDA)* provides an effective collection of tools satisfying this need and notably succeeding in several applications in science and engineering. More specifically, TDA and, in particular, *persistent homology* enable to endow (almost) any kind of datasets (e.g., complex networks, point clouds, and multi-variate functions) with a notion of shape (more properly, with a topological structure) and, based on that, to study the considered data in terms of its topological features. Thanks to their proven stability, the topological descriptors obtained by such a strategy have revealed to be effective as criteria for discriminating and classifying data. Unfortunately, the retrieved information, typically represented by multi-sets of points in $\mathbb{R}^2$ and lacking a definition of inner product, cannot be straightly applied in statistics and machine learning. Recently, in order to overcome this limitation and in view of fully integrating topology among the tools that any statistician and data scientist can fruitfully adopt, kernels for persistent homology have been proposed in the literature. The main aim of this paper is, after having introduced all the required preliminaries (Section 2), to overview the currently available kernels introduced in TDA (Section 3).

2 Topological Notions

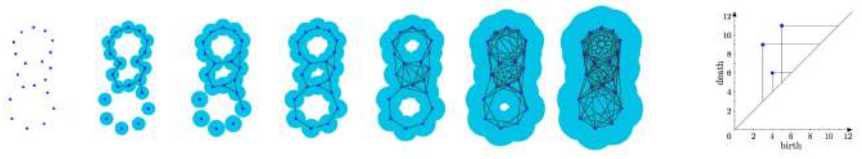
In this section, we introduce some preliminary notions at the basis of our work, namely simplicial complexes and persistent homology.

Simplicial Complexes. Simplicial complexes are collections of well-glued bricks, called simplices, typically adopted to represent discretized objects. Formally, a *k-simplex* σ is the convex hull of $k+1$ affinely independent points. A 0-simplex is a single point, a 1-simplex an edge, a 2-simplex a triangle, a 3-simplex a tetrahedron, and so on. Given a k-simplex σ, the dimension of σ is defined to be k and denoted as $dim(\sigma)$. Any simplex which is the convex hull of a non-empty subset of the points generating σ is called a *face* of σ. A *simplicial complex* Σ is a finite set of simplices which satisfies the gluing conditions requiring that each face of a simplex in Σ belongs to Σ, and each non-empty intersection of any two simplices in Σ is a face of both. We define the *dimension* of a simplicial complex Σ, denoted as $dim(\Sigma)$, as the largest dimension of its simplices.

Homology. Homology is a powerful topological tool which enables to describe a shape in terms of its "holes". More formally, given a simplicial complex Σ, the chain complex $C_*(\Sigma) := (C_k(\Sigma), \partial_k)_{k\in\mathbb{Z}}$ associated with Σ consists of: vector spaces $C_k(\Sigma)$ (over $\mathbb{Z}_2$) generated by the k-simplices of Σ; homomorphisms $\partial_k : C_k(\Sigma) \to C_{k-1}(\Sigma)$, called boundary maps, which encode the boundary relations between the k-simplices and the $(k-1)$-simplices of Σ and such that $\partial_k \circ \partial_{k+1} = 0$. We denote as $Z_k(\Sigma) := \ker(\partial_k)$ the group of the k-cycles of Σ and as $B_k(\Sigma) := Im(\partial_{k+1})$ the group of the k-boundaries of Σ. Then, we define the *k^{th} homology group of Σ* as

$$H_k(\Sigma) := H_k(C_*(\Sigma)) = \frac{Z_k(\Sigma)}{B_k(\Sigma)}.$$

A non-null element of $H_k(\Sigma)$ is an equivalence class of cycles that are not the boundary of any collection of $k+1$-simplices of Σ. Such classes represent, in dimension 0, the connected components of complex Σ, in dimension 1, its tunnels and its loops, in dimension 2, the shells surrounding voids or cavities, and so on.



(a) (b)

Fig. 1 (a) A filtration of a simplicial complex Σ obtained starting from a set of points and increasing the radius of the balls centered in each point. A k-simplex generated by vertices $v_0,\ldots,v_k$ is created when every two balls centered in $v_0,\ldots,v_k$ have a non-null intersection. (b) The persistence diagram collecting the persistence pairs describing the evolution of the 1^{st} homology groups of the filtration depicted in (a). Images courtesy of [2].

Persistent Homology. In applications, quite rarely a dataset can be described by a unique simplicial complex. Conversely, there are common constructions (such as the one achieved by the Vietoris-Rips complexes [12]) enabling for associating with a data a growing collection of simplicial complexes. Persistent homology [8] represents a development of standard homology aiming at studying the changes in homology that occur during the evolution of such a collection. Given a simplicial complex Σ, a filtration of Σ is a finite sequence of subcomplexes $\Sigma^f := \{\Sigma^p \,|\, 0 \leq p \leq m\}$ of Σ such that $\emptyset = \Sigma^0 \subseteq \Sigma^1 \subseteq \ldots \subseteq \Sigma^m = \Sigma$ (see Figure $1(a)$). For $p,q \in \{0,\ldots m\}$ such that $p \leq q$, the (p,q)-*persistent* k^{th} *homology group* $H_k^{p,q}(\Sigma)$ of Σ consists of the k-cycles included from $C_k(\Sigma^p)$ into $C_k(\Sigma^q)$ modulo boundaries. Formally, it can be defined as $H_k^{p,q}(\Sigma^f) := Im(i_k^{p,q})$, where $i_k^{p,q}$ denotes the linear map between $H_k(\Sigma^p)$ and $H_k(\Sigma^q)$ induced by the inclusion of complexes between Σ^p and Σ^q. While homology captures cycles in a shape by factoring out the boundary cycles, persistent homology allows for the retrieval of cycles that are non-boundary elements from a certain step p of the filtration and that will turn into boundaries in some subsequent step q. Such a contribution can be represented as a pair $(p,q) \in \{0,\ldots,m\} \times (\{0,\ldots,m\} \cup \infty)$. These pairs, called persistence pairs, can be visualized as a collection, called *persistence diagram*, of points in $\mathbb{R}^2$ (see Figure $1(b)$). Specifically, persistence pairs lay in the portion of the first quadrant of $\mathbb{R}^2$ above the main diagonal. Points far from the diagonal are typically considered as associated with relevant topological features while points close to the diagonal are usually interpreted as noise. The relevance of persistence diagrams as effective topological descriptors is confirmed by several stability results (see, for instance,

[5]) ensuring that slight perturbations in the original dataset will produce similar persistence diagrams.

3 Persistence-based Kernels

Thanks to their stability, the topological information and, specifically, persistence diagrams are effective data discriminants. On the other hand, interfacing persistence diagrams directly with statistics and machine learning poses technical difficulties, because the space of persistence diagrams is not endowed with a structure of an inner product or, more properly, of a Hilbert space structure. This lack prevents that lengths, angles, and means of persistence diagrams can be defined as well as that kernel-based learning methods such as kernel SVMs or PCAs [11] can be adopted.

Kernel Trick. Given an input space X, a *kernel* for X is a map $k : X \times X \to \mathbb{R}$ such that there exist a Hilbert space H and a map $\phi : X \to H$, called *feature map* for which, for any $x, y \in X$, $k(x,y) = \langle \phi(x), \phi(y) \rangle$. Equivalently, k is a kernel if the following diagram commutes:

$$\begin{array}{ccc} X \times X & \xrightarrow{\;k\;} & \mathbb{R} \\ {\scriptstyle \phi\times\phi}\downarrow & \nearrow_{\langle\cdot,\cdot\rangle} & \\ H \times H & & \end{array}$$

Recall that a Hilbert space H is a complete metric space with respect to the distance induced by the inner product $\langle \cdot, \cdot \rangle$. Given a (pseudo) distance $d : X \times X \to \mathbb{R}$ of a space X, a kernel k for X is called *stable* with respect to d if there exists a constant $C > 0$ such that, for any $x, y \in X$,

$$\|\phi(x) - \phi(y)\|_H \leq C \cdot d(x,y),$$

where $\| \cdot \|_H$ is the norm induced by the inner product of H.

Kernels for Persistent Homology. The idea of defining a kernel for the space X of persistence diagrams has been introduced in the late nineties in [9, 7] but it has been widely adopted just in the last few years. Usually, in the definition of a persistence-based kernel, the feature map is explicitly provided and the chosen Hilbert space is typically the $L^2(\mathbb{R}^2)$ space of the square-integrable functions. In the following, we will list and briefly discuss the main features of all (to the best of our knowledge) persistence-based kernel introduced in the literature.
Roughly, we can classify them into four groups:

- Gaussian kernels [11, 10, 1];
- persistence landscapes [2];
- sliced Wasserstein kernel [3];

- kernels for multi-parameter persistent homology [6].

The first class of persistence-based kernels is defined thanks to the explicit introduction of a feature map ϕ. Focusing on [11], the map ϕ sends a persistence diagram D into a square-integrable function $\phi(D)$ on $\mathbb{R}^2$ defined as the solution of a certain heat diffusion problem satisfying suitable boundary conditions and setting as an initial condition a sum of Dirac deltas centered at each point (p,q) of the persistence diagram D. In a nutshell, this is equivalent to returning an L^2 function having a Gaussian peak centered at each point of the considered persistence diagram. Moreover, in order to obtain a stable kernel, the height of each peak is set as proportional to the distance of the corresponding point (p,q) from the diagonal of the first quadrant of $\mathbb{R}^2$.

The strategy adopted in [2] is called persistence landscapes and, as in the previous case, it is based on the definition of a proper feature map from the space of the persistence diagrams to $L^2(\mathbb{R}^2)$. In short words, the L^2 function associated to a persistence diagram D is defined as the map sending the point $(x,y) \in \mathbb{R}^2$ into the number of persistence pairs $(p,q) \in D$ such that $p < x < y < q$.

A completely different strategy is adopted in [3]. In this case, in fact, a feature map is not explicitly defined. Given a real value $\sigma > 0$, a kernel $k : X \times X \to \mathbb{R}$ for X can be defined as

$$k(x,y) := \exp\left(-\frac{f(x,y)}{\sigma^2}\right)$$

as long as f satisfies the suitable condition of being a conditionally negative definite function. Based on this fact, the introduction in [3] of a proper conditionally negative definite function, called sliced Wasserstein distance, on pairs of persistence diagrams is a sufficient condition for defining a new persistence-based kernel.

Finally, in [6], the authors have introduced a strategy for extending a kernel for persistent homology to a kernel for multi-parameter persistent homology. This latter is a generalization of standard persistent homology but it considers filtrations of simplicial complexes evolving in accordance with more than just one parameter. Inspired by the definition of a distance between multi-parameter persistence modules [4], the strategy presented in [6] allows for returning a kernel for multi-parameter persistent homology given a kernel for persistent homology. Moreover, if the input kernel is stable and can be computed in polynomial time, the same properties will be inherited by the newly retrieved kernel for multi-parameter persistent homology.

4 Conclusions

In this short paper, we have given a quick and compact excursus on topological data analysis and on the adoption of kernels to make the topological information suitable

for statistical analyses. This research field is still far from being completely investigated and we are sure that a deeper integration between topologists and experts in statistics and machine learning can seriously improve the effectiveness of such strategies.

Topological and Mixed-type learning of Brain Activity

Determinanti Topologiche e di tipo misto per pattern di attivazione in dati di neuroimmagini

Tullia Padellini, Pierpaolo Brutti, Riccardo Giubilei

Abstract Topological characterization of brain imaging data is gaining momentum in the statistical literature, however, the resulting representation of brain imaging data are often defined in complex spaces, not amenable for standard statistical methods. Ad hoc procedures must thus be adopted in order to perform standard statistical tasks such as regression or classification with topological summaries, drastically limiting their use. Exploiting distance-covariance based tests of independence, which can assess the presence of association between object defined in different metric spaces, we build a new class of conditional inference trees, which we call *energy trees*, that allows to use topological summaries together with more standard covariates, such as categorical variables or graphs, for the analysis of fMRI data.
Abstract *Nonostante sintesi topologiche stiano acquisendo popolarità nell'analisi dei dati di brain-imaging, spesso la complicata struttura degli spazi in cui sono definite preclude il loro utilizzo in metodi statistici classici. Problemi standard di classificazione e regressione con covariate topologiche possono comunque essere risolti, ma solo tramite procedure ad hoc, cosa che pone un limite alla diffusione di questo tipo di strumenti. In questo lavoro introduciamo una nuova classe di alberi di regressione che, sfruttando test di indipendenza basati su distance-covariance, permettono di usare variabili "complesse" (come quelle topologiche) e "semplici" (come quelle numeriche e categoriche) simultaneamente.*

1 Topological Summaries of Brain Activity

The ever-growing complexity of modern data has been fostering the development of new tools for statistical analysis, whose aim is to provide easily interpretable and low dimensional representations. This is especially true for brain imaging data such as EEG and fMRI, which represent a challenge for statisticians as well as clinicians due to their pervasive yet still unknown dependency structure. The emerging field of Topological Data Analysis (TDA) has shown to be able to provide new insights on brain activity [8, 3]; as it characterizes data through connected structures of any dimension (i.e. connected components in dimension 0, loops in dimension 1 and so on), in fact, TDA provides information not only which on areas of the brain are connected (i.e. work together) but also what kind of connection relates them.

In short, Topological Data Analysis is a growing branch of statistics, devoted to the study of the connectivity structure of the data, typically summarised in terms of connected components (or dimension 0 topological features), loops (or dimension 1 features) or higher dimensional voids.

While some of these feature have been object of interest in network analysis for some time [7], what makes TDA a new approach is the mathematical formulation of these topological invariants. As opposed to network analysis, which is typically more concerned with the presence of connection rather than with its nature, the main goal of TDA is to estimate Homology Groups of the data, which, depending on their dimension, inform us on different types of connectivity. More specifically, for a generic space X, the Homology Groups of dimension 0 ($H_0(X)$) represent its "plain" connected components, those of dimension 1 ($H_1(X)$) represent its cyclical structures or loops and so on [11].

Since the resolution of the data, which may vary depending on the sampling density, noise level and other factors that are in no relation with the shape we are trying to uncover, affects their topological structures, TDA computes Homology Groups at different scales, i.e. at different levels of aggregation. The topological features found at each scale are then ranked according to how persistent they are with respect to the aggregation level; the longer in the aggregation scheme a feature "survives", the more important it is. If a feature is very dependent on the connectivity structure we impose by selecting a reference scale for the analysis, it may be noise, and may be neglected. The persistence of every feature in the data is collected into a multiset

$$D = \{(b_i, d_i), \quad i = 1, \ldots, n_D\}$$

called the *Persistence Diagram*, which records all the different scales at which feature i can be found, from when it first appears (b_i, the "birth-time"), to the level of aggregation at which it disappears (d_i, the "death-time").

Persistence Diagrams can be compared through the Wasserstein distance, which, for

a pair of Persistence Diagrams D, D' can be defined as follows

$$W_p(D,D') = \left[\inf_{\gamma} \sum_{x \in D} \|x - \gamma(x)\|^p \right]^{\frac{1}{p}},$$

where the infimum is taken over all bijections $\gamma : D \mapsto D'$.

Brain imaging data are the ideal playground to explore these new set of tools, due to the complexity of their dependency structure. In order to produce understandable representations, brain activity is typically studied by building brain networks, which consist in relating areas of the brain which are activated together. In a functional brain network, areas of the brain are represented by nodes and edges are drawn by thresholding some measure of similarity [4]. Brain activity is then investigated through the topology of the network, at the resolution given by the threshold used for building the graph [2].

One of the advantages of using TDA tools is that they are multi–scale by definition, hence it is not necessary to choose such a threshold. The network can be investigated at every resolution, hence no information is lost. More importantly, TDA allows to investigate different types of dependence beside connected components, such as loops and voids, which may represent more complex activation patterns.

2 Energy trees

While some work has been done on investigating the brain network topology, even if at a fixed scale, yet the use of TDA beside descriptive statistics is still largely unexplored [1]. The space of Persistence Diagrams has in fact the noticeable shortcoming of only having a metric structure, and does not allow for the vector-space representation needed for most statistical algorithm [10]. In practice this means that it is either necessary to convert it into a vector by means of feature extractions, which inevitably result in a loss of information, or to design procedures especially tailored for its metric space, which makes it impossible to mix it with other types of covariates.

As both solutions seem rather limiting, we develop a new procedure, which extends Regression trees to the case of mixed-type data. We base our proposal on Conditional Inference Trees (ctree)[5], a class of methods that exploits independence tests for the choice of the splitting variable when building the tree.

Let Y be a response variable to be predicted by a set of covariates $X_1, \ldots, X_k$, and let $y = (y_1, \ldots, y_n)$ and $x = (x_1, \ldots, x_n)$ with $x_i = (x_{1i}, \ldots, x_{ki})$ be the corresponding observed sample. The ctree algorithm can be summarized in the following steps:

Step 1 Test the global null hypothesis of independence between $X_1, \dots, X_k$ and Y. If this hypothesis is rejected, select the covariate X_{j^*} with the strongest association to Y, otherwise stop.

Step 2 Partition the support $\mathscr{X}_{j^*}$ of the selected covariate X_{j^*} onto two sets A and $\bar{A}$ and define

$$x_A = \{x_{ji}, \text{ with } j = 1, \dots, k \text{ and } i \text{ s.t. } x_{j^*i} \in A\} \qquad x_{\bar{A}} = x \setminus x_A$$

Step 3 Recursively repeat **Step 1** and **Step 2** for x_A and $x_{\bar{A}}$.

Our extension of this algorithm, the Energy tree (etree), allows for mixed-type covariates, by adopting an energy-based test in **Step 1** and a clustering procedure to define the sets A and $\bar{A}$ in **Step 2**. The key feature of energy-based test is that it allows to test for the presence of association between random objects defined in different metric spaces [9]. This is especially relevant for the case of Persistence Diagrams, whose space, when endowed with the Wasserstein distance, is metric, however is a more general procedure and can be exploited to combine complex objects such as functional data or graphs together with more standard scalar variables in regression problems.

3 Nathan Kline Institute-Rockland Sample

We conclude by testing etree on real brain imaging data taken from the Nathan Kline Institute-Rockland Sample (NKI-RS), an ongoing study aimed at uncovering links between physiological and psychological assessments, genetic information, and neuroimaging data [6]. We consider a sample of $n = 158$ subjects, and we try to investigate the relationship between brain connectivity and IQ score, which is taken to be the response variable in our regression model. Our goal is to understand whether brain activity is best understood by means of *structural* or *functional* brain connectivity, and how to combine them.

In order to account for both kinds of connectivity, we take as covariates Diffusion Tensor Imaging (DTI), from which we infer the *anatomical* connectivity between brain areas, and functional MRI (fMRI), which embeds the *functional* connectivity instead. Since raw images of both DTI and fMRI are preprocessed and aggregated on the Craddock 200 Atlas, for each tool and each subject we have measurements on 200 areas of the brain (usually denoted by Region of Interest or ROI). DTI and fMRI data in their vector form may not be very informative, we thus adopt a different representation for them to isolate connectivity information. We represent the DTI as a graph, where each ROI is a node and an edge is drawn if the two ROI are physically connected, and we build Persistence Diagrams from the fMRI, where the Homology Groups are computed for the ε-correlation graph that has the ROI as node and the edges representing a correlation between them that is higher than ε, while the "resolution" level across which "features persists" is taken to be the

threshold ε. The difference in the choice of summary is motivated by the fact that we are trying to represent two different kinds of connectivities. While a graph may be a simpler yet reasonable representation for the structural connectivity in fact, it may be limiting in the case of the functional one, as there may be relevant information at different correlation levels.

Figure 1 shows the etree for the NKI-RS data, fitted using the `etree` R-package. Nodes denoted with "1" correspond to splits with respect to the structural graph, while nodes denoted by "2" correspond to splits with respect to the functional Persistence Diagram. Functional connectivity seems to be more discriminative than Structural one, as most of the splits are determined by the Persistence Diagram. This is somehow expected, as it is intuitive to think that brain activity is best understood in terms of assessing which areas work together and how. At the same time, it is interesting to see how the structural component does retain some predictive power, meaning that the anatomic component cannot be completely neglected. Finally, we wish to stress that at this preliminary stage of the analysis we did not include other covariates, such as age or sex, as their impact on their connectivity structure is unclear and they could be confounders, however the method is flexible enough to easily account for them.

Bayesian Statistics

A Bayesian approach for modelling dependence among mixture densities

Un modello bayesiano per indurre dipendenza tra misture di densità

Mario Beraha, Matteo Pegoraro, Riccardo Peli and Alessandra Guglielmi

Abstract We propose a Bayesian model for areal data, when multiple observations are available for each area. This situation is often encountered in practical applications, for example when geo-referenced data are collected in an aggregated form, reporting only the region or state instead of the exact GPS location. We propose to model the density of each area through a finite mixture of Gaussian distributions, for accurately approximating smooth densities. The prior for the weights of the mixtures encourages densities referring to areas that are geographically close to be similar. We derive efficient Bayesian inference based on Markov Chain Monte Carlo (MCMC) simulation and illustrate the proposed approach through simulation studies.

Abstract *Proponiamo un modello bayesiano per dati areali, qualora più osservazioni siano disponibili in ogni area. Questa situazione si incontra spesso nelle applicazioni, ad esempio quando dati georeferenziati vengono raccolti in maniera aggregata, riportando solamente la regione o lo stato invece dell'esatta posizione GPS. Proponiamo di modellare la densità in ogni area attraverso misture finite di distribuzioni gaussiane, al fine di approssimare accuratamente densità regolari. La distribuzione a priori dei pesi delle misture induce similarità tra densità di aree che sono geograficamente vicine. Basandoci su un algoritmo Markov Chain Monte Carlo (MCMC), deriviamo un approccio efficiente per l'inferenza bayesiana e illustriamo il metodo proposto in casi simulati.*

1 Introduction

Finite mixture models provide an extremely rich and flexible framework, that can easily be employed to approximate densities that do not belong to standard parametric families as well as to group together observations for clustering purposes. Starting from early works [6], a huge literature has been developed around the topic; see for example [3, 4] for a detailed discussion. Although mixture models are often used in problems with exchangeable samples from a single unknown distribution, recent attention has been given to extension for multiple dependent distributions.

In spatial applications, it is often the case that data arising nearby exhibit a similar behaviour. For geo-referenced data, this similarity can be expressed assuming that data geographically close should also be close in distribution such as in the case of the generalized spatial Dirichlet Process [2], for example. On the other hand, when dealing with areal data, the notion of geographical distance is replaced by a definition of neighborhood and the similarity can be introduced using the family of Conditionally Autoregressive (CAR) distributions.

In this work, we consider the problem of modelling areal data, when, for each area $i = 1,\dots,I$, a set of observations $y_{ij},\ j = 1,\dots,N_i$ is available. This is a common scenario in real world applications, for example when geo-referenced data are presented in an aggregated form, e.g. reporting only the region or state instead of the exact GPS location, possibly to protect users' privacy.

In this setting, the usual CAR models would imply that data in each area are suitably modelled by a single parametric family, for example the Gaussian distribution. This assumption can be over-restrictive, as in the case when data in each area present a large heterogeneity because of the aggregation procedure. With this aim in mind, we propose to model the I distributions, each associated to an area, through a finite mixture of Gaussian distributions, keeping in mind the flexibility of Gaussian mixture models to accurately approximate smooth densities. We let all the mixtures share the same set of atoms, while introducing similarity between different mixtures through a novel CAR model for vectors on the simplex, that we employ as a prior for the weights of the mixtures.

2 Spatially dependent mixture models

Consider data $\boldsymbol{y}_1,\dots,\boldsymbol{y}_I$, where $\boldsymbol{y}_i = (y_{i1},\dots,y_{iN_i})^T$. Assume that a neighboring structure G between the I different areal units is known. We can assume G as a $I \times I$ matrix, its entries g_{ij} indicating the strength of the spatial association between two different areas. It might be useful to think $g_{ij} = 1$ if i and j are neighbors and 0 otherwise, but we will not be limited to this particular case.

The conditional distribution of our data is specified as follows:

$$y_{ij} \mid \mathbf{w}_i, \boldsymbol{\mu}, \boldsymbol{\sigma}^2 \overset{\text{iid}}{\sim} \sum_{h=1}^{H} w_{ih} \mathcal{N}(\mu_h, \sigma_h^2) \quad j = 1,\dots,N_i \tag{1}$$

where $\mathbf{w}_i = (w_{i1}, \cdots, w_{iH})^T$ is a H–dimensional vector in the simplex S^H, i.e $w_{ij} \geq 0$, $\sum_j w_{ij} = 1$ for each $i = 1, \cdots, I$ and $\mathscr{N}(\mu, \sigma^2)$ denotes the the Gaussian density with mean μ and variance σ^2.

Observe how in (1) the atoms (μ_h, σ_h^2) are shared across all the spatial locations. This is a key aspect of our model as it allows to introduce dependency between mixtures associated to different areas only through the prior for the weights.

2.1 The Logistic MCAR prior

To define a joint distribution for vectors on the simplex S^H, we start from the logistic-normal distribution in [1]. Formally, we say that $\boldsymbol{w} \in S^H$ follows a logistic-normal distribution of parameters $\boldsymbol{\mu} \in \mathbb{R}^{H-1}$, $\Sigma \in \mathbb{R}^{(H-1)\times(H-1)}$ if its additive log-ratio transformation $\widetilde{\boldsymbol{w}} := \text{alr}(\boldsymbol{w}) \sim \mathscr{N}_{H-1}(\mu, \Sigma)$, where $\text{alr} : \boldsymbol{w} \mapsto \widetilde{\boldsymbol{w}}$ is defined as:

$$\widetilde{w}_i = \log \frac{w_i}{w_H}, \quad i = 1, \ldots, H-1 \tag{2}$$

We consider instead the following model on the transformed variables $\widetilde{\boldsymbol{w}}_i$, $i = 1, \cdots, I$: the alr transformation of the mixture weights $\boldsymbol{w}_i$ at area i is given by a Multivariate Conditionally Autoregressive (MCAR) model

$$\widetilde{\boldsymbol{w}}_i \mid \widetilde{\boldsymbol{w}}_{-i}, \Sigma, \rho \sim \mathscr{N}_{H-1}\left(\rho \sum_j g_{ij} \widetilde{\boldsymbol{w}}_j, \Sigma\right) \quad i = 1, \cdots, I \tag{3}$$

It is well known that this model defines a unique joint distribution when $\rho \in (-1, 1)$. See [5] for a comprehensive overview of MCAR distribution.

Definition 1. We say that a sequence of vectors $(\boldsymbol{w}_1, \ldots, \boldsymbol{w}_I)$ follows a Logistic Multivariate CAR distribution of parameters (ρ, Σ) on the adjacency graph G, if the transformed variables $(\widetilde{\boldsymbol{w}}_1, \ldots, \widetilde{\boldsymbol{w}}_I)$, where $\widetilde{\boldsymbol{w}}_i = \text{alr}(\boldsymbol{w}_i)$ for each $i = 1, \cdots, I$, follow the MCAR model with the same parameters, and we write $(\boldsymbol{w}_1, \ldots, \boldsymbol{w}_I) \sim \text{LogisticMCAR}(\rho, \Sigma; G)$

2.2 The Bayesian model

We assume that observations $\{y_{ij}\}$ are conditionally independent between areas and iid within each area according to likelihood (1), with the following prior for the parameters:

$$(\boldsymbol{w}_1, \ldots, \boldsymbol{w}_I) \mid \rho, \Sigma \sim \text{LogisticMCAR}(\rho, \Sigma; G) \quad \mu_h, \sigma_h^2 \overset{\text{iid}}{\sim} P_0 \quad h = 1, \cdots, H \tag{4}$$

where P_0 is the *base measure*; we assume P_0 as an absolutely continuous distribution on $\mathbb{R} \times \mathbb{R}^+$. In our examples, we have assumed P_0 to be the well known Normal-inverse-Gamma distributions with parameters μ_0, a, b, λ, i.e. $\mu_h \mid \sigma_h^2 \sim \mathscr{N}\left(\mu_0, \sigma_h^2 \lambda^{-1}\right)$, $(\sigma_h^2)^{-1} \sim \text{Gamma}(a, b)$.

The model can be extended to include hyper-priors on the parameters of the LogisticMCAR prior. Specifically, we choose $\Sigma \sim \text{Inv-Wishart}(\nu, V)$ and $\rho \sim \mathscr{U}(0, 1)$.

Note that, though (3) gives a unique multivariate distribution for every $\rho \in (-1,1)$, we assume $\rho > 0$ to ensure the similarity among spatial neighbours, as in [5].

3 Simulation studies

We present two simulation studies to illustrate the flexibility of our model in capturing the spatial dependence in the densities among close areas. In the first simulation example, we make a comparison with the Hierarchical Dirichlet Process (HDP)-mixture model, whereas in the second one we apply our model to data generated from spatial dependent densities. We have built a MCMC scheme for simulating from the posterior, and we have coded it in C++. We do not give details of the algorithm here. We fix the hyperparameters of the HDP such that the expected number of components matches the parameter H of our model. We run the MCMC algorithm for 20,000 iterations, discarding the first 10,000 as burn-in, with thinning equal to 5, for a final sample size of 2,000.

As a metric to compare the density estimates, we use the Monte Carlo estimate of the Hellinger distance between the estimated densities and the true ones.

3.1 Non-Gaussian simulated data

We consider three scenarios. In each scenario we generate, for $I = 6$ different spatial areas, an iid sample from a density that is not the Gaussian one. The three scenarios vary with the number of data in each area and with the data generating densities employed, as reported in Table 1. They cover extremely different cases: in Scenario I a huge number of data is available in each area, so that borrowing strength from nearby areas would be superfluous; we actually expect our model to perform worse than the HDP, being the latter fully nonparametric. On the other hand, in Scenario II there are three areas (2, 4 and 6) with few data points (only 10). In this situation we expect our model to express its strength and give a better density estimate than the HDP, especially in those areas where few data are present. Finally, Scenario III is an in-between situation, where not so many observations as in Scenario I are available in each area.

	Scenario I				Scenario II				Scenario III			
Area	Density	N_i	d_H sp	d_H HDP	Density	N_i	d_H sp	d_H HDP	Density	N_i	d_H sp	d_H HDP
1	$t(6,-4,1)$	1000	0.074	0.029	$t(6,-4,1)$	1000	0.087	0.054	$t(6,-4,1)$	100	0.045	0.366
2	$t(6,-4,1)$	1000	0.074	0.026	$t(6,-4,1)$	10	0.089	0.162	$t(6,-4,1)$	100	0.045	0.364
3	$SN(4,4,1)$	1000	0.088	0.069	$SN(4,4,1)$	1000	0.098	0.074	$SN(4,4,1)$	100	0.084	0.452
4	$SN(4,4,1)$	1000	0.088	0.069	$SN(4,4,1)$	10	0.0101	0.202	$SN(4,4,1)$	100	0.084	0.452
5	$\chi^2(3,0,1)$	1000	0.091	0.096	$\chi^2(3,0,1)$	1000	0.103	0.098	$cauchy(0,1)$	100	0.044	0.291
6	$\chi^2(3,0,1)$	1000	0.091	0.096	$\chi^2(3,0,1)$	10	0.103	0.228	$cauchy(0,1)$	100	0.046	0.283

Table 1: Data generating densities in each area; t denotes the t-distribution, while SN the skew normal.

Table 1 includes also Monte Carlo estimates of the Hellinger distance between the true density and the estimate under our model (sp) and the HDP-mixture model

(HDP). From Table 1, we see that our model performs slightly worse than the HDP-mixture in Scenario I, but overall the density estimates are close enough to the true density; moreover, by visual inspection of the plots, not reported here, they are similar to the HDP-mixture density estimates. As mentioned before, under Scenario II, our model gives a better density estimate (than the HDP-mixture) in areas 2, 4 and 6, where only 10 data points are available; see Figure 1. Interestingly, our model performs much better, in all the areas, under Scenario III. We believe this is due to the presence of extreme data in areas 5 and 6, where we generate data from a Cauchy distribution. This behavior is evident from Figure 1, being the 95% pointwise credible interval much wider in HDP than in our approach.

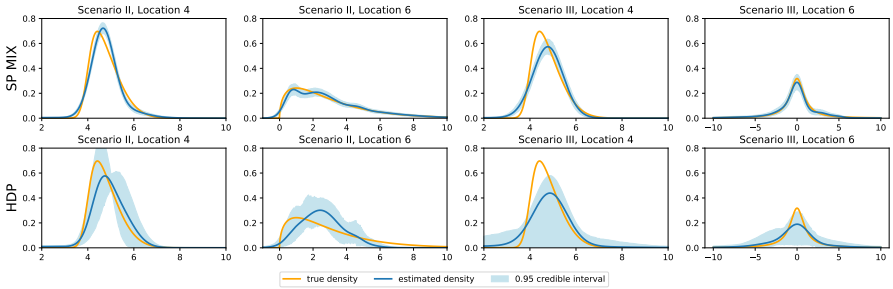

Fig. 1: Scenario II and III, non-gaussian data: estimated and true densities for areas 4 and 6

3.2 Simulation from spatially dependent weights

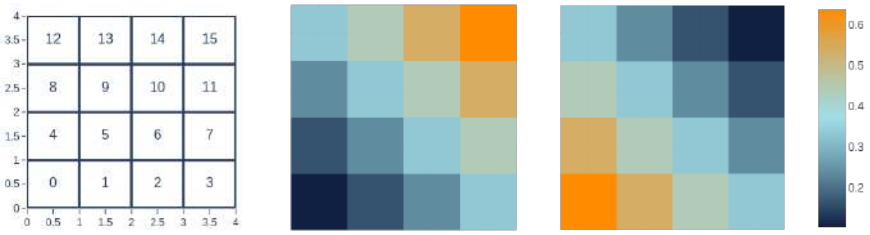
In the second simulation case, we consider 16 areas displayed in Figure 2a. Two areas are neighbors if they share an edge. At the i-th area, we draw a sample according to this distribution

$$y_{ij} \overset{\text{iid}}{\sim} w_{i1}\mathcal{N}(-5,1) + w_{i2}\mathcal{N}(0,1) + w_{i3}\mathcal{N}(5,1) \quad j = 1,\dots,100 \tag{5}$$

where the weights are chosen as $alr^{-1}(\tilde{\boldsymbol{w}}_i)$ and the transformed weights $\tilde{\boldsymbol{w}}_i$ have the following form

$$\tilde{w}_{i1} = 0.3(x_i - 2) + 0.3(y_i - 2) \quad \tilde{w}_{i2} = -0.3(x_i - 2) - 0.3(y_i - 2) \tag{6}$$

where (x_i, y_i) are the coordinates of the area center. In this way, we have introduced a strong spatial dependence, induced by (6), among the weights of different areas. The simulated weights $\{w_{i1}\}$ and $\{w_{i2}\}$ are shown in Figures 2b and 2c; of course $w_{i3} = 1 - w_{i1} - w_{i2}$. After running the MCMC sampler, we show the estimated densities in four areas in Figure 3. As expected, our approach produces accurate estimates in areas surrounded by four neighbors or whenever the true density is close to the average of the nearby densities. This is not the case in areas 0 and 15, where, indeed, we lack accuracy in density estimation.



(a) Areas (b) w_{i1} (c) w_{i2} (d)

Fig. 2: Areas and simulated weights for data in Section 3.2

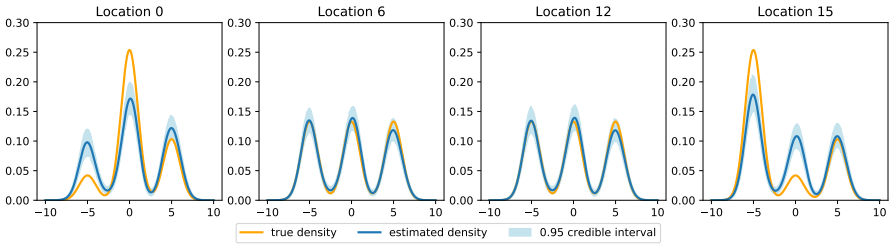


Fig. 3: Simulated data from spatially dependent weights: estimated and true densities for four locations.

4 Discussion and Conclusions

In this paper we present a new model for spatial dependent densities. In particular, each density is modeled as a mixture of Gaussian kernels with a Logistic MCAR prior on the weights that induces similarity between nearby areas. Via MCMC, we estimate the densities of different areas in simulation examples, showing the goodness of fit of our model.

A change of glasses strategy to solve the rare type match problem

Un cambio di prospettiva per risolvere il problema del rare type match

Giulia Cereda and Fabio Corradi

Abstract We propose a solution to a forensic statistics problem known as the "rare type match case". It happens when the characteristics of the crime and the suspect's traces match but they have not been observed yet in previously collected databases. The proposed solution relies on a "change-of-glasses" strategy and consists of ignoring the specific evidence characteristics thus only modeling equalities and inequalities among different types. For the rare type match case this reduces to consider the event of seeing twice a never observed type, along with a database, now coded in form of a partition, losing reference to the specific characteristics observed. We propose to use a Bayesian nonparametric approach and derive the likelihood ratio required for forensic assessment. MCMC inference is carried on and compared to MLE through a toy example.

Abstract *Si propone una soluzione al problema forense "match di tipo raro", che si verifica quando la traccia trovata sulla scena del crimine e quella di un sospetto corrispondono ma non sono mai state osservate in precedenza. La strategia proposta è un "cambio di occhiali" in cui si ignora la specifica caratteristica delle tracce osservate, modellizzando solamente uguaglianze e disuguaglianze tra le diverse caratteristiche. Per il match di tipo raro, questo significa considerare l'evento di osservare due volte una nuova caratteristica, senza riferimento a quale essa sia, insieme a un database codificato sotto forma di partizione. Proponiamo per questo problema un approccio Bayesiano non parametrico, derivando il rapporto di verosimiglianza richiesto dal protocollo forense insieme a un'inferenza MCMC e stimatori di massima verosimiglianza per i parametri.*

Introduction

On the crime scene, a trace has been retrieved showing characteristics that match the suspect's characteristics. The forensic statistician, who is given this piece of evidence along with a database of reference containing n traces, is asked to assess the likelihood ratio (LR), in order to weight the data D under the prosecution's (identification) and the de-

fence's (no-identification) hypotheses, h_p and h_d:

$$\mathrm{LR} = \frac{\Pr(D \mid H = h_p)}{\Pr(D \mid H = h_d)}. \tag{1}$$

In the rare type match case no other traces with the same characteristics are among those contained in the database of reference and the "rarity principle" is not operational since there are no frequencies to evaluate the rarity.

We propose a "change-of-glasses strategy", which considers the event that a never observed characteristic has been observed twice regardless of its specific type. Overall, data D are made of $n+2$ observations (n from a database and two traces from the suspect and crime scene). We are thus reducing D to a partition of the set $[n+2] = \{1,...,n+2\}$, by assigning to each class the indexes of the observations with equal characteristics.

Focusing on partitions allows us to use a nonparametric Bayesian approach. More specifically, as proposed in [2], we make use of the two-parameter Poisson Dirichlet prior to model the relative ranked sizes of the classes of the partition. This choice is motivated by the power-law shape often encountered using forensic data, such as Y-STR profiles.

1 Random partitions: an example

Consider a sequence of integer-valued random variables $I_1,...,I_n$, representing units with some characteristics expressed by the value of the Is and the equivalence relation $i \sim j$ if and only if $I_i = I_j$. The equivalence classes formed by subsets of indices with identical I form a random partition of $[n]$, which will be denoted as $\Pi_{[n]}(I_1, I_2, ..., I_n)$. For instance, the following random partition

$$\pi_{[10]} = \{\{1,3\},\{2,4,10\},\{5,6\},\{7\},\{8\},\{9\}\} \tag{2}$$

corresponds to $I_1 = I_3$, $I_2 = I_4 = I_{10}, I_5 = I_6$, while I_7, I_8, and I_9 are singletons. What we have retained is the composition of the classes themselves, but we have lost the information about the characteristics of each I_i. Assume partition $\pi_{[10]}$ as representing a database of 10 individuals. The rare type match case partition is obtained by augmenting $\pi_{[10]}$ by:

$$\pi_{[12]} = \{\{1,3\},\{2,4,10\},\{5,6\},\{7\},\{8\},\{9\},\{11,12\}\}.$$

The 11-th and the 12-th observed traces constitute a new class by themselves since they are equal one another but different from those previously observed. The strategy is thus to focalise on the classes of the partition, taking only account of similarities and dissimilarities among traces.

2 The two-parameter Poisson-Dirichlet distribution

The two-parameter Poisson Dirichlet distribution [8], is a distribution over the infinite simplex of the form $\nabla_\infty = \{(p_1, p_2, ...) \mid p_1 \geq p_2 \geq ... > 0, \sum p_i = 1\}$. It has two parameters, $\alpha \in [0,1)$, and $\theta > -\alpha$ and operatively can be constructed in two steps by sorting the well-known GEM(α, θ) [5] also known as 'stick breaking prior'. One of the interesting feature of PD is its ability to represent different power-law distributions. By assuming that there is an infinite number of different characteristics, that their ordered frequencies follow a two-parameter PD distribution, and that the database is an i.i.d. sample from $\mathbf{p}$,

$$\mathbf{P} \mid \alpha, \theta \sim \mathrm{PD}(\alpha, \theta), \quad I_1, \ldots, I_n \mid \mathbf{P} = \mathbf{p} \sim_{\text{i.i.d}} \mathbf{p} \tag{3}$$

then, for all $n \in \mathbb{N}$, the random partition $\Pi_{[n]} = \Pi_{[n]}(I_1, ..., I_n)$ has the following distribution:

$$\Pr(\Pi_{[n]} = \pi_{[n]} | \alpha, \theta) = \frac{[\theta + \alpha]_{k-1;\alpha}}{[\theta + 1]_{n-1;1}} \prod_{i=1}^{k} [1 - \alpha]_{n_i - 1;1}, \tag{4}$$

where $\forall x, b \in \mathbb{R}, a \in \mathbb{N}$, $[x]_{a;b} := \begin{cases} \prod_{i=0}^{a-1}(x + ib) & \text{if } a \in \mathbb{N}\backslash\{0\} \\ 1 & \text{if } a = 0 \end{cases}$, and n_i is the size of the ith class of $\pi_{[n]}$.

Relation (4), known as the *Pitman sampling formula* [6], will be used as likelihood for deriving inference for α and θ by using an MCMC scheme.

There is an alternative characterization of this model, called "Chinese restaurant process", studied in detail in [7]. It is defined as follows: consider a restaurant with infinitely many tables, each one infinitely large. Let $S_1, S_2, ...$ be integer-valued random variables representing the seating plan of the restaurant: tables are ranked in order of first occupancy: $S_i = j$ means that the ith customer seats at the jth table. The process is described by the following conditional probabilities:

$$S_1 = 1, \qquad \Pr(S_{n+1} = j | S_1, ..., S_n) = \begin{cases} \dfrac{\theta + k\alpha}{n + \theta} & \text{if } j = k + 1 \\ \dfrac{n_j - \alpha}{n + \theta} & \text{if } 1 \leq j \leq k \end{cases} \tag{5}$$

where k is the number of tables occupied by the first n customers, and n_j is the number of customers already occupying table j. The process depends on two parameters α and θ constrained as the PD parameters. Clearly $S_1, ..., S_n$ are not i.i.d., nor exchangeable but in [7] it is shown that $\Pi_{[n]}(S_1, ..., S_n)$ is distributed as $\Pi_{[n]}(I_1, ..., I_n)$, with $I_1, ..., I_n$ defined by (3) and they are distributed according to the Pitman sampling formula (4).

3 Likelihood ratio

Reducing the data to partitions and assuming that the two-parameter Poisson Dirichlet distribution models the ordered frequencies of the (infinite) characteristics, the LR in (1) can be defined and derived as follows:

$$\begin{aligned}
\mathrm{LR} &= \frac{p(\pi_{[n+2]} \mid h_p)}{p(\pi_{[n+2]} \mid h_d)} = \frac{p(\pi_{[n+2]}, \pi_{[n+1]} \mid h_p)}{p(\pi_{[n+2]}, \pi_{[n+1]} \mid h_d)} && \text{since } \pi_{[n+1]} \subset \pi_{[n+2]} \\
&= \frac{p(\pi_{[n+2]} | \pi_{[n+1]}, h_p) p(\pi_{[n+1]} \mid h_p)}{p(\pi_{[n+2]} | \pi_{[n+1]}, h_d) p(\pi_{[n+1]} \mid h_d)} \\
&= \frac{1}{p(\pi_{[n+2]} \mid \pi_{[n+1]}, h_d)} && \text{since } \Pi_{[n+1]} \perp\!\!\!\perp H \text{ and } p(\pi_{[n+2]} | \pi_{[n+1]}, h_p) = 1 \\
&= \frac{1}{\int p(\pi_{[n+2]} | \pi_{[n+1]}, \alpha, \theta, h_d) p(\alpha, \theta | \pi_{[n+1]}, h_d) d\theta d\alpha} \\
&= \frac{1}{\int \frac{1-\alpha}{n+1+\theta}\, p(\alpha, \theta \mid \pi_{[n+1]}, h_d) d\alpha d\theta} && \text{by (5)}
\end{aligned} \tag{6}$$

Note that under h_p the $n+2$-th and the $n+1$th characteristics are equal with probability 1. Result (6) is formally reminiscent of the likelihood ratio employed in usual forensic identification, whenever the same characteristic is observed from the crime's and the suspect's trace. There, the crucial quantity – to be integrated with respect to the posterior distribution of unknown parameters – is the probability of observing the suspect's evidence given the database enlarged with the crime trace, under the defense hypothesis [3]. Changing glasses, we now integrate, with respect to the posterior of the Poisson Dirichlet parameters, the event of observing the $n+2$-th profile, identical to the $n+1$th, both never observed before. Using a prior PD, the probability of this event, conditionally to the model parameters is provided by (5) (bottom line with $n_i = 1$) and is equal to $\frac{1-\alpha}{n+1+\theta}$. Also, from (6), it is apparent the crucial role played by the posterior of α and θ, obtained by conditioning on $\pi_{[n+1]}$. This motivates our interest in studying inference on the PD parameters.

4 MCMC inference

For a budget of T simulations, Algorithm 1 summarizes the implementation of the Metropolis-Hastings inference for the parameters (α, θ) of the Poisson Dirichlet distribution, conditionally to an observed random partition $\pi_{[n]}$.

Algorithm 1 MH

for $t = 1, ..., T$ **do**
  Propose a θ_{t+1}, α_{t+1} from $p(\theta_{t+1}|\theta_{t^*})p(\alpha_{t+1}|\alpha_{t*})$
  Evaluate the ratio $R = \frac{\ell(\theta_{t+1},\alpha_{t+1};\pi_{[n]})}{\ell(\theta_{t^*},\alpha_{t^*};\pi_{[n]})} \frac{p(\theta_{t+1})}{p(\theta_{t^*})} \frac{p(\alpha_{t+1})}{p(\alpha_{t^*})} \frac{p(\theta_{t^*}|\theta_{t+1})}{p(\theta_{t+1}|\theta_{t^*})} \frac{p(\alpha_{t^*}|\alpha_{t+1})}{p(\alpha_{t+1}|\alpha_{t^*})}$
  Accept θ_{t+1} with probability R
end for

In particular, we propose as prior for θ: $\theta \sim U(0, \theta_{max})$ and $p(\theta_{max}|\theta_0, \tau) = \tau\theta_0^{\tau}(\theta^{-\tau-1})$, a Pareto$(\theta_0, \tau)$. This requires to express a prior opinion on θ_0, the smallest value that θ_{max} can assume. As prior for α: $\alpha \sim \text{Unif}(0,1)$.

The proposal distribution for θ is $\theta_{t+1} \mid \theta_{t^*} \sim \text{Exp}(\frac{1}{\theta_{t^*}})$, so the mean of the proposal distribution is equal to the last accepted θ_{t^*}. The proposal for α is a reflecting random walk to take into account that $\alpha \in [0,1]$.

5 A simulated example

To derive inference for the two parameters we explore two methods:

1. MLE estimators $\widehat{\alpha}_{\text{MLE}}$ and $\widehat{\theta}_{\text{MLE}}$ obtained by using the Pitman's sampling formula (4).
2. the Metropolis Hasting method described in Section 4 that provides a sample from the posterior of α and θ given an observed partition of size $\pi_{[n]}$.

The likelihood ratio of formula (6) can be obtained by plugging-in the MLE estimates for method 1, or by Montecarlo approximation using the MCMC sample, for method 2.

In order to compare the two approaches, we apply them to observed partitions obtained from two distinct populations that are distributed according to the two-parameter Poisson Dirichlet with known parameters. This allows us to concentrate on the quality of the

inference and intentionally avoid the influence of possible model mi-specification. More specifically, we create two distinct populations of size $N = 10^6$ using the Chinese Restaurant process (5), then we draw a sample of size $n = 1000$ for each population, and obtain the corresponding partition $\pi_{[1000]}$. The true parameters of each population and the MLE estimators are shown in Table 1.

	True values		MLE		MCMC specifications				Effective sample size	
	α	θ	α_{MLE}	θ_{MLE}	n. iterations	thinning	burn-in	accepted	α	θ
Example 1	0.5	20	0.48	19.37	10^6	50	75'000	18'500	44'893.88	54'257.52
Example 2	0.2	2	7×10^{-7}	3.57	10^6	80	100'000	11'250	32'075.81	56'373.49

Table 1 Values of α and θ used to simulate two populations of size $N = 10^6$ along with the MLE for α and θ, obtained from a i.i.d sample of size $n = 1000$ reduced in form of partition. The specifications of the Metropolis Hasting algorithm are also displayed, along with the effective sample size.

To stress the inferential procedures, the partition sample of the first example (from Population 1) is very close to the average partition obtained by repeatedly applying the simulation process. On the opposite, the partition sample of the second example (from Population 2) is more "pathological", since it is quite different from the average partition. In particular, it is outstanding with regard to the number of singletons observations (only two) and of duplets (four). This heterogeneity allows us to have an insight into the robustness of the two methods over "extreme" observations from the population. As expected, in the second example the MLE provides a weak inference. The Metropolis Hasting algorithm is used with $S = 10^6$ iterations: burn-in and thinning interval are assessed by using the diagnostic tests of the R package `coda` (see Table 1).

Figure 1 shows the MLE estimates and true values along with the posterior distributions of $\alpha, \theta \mid \pi_{[n+1]}$ obtained with MH with 95% credible intervals. In the first example, both methods provide good inference for α and θ, while in the second case, with the pathological partition, MLE is practically useless for α and bad for θ. The MCMC approach, even though not optimal, represents an improvement, since at least the true values for α and θ are reached by the credible intervals. The same considerations can be made regarding LR values (last column of Figure 1).

6 Conclusions

At first glance, the rare type match problem appears as an odd issue. Actually the "not yet observed" condition is very common also with the most widespread forensic identification evidence, the autosomal DNA-STR profiles. Indeed, if considered as whole profiles, they are often unique and only resorting to some independence assumptions it is possible, to consider each locus separately. In other circumstances, if such forms of independence do not hold, as it happens for the Y-STR profiles or for non-genetic characteristics, the rare type match problem remains a common and challenging issue. Our proposal is very general and only relies on a few conditions, such as the existence of a high number of different modalities for the considered characteristic and their power-law behavior. For the Y-STR rare type match problem, [1] proposed a different solution that does not reduce data to a partition but makes use of some genetic assumptions and the knowledge of some population parameters (such as mutation rates, and IBD parameters). In the future, it will be interesting to compare their approach with ours. Other areas of application concern important qualitative evidence used in forensic science for identification, such as glass

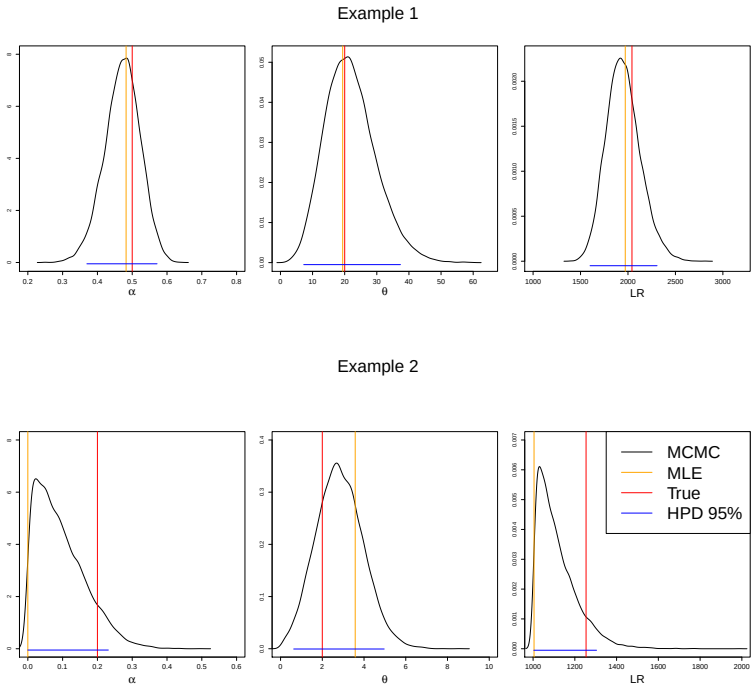

Fig. 1 Comparison of the inference provided by MCMC simulation and MLE. The first column corresponds to inference for α, the second column for θ, and the third column to the LR values obtained by plugging in MLE estimate or by Montecarlo approximation of the integral. The vertical lines represent the true value (red) and the MLE estimates (orange). The credible intervals with probability 95% of the distribution obtained through MH are also displayed through horizontal blue segments.

fragments and tire marks. Many efforts have been devoted to solve the rare type match problem in these areas, see [4] and we hope our contribution would be helpful.

A new prior distribution on the simplex: the extended flexible Dirichlet

Una nuova distribuzione a prior sul simplesso: l'extended flexible Dirichlet

Roberto Ascari, Sonia Migliorati and Andrea Ongaro

Abstract The Dirichlet is a very popular prior distribution for the multinomial's probability vector parameter, due to its simplicity. Nonetheless, the Dirichlet density function cannot model many reasonable shapes (i.e. multi-modalities and/or positive covariances). This work aims to perform a preliminary study of the extended flexible Dirichlet (EFD) as a possible prior distribution. In particular, we show that the EFD prior is conjugate to the multinomial scheme and explain how the hyper-parameters change once a sample is observed.

Abstract *La distribuzione Dirichlet è spesso utilizzata come distribuzione a priori per il vettore di probabilità di una distribuzione multinomiale. Nonostante la sua semplicità, la funzione di densità della Dirichlet non riesce a modellare molti fenomeni che possono prensentarsi (ad esempio, multi-modalità e/o covarianze positive). L'obiettivo di questo lavoro è quello di condurre uno studio preliminare della distribuzione extended flexible Dirichlet (EFD) come possibile alternativa. In particolar modo, andremo a dimostrare che la EFD è una distribuzione a priori coniugata alla multinomiale e spiegheremo come gli iperparametri vengono aggiornati tramite le osservazioni campionarie.*

1 Introduction

The Dirichlet distribution is the most widespread prior distribution for parameters defined on the D-part simplex $\mathscr{S}^D$. It provides a convenient conjugate prior for Bayesian analyses involving multinomial proportions (e.g. in population genetics studies [3] or in modeling the proportion of people suffering from a disease [6]). In addition, it represents the standard prior for the mixing weights within mixture models [4]. More recently it is often encountered in the context of topic modeling in natural language processing, where it's commonly used as part of a latent Dirichlet allocation (LDA) model [1, 2]. Nonetheless, the Dirichlet has several drawbacks mainly due to its poor parameterization. In particular, variances are forced to be proportional to the corresponding means. Moreover, it cannot model multi-modalities and/or positive covariances.

Aim of this work is to explore the performance of the extended flexible Dirichlet (EFD) [5] as a prior distribution for parameters defined on the simplex. The EFD is an identifiable finite mixture with Dirichlet components, i.e.:

$$\text{EFD}(\boldsymbol{\theta};\boldsymbol{\alpha},\boldsymbol{\tau},\mathbf{p}) = \sum_{r=1}^{D} p_r \text{Dir}(\boldsymbol{\theta};\boldsymbol{\alpha}+\tau_r\mathbf{e}_r), \tag{1}$$

where $\text{Dir}(\cdot;\boldsymbol{\alpha})$ denotes the Dirichlet distribution with parameter $\boldsymbol{\alpha}$, $\boldsymbol{\theta}$ and $\mathbf{p}$ lie in $\mathscr{S}^D$, $\boldsymbol{\alpha} = (\alpha_1,\ldots,\alpha_D)^\intercal$, $\boldsymbol{\tau} = (\tau_1,\ldots,\tau_D)^\intercal$, $\alpha_r > 0$, $\tau_r > 0$, $r = 1,\ldots,D$, and $\mathbf{e}_r$ is a vector of zeros except for the r-th element which is equal to one. Its probability density function (p.d.f.) can be written as:

$$f_{\boldsymbol{\theta}}(\boldsymbol{\theta};\boldsymbol{\alpha},\boldsymbol{\tau},\mathbf{p}) = \left(\prod_{r=1}^{D}\frac{\theta_r^{\alpha_r-1}}{\Gamma(\alpha_r)}\right)\sum_{i=1}^{D} p_i \frac{\Gamma(\alpha^+ + \tau_i)\Gamma(\alpha_i)}{\Gamma(\alpha_i+\tau_i)}\theta_h^{\tau_i} \tag{2}$$

where $\alpha^+ = \sum_{r=1}^{D}\alpha_r$.

The Dirichlet is obtained as special case of the EFD distribution setting:

$$\begin{cases} \tau_r = 1 \\ p_r = \bar{\alpha}_r = \frac{\alpha_r}{\alpha^+} \end{cases} \qquad r = 1,\ldots,D. \tag{3}$$

Adding the equality $\alpha_r = 1$, $r = 1,\ldots,D$, to conditions (3), it is possible to obtain a uniform distribution on $\mathscr{S}^D$, meaning that the EFD can be used as weakly informative prior.

The mixture component means can be written as:

$$\boldsymbol{\lambda}_r = \frac{\boldsymbol{\alpha}+\tau_r\mathbf{e}_r}{\alpha^+ + \tau_r} = \frac{\alpha^+}{\alpha^+ + \tau_r}\bar{\boldsymbol{\alpha}} + \frac{\tau_r}{\alpha^+ + \tau_r}\mathbf{e}_r, \qquad r = 1,\ldots,D. \tag{4}$$

From Equation (4) it is possible to observe that each component mean can be expressed as a weighted mean of two vectors: a common barycenter $\bar{\boldsymbol{\alpha}} = \boldsymbol{\alpha}/\alpha^+$ and one vertex of the simplex. Each τ_r affects only the r-th cluster barycenter: the higher

τ_r the closer $\boldsymbol{\lambda}_r$ to $\mathbf{e}_r$. An example of component mean configuration with $D = 3$ is given in Figure 1 (dashed lines): given $\bar{\boldsymbol{\alpha}}$ (red square), when τ_r varies each $\boldsymbol{\lambda}_r$ can lie on the dashed segment joining the corresponding vertex $\mathbf{e}_r$ and $\bar{\boldsymbol{\alpha}}$.

The first two moments of the EFD have the form:

$$\mathbb{E}[X_i] = \alpha_i k_1 + \tau_i \frac{p_i}{\alpha^+ + \tau_i}, \tag{5}$$

$$\mathrm{Var}(X_i) = \alpha_i^2(k_2 - k_1^2) + \frac{p_i\tau_i(2\alpha_i + \tau_i + 1)}{(\alpha^+ + \tau_i)(\alpha^+ + \tau_i + 1)} + \alpha_i k_2 - \frac{p_i^2\tau_i^2}{(\alpha^+ + \tau_i)^2} - k_1\frac{2\alpha_i p_i \tau_i}{\alpha^+ + \tau_i}, \tag{6}$$

$$\begin{aligned}\mathrm{Cov}(X_i, X_l) = \alpha_i\alpha_l(k_2 - k_1^2) - \frac{p_i p_l \tau_i \tau_l}{(\alpha^+ + \tau_i)(\alpha^+ + \tau_l)} + \\ + \frac{\alpha_i p_l \tau_l}{\alpha^+ + \tau_l}\left(\frac{1}{\alpha^+ + \tau_l + 1} - k_1\right) + \frac{\alpha_l p_i \tau_i}{\alpha^+ + \tau_i}\left(\frac{1}{\alpha^+ + \tau_i + 1} - k_1\right),\end{aligned} \tag{7}$$

$(i, l = 1, \ldots, D, i \neq l)$ where: $k_1 = \sum_{r=1}^{D} \frac{p_r}{\alpha^+ + \tau_r}$ and $k_2 = \sum_{r=1}^{D} \frac{p_r}{(\alpha^+ + \tau_r)(\alpha^+ + \tau_r + 1)}$.

An analysis of these expressions shows two very interesting properties of the EFD, i.e. variances are not necessarily proportional to the corresponding means, and covariances may take positive values. This overcomes some of the major drawbacks of the Dirichlet distribution. In particular, note that positive correlations on the simplex can be useful in many scenarios, e.g. modelling topic correlation in LDA [1, 2].

2 EFD as prior for the multinomial model

Let us now focus on the basic, but very widespread, multinomial scheme. Suppose we observe a sample $\mathbf{x} = (\mathbf{x}_1, \ldots, \mathbf{x}_N)^\intercal$ from $\mathbf{X}_j|\boldsymbol{\theta} \sim \mathrm{Multinomial}(n_j, \boldsymbol{\theta})$, $j = 1, \ldots, N$. Then, the likelihood function is defined as:

$$f_{\mathbf{X}|\boldsymbol{\theta}}(\mathbf{x}) = \left(\prod_{j=1}^{N} \frac{n_j!}{x_{1j}! \ldots x_{Dj}!}\right)\left(\prod_{r=1}^{D} \theta_r^{\sum_{j=1}^{N} x_{rj}}\right). \tag{8}$$

Let $x_r^+ = \sum_{j=1}^{N} x_{rj}$, $\mathbf{x}^+ = (x_1^+, \ldots, x_D^+)^\intercal$ and $n^+ = \sum_{j=1}^{N} n_j$. We can select an $\mathrm{EFD}(\boldsymbol{\alpha}, \boldsymbol{\tau}, \mathbf{p})$ prior distribution for $\boldsymbol{\theta}$. Then, it is possible to write the posterior p.d.f. $f_{\boldsymbol{\theta}|\mathbf{x}}(\boldsymbol{\theta})$ as:

$$f_{\boldsymbol{\theta}|\mathbf{x}}(\boldsymbol{\theta}) = \left(\prod_{r=1}^{D} \frac{\theta_r^{\alpha_r + x_r^+ - 1}}{\Gamma(\alpha_r + x_r^+)}\right) \sum_{i=1}^{D} \frac{p_i^*}{p_+^*} \frac{\Gamma(\alpha^+ + n^+ + \tau_i)\,\Gamma\left(\alpha_i + x_i^+\right)}{\Gamma\left(\alpha_i + x_i^+ + \tau_i\right)} \theta_i^{\tau_i} \tag{9}$$

where $p_i^* = p_i \dfrac{(\alpha_i+\tau_i)^{[x_i^+]}}{(\alpha^+ + \tau_i)^{[n^+]}\alpha_i^{[x_i^+]}}$, $p_+^* = \sum_{r=1}^D p_r^*$, and $\alpha^{[x]} = \Gamma(\alpha+x)/\Gamma(\alpha)$. Equation (9) shows that the posterior is still an EFD distribution, so that the EFD is a conjugate prior for the multinomial likelihood. Specifically, we have:

$$\boldsymbol{\theta}|\mathbf{x} \sim \mathrm{EFD}(\boldsymbol{\alpha}+\mathbf{x}^+, \boldsymbol{\tau}, \mathbf{p}^*/p_+^*). \tag{10}$$

From (10) it is possible to make some considerations regarding the upgrade of the hyper-parameters. The sample updates the parameters $\boldsymbol{\alpha}$ and $\mathbf{p}$, whereas $\boldsymbol{\tau}$ is left unchanged. The parameter $\boldsymbol{\alpha}$ is updated exactly in the same way as the parameter of the Dirichlet. To understand prior to posterior modification induced by this parameter, it is convenient to derive the updated mean of the mixture components, i.e.:

$$\begin{aligned}
\boldsymbol{\lambda}_r^* &= \frac{\boldsymbol{\alpha}+\mathbf{x}^+ + \tau_r \mathbf{e}_r}{\alpha^+ + n^+ + \tau_r} \\
&= \frac{\alpha^+}{\alpha^+ + n^+ + \tau_r}\bar{\boldsymbol{\alpha}} + \frac{\tau_r}{\alpha^+ + n^+ + \tau_r}\mathbf{e}_r + \frac{n^+}{\alpha^+ + n^+ + \tau_r}\bar{\mathbf{x}}^+ \\
&= \frac{\alpha^+ + \tau_r}{\alpha^+ + \tau_r + n^+}\boldsymbol{\lambda}_r + \frac{n^+}{\alpha^+ + \tau_r + n^+}\bar{\mathbf{x}}^+
\end{aligned} \tag{11}$$

where $\bar{\mathbf{x}}^+ = \mathbf{x}^+/n^+$. The posterior mixture component mean vector can be expressed as a weighted average of the prior $\boldsymbol{\lambda}_r$ and the sample barycenter $\bar{\mathbf{x}}^+$. Thus, the $\boldsymbol{\lambda}_r^*$'s lie on the solid lines (as n^+ varies) displayed in Figure 1 . Here and in the following figures we set $D = 3$ to facilitate graphical representations.

The behavior of the posterior mixing weights $\mathbf{p}^*/p_+^*$ is more intricate and it can be best understood through a graphical analysis. Figures 2, 3 and 4 illustrate how the posterior mixing weights $\mathbf{p}^*/p_+^*$ depend on sample quantities.

Figure 2 is obtained increasing n^+ and computing $\mathbf{x}^+ = n^+ \cdot \bar{\mathbf{x}}^+$. From the right panel it emerges that increasing n^+ makes the component mean closest to $\bar{\mathbf{x}}^+$ to augment its posterior weight.

Figures 3 and 4 study the posterior weights behavior for various x_r^+. In general each weight p_r^*/p_+^* depends increasingly on the corresponding x_r^+, given the other x_i^+, $i \neq r$. This is shown in Figure 3, where x_3^+ has been fixed to 50. Furthermore, in Figure 4 the weights p_r^*/p_+^* $(r = 1,2)$ are plotted as functions of x_1^+ and x_2^+/x_1^+, still for given x_3^+. This choice serves to evidentiate the further feature that for large values of x_1^+ the weights depend essentially only on the ratio x_2^+/x_1^+.

The obtained results seem to indicate that the EFD displays an interesting behavior in terms of interpretability and dependence, and suggest that a deeper analysis of this prior is worth to be undertaken.

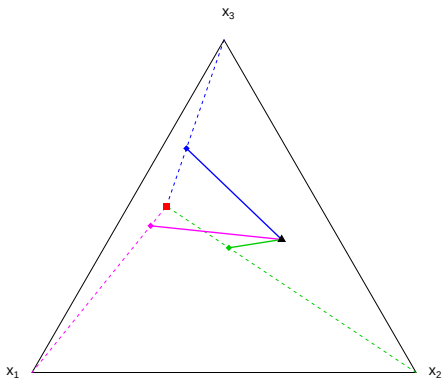

Fig. 1 Dashed lines represent the set of points where $\boldsymbol{\lambda}_r$'s can lie, solid lines represent the set of points where the $\boldsymbol{\lambda}_r^*$'s can lie ($r = \{1,2,3\}$). Colored diamonds represent $\boldsymbol{\lambda}_1$ (violet), $\boldsymbol{\lambda}_2$ (green) and $\boldsymbol{\lambda}_3$ (blue) with $\boldsymbol{\alpha} = (12,3,15)^\intercal$ (red square), $\boldsymbol{\tau} = (4,10,16)^\intercal$ and $\mathbf{x} = (0.15,0.45,0.4)^\intercal$ (black triangle).

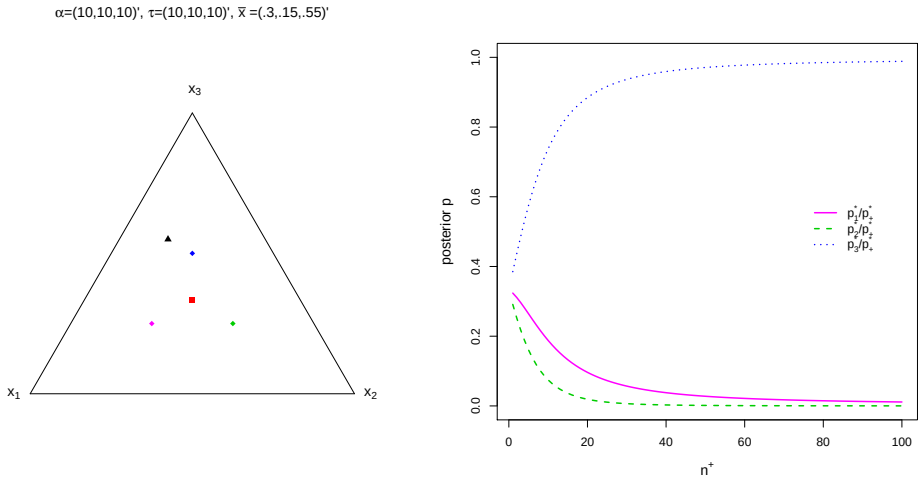

Fig. 2 Posterior mixing weights p_r^*/p_+^* as function of n^+. $\mathbf{p}$ is fixed equal to $(1/3,1/3,1/3)^\intercal$.

ABC model choice via mixture weight estimation

ABC model choice mediante stima del peso di mistura

Gianmarco Caruso, Luca Tardella, Christian P. Robert

Abstract Approximate Bayesian Computation (ABC) methods are widely employed to obtain approximations of posterior distributions without having to calculate likelihood functions. Nevertheless, the general impossibility to find statistics which are sufficient across models leads to unreliability of the classical tools for ABC model choice. To overcome this issue, a different kind of modelling is here proposed by replacing the traditional comparison between posterior probabilities of candidate models with posterior estimates of the weights of a mixture of these models. A simulation study highlights several strengths of this alternative approach, presenting it as a robust and flexible extension of the classical one.

Abstract *I metodi di ABC (*Approximate Bayesian Computation*) sono largamente utilizzati per ottenere approssimazioni di distribuzioni a posteriori senza dover calcolare funzioni di verosimiglianza. Tuttavia, in generale, non è possibile trovare statistiche che siano sufficienti tra modelli e ciò rende poco attendibili gli strumenti classici su cui si basa l'*ABC model choice*. Al fine di superare tale problema, si propone di rimpiazzare il tradizionale confronto tra probabilità a posteriori dei modelli candidati con la stima a posteriori dei pesi di una mistura di tali modelli. Uno studio di simulazione mette in luce diversi punti di forza di questo approccio alternativo, presentandolo come una robusta e flessibile estensione di quello classico.*

1 Introduction

In the last decades, *Approximate Bayesian Computation* (ABC, henceforth) methods have become popular as a class of likelihood-free algorithms which aim to draw samples from an approximate posterior distribution, in the cases where the likelihood is unavailable or intractable, but it is still possible to generate data from the corresponding distribution.
Suppose to observe a sample $\mathbf{y} = (y_1, \ldots, y_n)$ of realizations from iid random variables Y_i, $i = 1, \ldots, n$, with a (*complex*) density $p(\cdot|\theta)$, where θ is an unknown parameter of interest with prior distribution $\pi(\theta)$. In order to sample from an approximate posterior distribution of θ, one can use a basic version of ABC rejection sampling algorithm (Pritchard et al. 1999): the idea is to draw iid parameter values $\theta_1^*, \ldots, \theta_N^*$ from $\pi(\theta)$, and to use each of these values to generate a synthetic sample of iid pseudo-observations, $\mathbf{z}$, from the sampling distribution $p(\cdot|\theta)$. If $\mathbf{z}$ is *similar* to the observed data $\mathbf{y}$, the corresponding θ^* is accepted as a value generated from the posterior distribution $\pi(\theta|\mathbf{y})$.
The concept of *similarity* between two datasets is expressed by three tools: a vector of statistics (or *summaries*), a distance and a tolerance threshold. The vector of summaries $\eta(\cdot) = \big(\eta_1(\cdot), \ldots, \eta_k(\cdot)\big)$ is used to summarise the information contained in a dataset, so that a pair of vectors of k statistics is compared instead of a pair of vectors of n observations (being $k \ll n$). This vector of statistics is most often not sufficient, but the consequent loss of information is tolerated with the idea to avoid the *curse of dimensionality* and to reduce the running time of the ABC algorithms. The distance $\rho(\cdot)$ quantifies how much $\eta(\mathbf{z})$ is close to $\eta(\mathbf{y})$. The threshold ε allows to accept all the θ^*'s which generate datasets whose associated vector of summaries is *close enough* to the observed vector of summaries. Therefore, the posterior sample is generated from $\pi\big(\theta\big|\rho(\eta(\mathbf{y}), \eta(\mathbf{z})) < \varepsilon\big)$ as surrogate of $\pi(\theta|\mathbf{y})$: the more informative the vector of statistics $\eta(\mathbf{y})$ and the smaller ε, the better the approximation.

1.1 Classical ABC model choice and drawbacks

When M models are compared, one considers the model index $\mathscr{M}$ as an additional unknown parameter, with prior distribution $\pi(\mathscr{M} = m)$, $m = 1, \ldots, M$ (Grelaud et al. 2009). The classical ABC model choice algorithm is summarised in **Algorithm 1**.

Algorithm 1 classical ABC model choice (ABC-mc)

for $i = 1$ to N **do**
  repeat
    Generate m^* from the prior $\pi(\mathscr{M} = m)$
    Generate $\theta_{m^*}^*$ from the prior $\pi_{m^*}(\cdot)$
    Generate $\mathbf{z}$ from the sampling distribution $p_{m^*}\Big(\cdot\Big|\theta_{m^*}^*\Big)$
  until $\rho\big(\eta(\mathbf{z}), \eta(\mathbf{y})\big) < \varepsilon$
  Set $m^{(i)} = m^*$ and $\theta_i = \theta^*$
end for

The posterior probability of model m can be estimated with the frequency of acceptances from model m, namely $\hat{\pi}_\varepsilon(\mathscr{M}=m|\mathbf{y}) = \frac{1}{N}\sum_{i=1}^{N}\mathbb{I}(m^{(i)}=m)$, while $\hat{B}_{12,\varepsilon}(\mathbf{y}) = \frac{\pi(\mathscr{M}=2)}{\pi(\mathscr{M}=1)}\frac{\sum_{i=1}^{N}\mathbb{I}(m^{(i)}=1)}{\sum_{i=1}^{N}\mathbb{I}(m^{(i)}=2)}$ can be used to approximate the Bayes Factor (BF),

$$B_{12}(\mathbf{y}) = \int_{\Theta_1} p_1(\mathbf{y}|\theta_1)\pi_1(\theta_1)\,d\theta_1 \Bigg/ \int_{\Theta_2} p_2(\mathbf{y}|\theta_2)\pi_2(\theta_2)\,d\theta_2\,, \tag{1}$$

where $p_m(\mathbf{y}|\theta)$ is the likelihood function associated with the m-th model, $m = 1,2$. These approximations are valid as long as identical summaries, distance and tolerance threshold are used over both models.
Robert et al. (2011) thoroughly investigate the drawbacks of model choice in ABC. First of all, they show that the approximated BF, $\hat{B}_{12}(\mathbf{y})$, converges to the BF based on the vector of observed statistics, $\eta(\mathbf{y})$,

$$B^{\eta}_{12}(\mathbf{y}) = \int \pi_1(\theta_1)p_1^{\eta}\big(\eta(\mathbf{y})|\theta_1\big)\,d\theta_1 \Bigg/ \int \pi_2(\theta_2)p_2^{\eta}\big(\eta(\mathbf{y})|\theta_2\big)\,d\theta_2\,, \tag{2}$$

as ε goes to zero. This quantity is only based on the observed vector of statistics and, therefore, insufficient statistics yield a BF which converges to a quantity different from (1). Even in the favourable case where $\eta(\mathbf{y})$ is sufficient for both models, sufficiency *across* models can be hardly obtained and this leads to a discrepancy between (2) and (1) which cannot be computed. Insufficiency of the statistics for models or across models is thus the main source of unreliability of the ABC model choice based on the estimated BF.

2 ABC model choice via mixture weight estimation

The lack of confidence on the classical ABC model choice may be solved by introducing a different kind of modelling: the idea is to replace the inference on the posterior probabilities of the models with the posterior estimate of the weights of a mixture of the candidate models. This approach is an extension to the ABC realm of the inferential procedure proposed by Kamary et al. (2014). Here one considers the case of two candidate models (i.e. $M = 2$) sharing an unknown parameter of interest θ which has a common meaning for both models.
One considers the data $\mathbf{y}$ as produced by a mixture of $\mathscr{M}_1$ and $\mathscr{M}_2$, namely

$$\mathscr{M}_w : \mathbf{y} \sim w\,p_1(\mathbf{y}|\theta) + (1-w)\,p_2(\mathbf{y}|\theta), \quad 0 \le w \le 1\,, \tag{3}$$

with θ following a prior distribution $\pi(\theta)$ and associated to the sampling distribution $p_w(\cdot|\theta)$. The parameters w and θ will be considered independent *a priori*. Notice that this mixture model is an *encompassing* model since it contains both models as special cases: for $w = 1$ it is equivalent to $\mathscr{M}_1$, while for $w = 0$ it is equivalent to $\mathscr{M}_2$. The weight w represents the probability that an observation is sampled from p_1, so that it may be interpreted as the proportion of data which support $\mathscr{M}_1$.

A posterior inference on w may then offer interesting information about which one of the two models is the most suitable according to the observed data as well as the degree of support of one model against the other.
Algorithm 2 shows the way the ABC rejection sampling algorithm is applied on this mixture model in order to estimate θ and w.

Algorithm 2 ABC model choice via mixture weight estimation (ABC-mix)

for $i = 1$ to N **do**
  repeat
    Generate θ^* and w^* from their respective prior distributions
    Generate $\mathbf{z}$ from the sampling distribution $p_{w^*}(\cdot|\theta^*)$ of the model $\mathscr{M}_{w^*}$
  until $\rho\left(\eta(\mathbf{z}),\eta(\mathbf{y})\right) < \varepsilon$
  set $w_i = w^*$ and $\theta_i = \theta^*$
end for

This kind of modelling has several advantages. First of all, a whole posterior distribution on w allows, *inter alia*, for posterior point estimates, region of credibility, quantification of the uncertainty on the results and sensitivity analysis. On the other hand, the BF offers poor information since it is merely a scalar which suggests which model is more adequate and the relative degree of evidence of models. In addition, in the case where a same scalar value provided by the BF may seek either a misspecification of both models or a general acceptance of both - perhaps suggesting a more cautious approach via model averaging -, this new model choice approach may allow to conclude that both models or none could be acceptable, in the sense that a mixture of them may be a better choice. In particular, Kamary et al. (2014) show that this approach leads to a consistent testing procedure, not only when one of the two models is the true one, but also when neither are correct, since the posterior on w tends to concentrate around the value which minimizes the Kullback-Leibler divergence from the true distribution. A further attractive feature of this approach is the fact that it allows for improper priors on θ, where the BF totally prohibits this kind of assumption.
A standard prior for w is a symmetric $Beta(a_0,a_0)$, with $a_0 \in \mathbb{R}^+$ representing the degree of uncertainty *a priori* about the fact that one of the two candidate models is indeed the true one. A small a_0 may offer a regularization tool, being most of the density placed around the boundary values 0 and 1. For $a_0 \downarrow 0$, the proposed values from the prior distribution of w tends to be only 0's and 1's, so that the ABC-mix behaves like the ABC-mc with symmetric prior probabilities on the models. In this sense, the ABC-mc may be substantially seen as a limiting case of the ABC-mix.

3 Simulation study

One considers the case of comparison between two models, that is, the α-stable distribution (Borak, Härdle, and Weron 2005) and the skew-Normal distribution (Azzalini 2013), where the common unknown parameter is the location one. A reparametrisation of the location parameter of the skew-Normal distribution is con-

sidered, so that θ corresponds to the first moment of the two families of distributions. One considers the case where both models are wrong, since the data are iid simulations from a skew-*t* distribution (Azzalini 2013) with expected value equal to 0. The likelihood of the α-stable model is not available in closed form but it is possible to simulate from this model: the inference on the unknown parameter θ and the model choice are thus carried out through ABC-mc and ABC-mix. *Fig. 1* shows that the approximated posterior density of θ provided by ABC-mc is vague and tends to recover the corresponding prior, while ABC-mix produces posterior density estimates which put their masses around 0, in most of the cases.

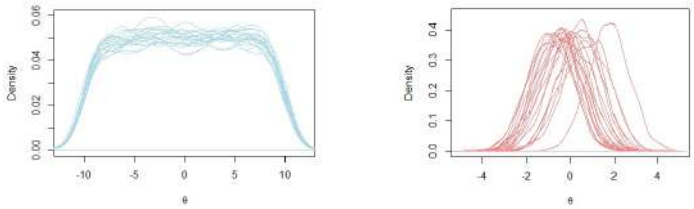

Fig. 1: Density estimate of the posterior distributions of θ *computed via ABC-mc* (left panel) *and ABC-mix* (right panel) *over* 20 *different datasets of* $n = 2000$ *iid samples from a skew-t with mean* $\theta = 0$*. Both algorithms are based on* 10^5 *simulations from* $\theta \sim Unif[-10,10]$*. The prior probabilities of the models are* 0.5 *(for ABC-mc) and* $w \sim Beta(0.5,0.5)$ *(for ABC-mix). The tolerance corresponds to an acceptance rate of* 0.01*. The distance used to measure the discrepancy between the observed and the j-th simulated vector of summaries (*$j = 1,\ldots,N$*) is* $\rho(\eta(\mathbf{y}),\eta(\mathbf{z}^j)) = \sum_{i=1}^{k} \frac{|\eta_i(\mathbf{z}^j)-\eta_i(\mathbf{y})|}{\text{mad}_{j=1}^{N}\eta_i(\mathbf{z}^j)}$*, where the denominator is the median absolute deviation (*mad*) of the i-th summary statistic over all the N simulations: this avoids a distance dominated by the variable with the greatest magnitude. The two summaries (i.e.* $k = 2$*) are the* mad*, which is a good option for ABC model choice (Marin et al. 2014), and the median.*

The difficulty for ABC-mc to provide reasonable posterior density estimates for θ can be understood by analysing the asymptotic behaviour of the posterior probability of the first model (i.e. the α-stable). In fact, *Fig. 2* shows that the posterior probability of the first model seems to converge to 0, by always supporting the second model. On the other hand, the weight of the first component of the mixture of the models, w, does not concentrate near one of the boundary values as the sample size increases. In particular, as n increases, the posterior medians of w tends to concentrate around 0.2, regardless of the prior specifications.

4 Conclusions

ABC-mix has shown better performances than ABC-mc when both models are misspecified, which is the most likely situation in real applications. ABC-mix behaves as a flexible extension of ABC-mc, since a tuning of the hyperparameter a_0 of the prior of the weight w offers a further dimension to the prior specification of the model. This allows to specify the degree of prior uncertainty about the true model and this may be useful as regularization tool or for carrying out sensitivity analysis.

A whole posterior on a mixture weight offers richer information than the one provided by the posterior probability of a model, it allows for measure of uncertainty on the estimates and it may lead to propose a mixture of the candidate models as better choice. Finally, it may be a valid solution to overcome the problem of insufficiency of the summary statistics *for* models and - above all - *across* models which dramatically affects the classical ABC model choice based on the BF.

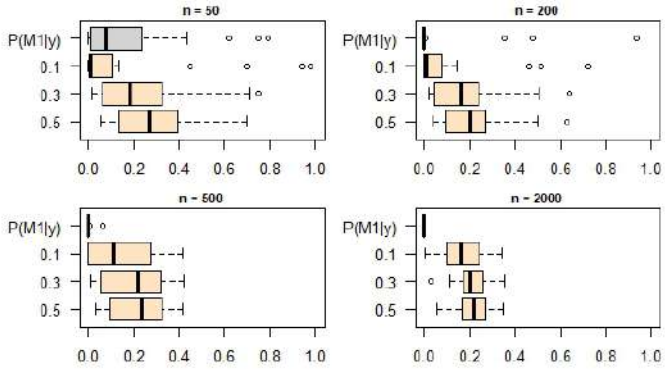

Fig. 2: Boxplot of the posterior medians of w for different values of a_0 (wheat) - *where* a_0 *is the hyperparameter of the prior* $Beta(a_0, a_0)$ *of w - and of the posterior probabilities* (grey) *of the* α*-stable model computed over* 20 *iid datasets from a skew-t with mean* $\theta = 0$ *for different sample sizes (*$n = 50, 100, 500, 2000$*). The posterior of w and the posterior probability of the first model have been estimated via ABC-mix and ABC-mc (respectively), both based on* 10^5 *simulations and an acceptance rate set to* 0.01.

An ABC algorithm for random partitions arising from the Dirichlet process

Un algoritmo ABC per partizioni aleatorie da un processo di Dirichlet

Mario Beraha and Riccardo Corradin

Abstract Dealing with latent random partitions might be a tedious task, due to mathematically and computationally tractability of the problem. We propose an approximate Bayesian computation (ABC) approach to deal with the estimation of random partitions latent in sets of exchangeable data. Furthermore, we present some preliminary simulation results of the novel proposal, investigating both the quality of the sample produced and the computational time required.

Abstract *Lavorare con partizioni aleatorie latenti può rivelarsi un compito impegnativo, a casua della intrattabilità, matematica e numerica, del problema. In questo lavoro, proponiamo un approccio ABC (Approximate Bayesian Computation) per stimare la partizione latente in una collezione di dati scambiabili. Presentiamo inoltre dei risultati preliminari su un esempio sintetico, dove investighiamo sia la qualità del'approssimazione prodotta e il costo computazionale.*

Key words: ABC, MCMC, random partition, Bayesian statistics

1 Introduction

Approximate Bayesian Computation (ABC) is a vibrant area of research that has been witnessing an exponential growth in the last decade. ABC provides a coherent methodology to deal with problems whose estimation can be intractable. We distinguish two main cases of intractability: when the problem is mathematically

intractable, e.g. when the likelihood is not available in analytical form, and when the problem is computationally intractable, i.e. it is not possible to provide an estimation in a reasonable time.

Although the ABC family encompasses a large variety of methods, in this work we are mainly concerns the class of ABC-MCMC algorithms, in the spirit of [7]. The goal of this methods is to perform Markov Chain Monte Carlo sampling from an invariant distribution sufficiently close to the posterior distribution of interest. The basic idea of ABC-MCMC is to replace the evaluation or sampling from intractable distributions with the calculation of a distance d between the observed data $\boldsymbol{y} = (y_1, \ldots, y_n)$ and a synthetic dataset $\boldsymbol{s} = (s_1, \ldots, s_n)$, generated from a surrogate model. Then, when the true and synthetic data are close, according to a metric d and with respect to a threshold ε, a Metropolis-Hastings step is performed.

The choice of the metric d and threshold ε is then crucial. Choosing the wrong distance or threshold may produce a chain that never moves from the initial state, while choosing a threshold too large may lead to sampling from a law that is very far from the posterior distribution of interest.

In this work, we derive an ABC-MCMC scheme to sample from the approximate law of the latent random partition $\boldsymbol{\rho}$ of a set of exchangeable observations $\boldsymbol{y} = (y_1, \ldots, y_n)$. We will show that, for a particular class of priors on the partitions, it is possible to obtain a proposal that leads to accepting all the values, as long as the distance of the synthetic data from the observed data is smaller than ε. Moreover, by choosing the Wasserstein metric as distance d, the random partition of $\boldsymbol{y}$ can be easily inferred from the random partition of the simulated data.

2 Exchangeable random partitions

The exchangeability assumption on the observed data, in the sense that the law of $\boldsymbol{y}$ is invariant with respect to permutations of the elements, plays a crucial role in our proposal. Furthermore, by assuming exchangeability for the data, the latent random partition $\boldsymbol{\rho}$ is exchangeable too. Let $[n] = \{1, 2, \ldots, n\}$ denotes a set of n integers. A partition of $[n]$ is a collection of non empty and mutually disjoints sets $\{C_1, \ldots, C_k\}$, i.e. $C_i \cap C_j = \emptyset$ for $i \neq j$ and such that $\cup_i C_i = [n]$.

By restricting our attention to the *exchangeable random partitions* cases, the probability distribution of $\boldsymbol{\rho}$ becomes a tractable object. From [8], a random partition $\boldsymbol{\rho}$ of the integers set $[n]$ is exchangeable if and only if $P(\boldsymbol{\rho} = \{C_i, \ldots, C_k\})$ depends on $\{C_i, \ldots, C_k\}$ only through the cardinalities of each block $n_i = |C_i|$, and there exists a symmetric function $\pi_k^{(n)}(n_1, \ldots, n_k)$ such that

$$P(\boldsymbol{\rho} = \{C_i, \ldots, C_k\}) = \pi_k^{(n)}(n_1, \ldots, n_k). \tag{1}$$

The function $\pi_k^{(n)}$ is termed *exchangeable partition probability function* (EPPF) and plays a key role in modern Bayesian nonparametric statistics.

We focus on random partitions structure arising from the Dirichlet process (DP), early introduced in [6], and we denote by ϑ its mass parameter. In this case, the EPPF has the following expression

$$\pi_k^{(n)}(n_1,\ldots,n_k) = \frac{\vartheta^k}{(\vartheta)_{(n)}}\prod_{i=1}^{k}(n_i-1)!, \tag{2}$$

where the $(\vartheta)_{(n)} = \vartheta(\vartheta+1)\ldots(\vartheta+n-1)$ denotes the Pochhammer symbol. Although an EPPF as in (2) can be extended in several directions, mainly to more general structures or to the partially exchangeable case. We furthermore denote by $\boldsymbol{\theta} \sim DP(\vartheta, G_0)$ a sample distributed as a DP with mass parameter ϑ and base measure G_0, such that the distribution of the latent random partition in $\boldsymbol{\theta}$ is fully described by (2).

3 The ABC-MCMC algorithm

Let $\boldsymbol{y}$ be a set of exchangeable observations, and consequentially the latent random partitions $\boldsymbol{\rho}$ object of interest is exchangeable as well. Common strategies to deal with exchangeable latent random partitions in a DP context mostly resort to MCMC methods, see for example [3] and the discussion within. We propose a simple algorithm, also from the implementation's point of view, with the drawback that it produces samples from an approximation of the posterior distribution. Nevertheless, we are able to control the degree of the approximation by varying the threshold parameter ε. The proposed algorithm is essentially an extension of the ABC-MCMC introduced in [7] to the random partition case, where we employ as proposal distribution $q(\boldsymbol{\theta} \to \boldsymbol{\theta}')$ the predictive law of $\boldsymbol{\theta}' \mid \boldsymbol{\theta}$, i.e.

$$P(\boldsymbol{\theta}' \mid \boldsymbol{\theta}) = P(\theta_1' \mid \boldsymbol{\theta})P(\theta_2' \mid \theta_1', \boldsymbol{\theta})\ldots P(\theta_n' \mid \theta_1', \ldots, \theta_{n-1}', \boldsymbol{\theta}), \tag{3}$$

where $P(\theta_i' \mid \theta_1', \ldots, \theta_{i-1}', \boldsymbol{\theta})$ denotes the generic predictive distribution for the i-th element, and by assuming a $DP(\vartheta, G_0)$ governing sequence of elements, it becomes

$$P(\theta_i' \in dt \mid \theta_1', \ldots, \theta_{i-1}', \boldsymbol{\theta}) = \frac{\vartheta}{\vartheta+n+i-1}G_0(dt) + \sum_{j=1}^{k}\frac{n_j}{\vartheta+n+i-1}\delta_{\theta_j^*}(dt), \tag{4}$$

where θ_j^* denotes the j-th unique element in $\{\boldsymbol{\theta}, \theta_1', \ldots, \theta_{i-1}'\}$ and n_j its frequency.

Observe that, similarly to Gibbs sampling step, this choice produces an acceptance rate α of the Metropolis-Hastings step equal to 1, indeed

$$\alpha = \min\left(1, \frac{P(\boldsymbol{\theta}')q(\boldsymbol{\theta} \to \boldsymbol{\theta}')}{P(\boldsymbol{\theta})q(\boldsymbol{\theta}' \to \boldsymbol{\theta})}\right) = \min\left(1, \frac{P(\boldsymbol{\theta}')P(\boldsymbol{\theta}' \mid \boldsymbol{\theta})}{P(\boldsymbol{\theta})P(\boldsymbol{\theta} \mid \boldsymbol{\theta}')}\right) = 1.$$

By exploiting a proposal distribution as in (4), we propose a partition that reflects a trade-off between the prior guess, expressed in terms of new values sampled from $G_0(\cdot)$, and the groups already observed in the previous state $\boldsymbol{\theta}$. With this particular choice, we encompass a problem commonly arising in the random partition framework, where a random sampling on the partitions' space leads most of the cases to get an unrepresentative element of the partition of the data.

As mentioned in the introduction section, a sensible choice to be made is the metric for the comparison of the observed and the synthetic data. Despite the multitude of possible distance known in literature, we assume the Wasserstein metric as distance d, in the spirit of [1, 2]. We refer to [10] for technical details and historical background on the Wasserstein distance. In our framework, we aim at comparing the two empirical distributions of observed and synthetic data, $\boldsymbol{y}$ and $\boldsymbol{s}$ respectively, with the same number of elements. Denoting by $W_q(\boldsymbol{y},\boldsymbol{s})$ the Wasserstein distance between the empirical distributions of $\boldsymbol{y}$ and $\boldsymbol{s}$, we have

$$W_q(\boldsymbol{y},\boldsymbol{s}) = \min_{P \in M_{n\times n}} \left(\sum_{i,j} |y_i - s_j|^q P_{ij} \right)^{1/q}, \tag{5}$$

where $M_{n\times n}$ denotes the set of matrices with size $n \times n$, non-negative entries, and with each row and column summing up to n^{-1}. For the framework considered, since $\boldsymbol{y}$ and $\boldsymbol{s}$ have the same number of elements, there exist a solution P^* to the optimization problem (5), which corresponds to a matrix with only one non-zero element for each row and for each column, see [2, 9] for further details. The matrix P^* describes also a permutation $\lambda : \mathbb{N}_n \to \mathbb{N}_n$ such that the distance between $\boldsymbol{y}$ and $\boldsymbol{s}_\lambda$ is minimized, where $\boldsymbol{s}_\lambda$ denotes the set of elements $\boldsymbol{s}$ reordered with respect to λ. Thus we use $\boldsymbol{\rho}_\lambda$, the partition of $\boldsymbol{\theta}'_\lambda$ latent parameters of the reordered vector $\boldsymbol{s}_\lambda$, as proposed elements in the ABC-MCMC algorithm.

Algorithm 1: ABC-MCMC

```
[1] Inizialize θ^(0) and ρ^(0);
[2] for each iteration r = 1,...,R do
[3]     propose a move from θ^(r−1) to θ' with proposal distribution q(θ^(r−1) → θ')
          according to (3) and (4);
[4]     sample s vector of synthetic data according to a kernel, S_i ~ k(s, θ'_i);
[5]     if W_q(y, s) ≤ ε then
[6]         accept ρ'_λ as new state and go to the next iteration;
[7]     else
[8]         go back to [3];
[9] end
```

In Algorithm 1 we report the pseudo-code for the implementation of a generic ABC-MCMC sampling scheme, proposing the synthetic data from a kernel function $k(s,\theta)$ and with proposal distribution according to (3) and (4). Due to the generality

of algorithm 1, the same procedure can be applied to either univariate and multivariate observed data $\boldsymbol{y}$ by setting an opportune kernel function $k(s,\theta)$.

4 Simulation study

In this paper, we report the results of a preliminary simulation study. We consider sets of simulated data $\boldsymbol{y} = y_1,\ldots,y_n$ coming from a mixture of equally weighted Gaussian components

$$y_i \overset{\text{iid}}{\sim} \frac{1}{3}\mathcal{N}(-5,1) + \frac{1}{3}\mathcal{N}(0,1) + \frac{1}{3}\mathcal{N}(5,1) \quad i = 1,\ldots,n,$$

and we compare the proposed ABC-MCMC algorithm with the marginal sampler for the Dirichlet mixture model (DPM) implemented in the R package `BNPMix` [4]. For both models, the point estimates of the partition were obtained the least square procedure described in [5]. In order to get a fair comparison, we set both the likelihood in the DPM $f(y \mid \theta)$ and the synthetic data generating kernel k in 1 to be the Gaussian density with parameters $\theta = (\mu,\sigma^2)$. We set as G_0 in (4) and the base measure in the DPM are the Normal-inverse-gamma prior with matching parameters. We consider four different sample sizes $n \in \{40,80,160,320\}$, and the study was replicated 100 times. Convergence of the chains was assessed by visual investigations of randomly selected replicates, without finding any indication against it.

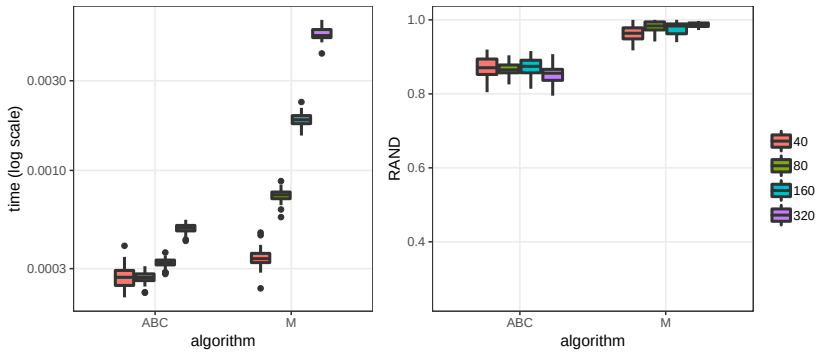

Fig. 1: Left plot: time for a single iteration (log-scale). Right plot: RAND index of the partition estimate from the posterior distribution and the true partition. Different sample sizes. In each plot a comparison of ABC-MCMC algorithm (ABC) and the marginal sampler (M). Results aggregated over 100 of replications.

Figure 1 reports the result of both algorithms. It is clear that the our model outperforms the marginal sampler in terms of time per iteration, while retaining a comparable ability to estimate the latent partition of the data.

5 Discussion and future work

In this work we presented an ABC-MCMC algorithm for the estimation of random partitions. The two main novelties in our approach were using the predictive law $P(\boldsymbol{\theta}' \mid \boldsymbol{\theta})$ as proposal distribution in the ABC algorithm and the use of Wasserstein metric to evaluate the distance of observed and synthetic data.

There are numerous criticalities to our approach that we want to address in the future. First of all, it remains unclear how to properly choose the parameter ε, the threshold value used to accept or discard a synthetic dataset. This threshold has an impact on the efficiency of our algorithm and we would like to derive a strategy to avoid its specification.

The second main question to be addressed is the extension to the multivariate setting. Although the theoretical development presented remains valid, computational issues may arise in the evaluation of the Wasserstein distance, and we aim to explore possible numerical approximate solutions to solve this step.

Out proposal is a first step in the direction to define a general ABC framework to random partitions, a key quantity in the Bayesian nonparametric setup. Indeed, although not explored here, we could use our ABC-MCMC algorithm to expand the range of application of the Bayesian nonparametric methodology to those models whose likelihood is intractable.

Bayesian Inference of Undirected Graphical Models from Count Data

Inferenza bayesiana di modelli grafici adirezionali da dati di conteggio

Pier Giovanni Bissiri, Monica Chiogna, Nguyen Thi Kim Hue

Abstract Bissiri et al. (2016) present a general Bayesian approach where the likelihood is replaced more generally by a loss function, which is used to derive the posterior distribution from the prior. In this paper, we exploit this idea for learning the structure of undirected graphical models over discrete variables.

Abstract *Bissiri et al. (2016) presentano un approccio bayesiano generalizzato in cui la verosimiglianza è sostituita da una funzione di perdita più generale, che viene utilizzata per derivare la distribuzione a posteriori dalla distribuzione a priori. In questo lavoro, l'approccio viene contestualizzato al problema di apprendimento della struttura di modelli grafici non direzionati per variabili discrete.*

1 General Bayes

Bissiri et al. (2016) propose a framework for general Bayesian inference which is based on the updating of a prior belief distribution to a posterior when the parameter of interest is connected to observations via a loss function rather than the traditional likelihood function, which is recovered as a special case. The parameter of interest θ_0 is the value minimizing the expected loss with respect to the unknown population probability distribution F_0 that generates the data. In other words, θ_0 minimizes the loss

$$\theta \in \Theta \to \int l(\theta, \mathbf{x}) \mathrm{d}F_0(\mathbf{x}), \tag{1}$$

where Θ denotes the parameter space and $l(\cdot, \mathbf{x})$ is a loss function on Θ for every piece of data $\mathbf{x}$.

From a classical perspective, a typical procedure for estimating the parameter θ is based on the minimization of the cumulative loss,

$$\sum_{i=1}^{n} l(\theta, \mathbf{x}_i) \tag{2}$$

where θ varies in Θ and $\mathbf{x}_1, \ldots, \mathbf{x}_n$ are the data. The loss (2) is clearly the finite sample version of $\int l(\theta, x) \mathrm{d}F_0(x)$.

In what follows, let the data be $(\mathbf{x}_1, \ldots, \mathbf{x}_n)$, where $\mathbf{x}_i \in \mathbb{R}^p$, $i = 1, \ldots, n$. Typically, in statistics, a parametric family of densities (or probability mass functions) $\mathscr{F} = \{f(\mathbf{x}, \theta) : \theta \in \Theta, \mathbf{x} \in \mathbb{R}^p\}$ is considered. In this setting, a loss function on the parameter space Θ arises naturally, which is called the self–information loss and is equal to the negative log–likelihood, namely:

$$\theta \to \log f(\mathbf{x}, \theta),$$

for every $\mathbf{x} \in \mathbb{R}^p$. In this case, let the unknown value θ_0 be defined as the minimum point of the expected loss (1) where $l(\theta, \mathbf{x})$ is the self–information loss. If the density of the unknown population probability distribution F belongs to $\mathscr{F}$ then θ_0 turns out to be the value such that the population density coincides with $f(\mathbf{x}, \theta_0)$. If instead the density of the unknown population probability distribution F does not belong to $\mathscr{F}$, then θ_0 is the value in Θ minimizing the Kullback–Leibler divergence between the probability distributions defined by the densities in $\mathscr{F}$ and the unknown population probability distribution F_0. Moreover, the estimate obtained minimizing (2) is the maximum likelihood one.

Due to robustness reasons, one may wish to replace the self–information loss with a more general loss $l(\cdot, \mathbf{x})$ which does not rely on particular assumptions about the unknown population distribution (see Hüber 2009). Estimators defined through minimization of losses of the form (2) are called *M–estimators*. They turn out to be particularly useful when a probability model for the data is too difficult to formulate or is unavailable. Another common circumstance in statistics is when the likelihood is intractable and is therefore replaced by a pseudo–likelihood. In such scenario, it is reasonable to let loss $l(\cdot, \mathbf{x})$ be the negative log-pseudo-likelihood and to obtain an estimate of the parameter θ_0 through minimization of the loss (2). Bissiri et al. (2016) present a general Bayesian extension of this idea of making inference while replacing the traditional likelihood with a general loss function. They aim at updating a prior distribution π of θ on the basis of the loss function l and they claim that the appropriate posterior distribution should be absolutely continuous with respect to the prior π with density proportional to $\exp\{-\lambda l(\cdot, \mathbf{x})\}$, where λ is a positive constant. This general form for a posterior distribution is also considered by Zhang (2006*a*,*b*), Jiang & Tanner (2008), Bissiri & Walker (2010) and Bissiri & Walker (2012).

Bissiri et al. (2016) and Bissiri & Walker (2019) characterize the general Bayesian approach through a set of assumptions, or axioms. The result given by Bissiri et al. (2016) is restricted to the case of Θ being a finite probability space, but Bissiri & Walker (2019) have improved this result including the case of Θ being a subset of the real line, besides reorganizing the set of axioms which the result is based on.

Let π be a (prior) probability measure on the parametric space Θ, let Θ be a (Borel) subset of the real numbers, and for every $\mathbf{x} \in \mathbb{R}^p$ let $l(\cdot,\mathbf{x})$ be a loss function defined on Θ that is a measurable function valued into $[0,\infty]$ and not identically infinite. Bissiri et al. (2016), Bissiri & Walker (2019) argue that a valid and coherent update of π on the basis of $\mathbf{x}$ is the probability measure $\pi_{\mathbf{x}}$ that is absolutely continuous with respect to π and

$$\mathrm{d}\pi_{\mathbf{x}}/\mathrm{d}\pi(\theta) = \frac{\exp\{-\lambda l(\theta,\mathbf{x})\}}{\int_{\Theta}\exp\{-\lambda l(\tau,\mathbf{x})\}\mathrm{d}\pi(\tau)} \tag{3}$$

for some $\lambda > 0$. Their argument is based on a set of axioms. In particular, the updating rule (3) ensures that a very natural coherence property is satisfied, since we end up with $\pi_{\mathbf{x}_1,\mathbf{x}_2}$ as the same object whether we update with $(\mathbf{x}_1,\mathbf{x}_2)$ together on the basis of the additive loss function $l(\cdot,\mathbf{x}_1)+l(\cdot,\mathbf{x}_2)$ or we update with $\{\mathbf{x}_1,\mathbf{x}_2\}$ one after the other, using first the loss $l(\cdot,\mathbf{x}_2)$ and then the loss $l(\cdot,\mathbf{x}_2)$. See Bissiri & Walker (2019) for all details.

In presence of n pieces of data $\mathbf{x}_1,\ldots,\mathbf{x}_n$, in virtue of this coherence property, the general posterior distribution takes the following form:

$$\mathrm{d}\pi_{\mathbf{x}_1,\ldots,\mathbf{x}_n}/\mathrm{d}\pi(\theta) = \frac{\exp\{-\lambda\sum_{i=1}^{n} l(\theta,\mathbf{x}_i)\}}{\int_{\Theta}\exp\{-\lambda\sum_{i=1}^{n} l(\tau,\mathbf{x}_i)\}\mathrm{d}\pi(\tau)}$$

The assessment of the calibrating parameter λ is a delicate issue. See, for instance, Bissiri et al. (2016), Holmes & Walker (2017), Syring & Martin (2018). In this paper, we consider the loss $l(\theta,\mathbf{x})$ being equal to $-\log L(\theta,\mathbf{x})$, where $L(\theta,\mathbf{x})$ is a pseudo–likelihood. Being such pseudo–likelihood intended as an approximation of the true likelihood, it is reasonable to assess $\lambda = 1$.

2 The proposal

Consider a p dimensional vector $\mathbf{X} = (X_1,\ldots,X_p)$ such that each random variable X_s corresponds to a node of a graph $G = (V,E)$ with index set $V = \{1,2,\ldots,p\}$. An edge between two nodes s and t will be denoted by (s,t). The neighbourhood of a node $s \in V$ is defined to be the set $N(s) = \{t \in V : (s,t) \in E\}$ consisting of all nodes connected to s. The random vector $\mathbf{X}$ satisfies the Markov property, namely X_s and $\mathbf{X}_{V\setminus\{N(s)\cup\{s\}\}}$ are conditionally independent given $\mathbf{X}_{N(s)}$.

When the structure of a graph is not known, its recovery is not an easy task. On assuming that the graph is perfectly Markovian, that is, it satisfies the global Markov property and its reverse implication, known as faithfulness, neighborhood

selection strategies learn the graph G by determining the neighborhood $N(s)$ of each node s. Estimating $N(s)$ often corresponds to variable selection in a (penalized) regression problem (Allen & Liu 2013) . Hue Nguyen & Chiogna (2018) propose a new algorithm for learning the structure of undirected graphs for (possibly right-truncated) count data by substituting regression strategies with hypothesis testing, following the lines of the PC algorithm (Spirtes et al. 2000). To infer a graphical model from data, PC-like algorithms use sequences of conditional independence tests. Hue Nguyen & Chiogna (2018) prove that their proposal has high-dimensional consistency properties when conditional independences are tested using Wald-type tests of conditional independence.

Although consistent in the limit of infinite observations, in finite settings performances of the algorithm may depend on the choice of the statistic used to perform the tests and on the chosen significance level. In this work, we try to overcome these limitations by adopting a Bayesian perspective (see also Banerjee & Ghosal (2015) for a different approach in the Bayesian setting).

To this aim, we assume that each conditional distribution of node X_s given other variables $\mathbf{X}_{V\setminus\{s\}}$ follows a Poisson distribution truncated at R, $R > 0$

$$\mathbb{P}_{\boldsymbol{\theta}}(x_s|\mathbf{x}_{V\setminus\{s\}}) = \exp\left\{\theta_s x_s + x_s\langle\boldsymbol{\theta}_s, \mathbf{x}_{V\setminus\{s\}}\rangle - \log x_s! - D(\langle\boldsymbol{\theta}_s, \mathbf{x}_{V\setminus\{s\}}\rangle)\right\}, \quad (4)$$

where $\boldsymbol{\theta} = \{\theta_{st} : s,t \in V, s \neq t\}$, $\boldsymbol{\theta}_s = \{\theta_{st},\ t \in V, t \neq s\}$ denotes the set of conditional dependence parameters, $\langle .,. \rangle$ denotes the inner product, and $D(\langle\boldsymbol{\theta}_s, \mathbf{x}_{V\setminus\{s\}}\rangle) = \log\left(\sum_{k=0}^{R} \exp\left\{\theta_s k + k\langle\boldsymbol{\theta}_s, \mathbf{x}_{V\setminus\{s\}}\rangle - \log k!\right\}\right)$. A missing edge between node s and node t corresponds to the condition $\theta_{st} = \theta_{ts} = 0$. On the other side, one edge between node s and node t implies $\theta_{st} \equiv \theta_{ts} \neq 0$.

The neighborhood selection strategy is related to the concept of pseudo-likelihood. We borrow the idea of resorting to a pseudolikelihood and consider the function:

$$L(\boldsymbol{\theta}) = \prod_{s\in V} \mathbb{P}_{\boldsymbol{\theta}}(x_s \mid \mathbf{x}_{V\setminus\{s\}}).$$

Let $\{\mathbf{x}^{(1)}, \ldots, \mathbf{x}^{(n)}\}$ be the collection of n samples with $\mathbf{x}^{(i)} = (x_{i1}, \ldots, x_{ip})$, $i = 1, \ldots, n$. In such setting, the generalized posterior is absolutely continuous with respect to the prior with density which is equal to:

$$\frac{\prod_{i=1}^{n}\prod_{s\in V}\mathbb{P}_{\boldsymbol{\theta}}\left(x_{is} \mid \mathbf{x}^{(i)}_{V\setminus\{s\}}\right)}{\mathbb{E}_{\pi}\left(\prod_{i=1}^{n}\prod_{s\in V}\mathbb{P}_{\tilde{\boldsymbol{\theta}}}\left(x_{is} \mid \mathbf{x}^{(i)}_{V\setminus\{s\}}\right)\right)}, \quad (5)$$

where the expectation in the denominator is intended to be taken with respect to a random element $\tilde{\boldsymbol{\theta}}$ with (prior) distribution π. We consider a prior π of the parameter vector $\boldsymbol{\theta}$ such that the elements θ_{st} of $\boldsymbol{\theta}$ are i.i.d. for every pair (s,t) such that $s,t \in V$ and $s < t$. Such prior is constructed in the following way: let $\{W_{st} : t,s \in V, s \neq t\}$ be a collection of i.i.d. random variables such that, for each s,t, W_{st} is equal to 1 with probability p, where $p \in (0,1)$, and is equal to zero with probability $1-p$ and let the θ_{st} be equal to zero if W_{st} is zero and let the conditional distribution of θ_{st}

given $W_{st} = 1$ be Normal with mean zero and variance σ^2, where σ^2 is a large value. In other words, $\theta_{st} = X_{st} W_{st}$ where X_{st} and W_{st} are independent and X_{st} is Gaussian with zero mean and variance σ^2. This is also equivalent to say that the distribution function of θ_{st} is equal to:

$$P(\theta_{st} \leq t) = (1-p)\,\delta_0((-\infty, t]) + p\,\Phi(t/\sigma),$$

for every $t \in \mathbb{R}$, where δ_0 is the probability distribution of a random variable degenerate at zero and Φ denotes the standard Normal distribution function.

The generalized posterior given by (5) can be simulated via the Metropolis–Hastings algorithm. Conditional independence tests can be based on the posterior probability of each individual coefficient, this being larger or smaller that 1/2.

Through extensive simulation studies, validity of the proposal can be illustrated numerically, along with its scalability to large graphs.

3 Conclusions

We presented a general Bayesian nonparametric approach for learning the structure of a graphical model when count data are at hand. The approach leverages the use of a pseudo likelihood as a loss function. Compared with the more common frequentist approaches, this strategy allows to deal with situations in which the existence of the joint distribution of the variables is not guaranteed. We developed appropriate procedures for posterior computation.

Bayesian IRT models in NIMBLE

Modelli IRT bayesiani in NIMBLE

Sally Paganin, Chris Paciorek, Perry de Valpine

Abstract IRT models relate observed data to some latent traits typically encoding item characteristics, as well as individual abilities. Often these lasts are assumed to follow a standard normal distribution, but there are situations in which such assumption may be unrealistic. A possible extension for such models uses a Dirichlet process mixture of normal distributions, which is seldom employed in real data analysis due to the lack of guidelines and software tools. We contribute to fill this gap by reviewing both parametric and semiparametric versions of such models. Using 2PL model as an example we also illustrate how these models can be easily implemented via the novel NIMBLE software.

Abstract *I modelli IRT caratterizzano la relazione tra dati osservati e variabili latenti. Quest'ultime solitamente descrivono sia caratteristiche degli item che l'abilità degli individui. Spesso si assume che tali abilità seguano la distribuzione di una normale standard, ma ci sono situazioni in cui tale assunzione non risulta appropiata. In questi casi, una possibile estensione si può ottenere utilizzando una mistura di distribuzioni normali per le abilità latenti basata sul processo di Dirichlet. Tuttavia questi modelli risultano essere poco diffusi in pratica a causa della mancanza di linee guide e software che li implentino. In questo lavoro presentiamo le versioni parametriche e non dei modelli IRT. Usando il modello 2PL come esempio, illustriamo anche come implementarli facilmente attraverso l'uso del software NIMBLE.*

Key words: 2PL, Bayesian nonparametrics, IRT, Dirichlet Process, NIMBLE.

1 Motivation

Item response theory (IRT) refers to a family of models that investigate the relationship between responses to a set of items and some latent traits, typically encoding

Department of Statistics, Department of Enviromental Science, Policy & Management
UC Berkeley e-mail: sally.paganin@berkeley.edu

individual or item characteristics. Such models are employed in different application domains, with educational measurement and psychometrics being the most popular. Models for binary responses are among the most common among IRT models, comprising the one, two or three parameter logistic models (1PL, 2PL and 3PL). These models assume that the probability of a correct answer is related to the individual's latent ability, as well as items difficulty and potentially other item characteristics.

Standard approaches rely on the assumption that latent abilities follow a standard normal distribution. This assumption is sometimes considered for computational convenience, but it may be unrealistic in many situations [9]. For example, [7] gives a comprehensive review of many psychometric datasets where the latent traits distribution does not respect the normality assumption and presents instead asymmetries, heavy-tails or multimodality.

Different proposals have been made in literature relaxing the normality assumption for the latent abilities. Arguably, the most general approach in a Bayesian framework uses a Dirichlet process [4] mixture of normal distributions as a nonparametric distributions for latent abilities. Such models are semiparametric because they retain other, parametric, assumptions of binomial mixed models. Within this approach, the semiparametric 1PL model has been the focus of more effort as well as software tool [6, **DPpackage**]. [10] investigate semi-parametric generalization of Rasch-type models from a theoretical perspective, while [5] provides results from simulation studies considering the 1PL model. An example using the 2PL model is given in [3], but there is a lack of comprehensive studies of such models as well as general tools for model estimation in real data analysis. In this work we review the semiparametric 1PL and 2PL models, and illustrate how to easily implement them in the NIMBLE software.

2 NIMBLE

NIMBLE [2] is a flexible R-based system for hierarchical modeling, which extends BUGS language used in WinBUGS, OpenBUGS, NAGS [8], providing efficient execution of algorithms via custom-generated C++ code. Besides offering new degrees of customization of MCMC algorithms, one of the latest NIMBLE features added support for MCMC inference for Bayesian nonparametric mixture models. In particular, NIMBLE provides functionality for fitting models using a Dirichlet process prior, either via the Chinese Restaurant Process (CRP) [1] or a truncated stick-breaking (SB) [11] representation of the Dirichlet process prior. These features allows Dirichlet process priors to be embedded in very general hierarchical models, supporting extensions of the approaches we illustrate here.

3 IRT models background

In this context, observed data are typically answers to exam questions or items from a set of individuals. Let y_{ij} denote the answer of an individual j to item i for $j = 1,\dots,N$ and $i = 1,\dots,I$, with $y_{ij} = 1$ when the answer is correct and 0 otherwise. Typically, different individuals are assumed to work independently, while responses from the same individuals are assumed independent conditional to the latent trait (*local independence assumption*). Hence each answer y_{ij}, conditionally to the latent parameters, is assumed to be a realization of a Bernoulli distribution, and the probability of a correct response is typically modeled via logistic regression.

In the two-parameter logistic (2PL) model, the conditional probability of a correct response is modeled as

$$\Pr(y_{ij} = 1|\eta_j,\lambda_i,\beta_i) = \frac{\exp\{\lambda_i(\eta_j-\beta_i)\}}{1+\exp\{\lambda_i(\eta_j-\beta_i)\}} \quad i = 1,\dots,I, j = 1,\dots,N, \tag{1}$$

where η_j represents the latent ability of the j-th individual for $j = 1,\dots,N$, while β_i and λ_i encode the item characteristics for $i = 1,\dots,I$. The parameter λ_i is often referred as *discrimination*, since items with a large λ_i are better at discriminating between subjects with different abilities, while β_i is called *difficulty* because the probability of a correct response is equal to 0.5 when $\eta_j = \beta_i$. Discrimination parameters λ_i are typically assumed positive. When $\lambda_i = 1$ for $i = 1,\dots,I$ model in (1) reduces to the one-parameter logistic (1PL) model. Often, conditional log-odds in (1) are reparametrized as $\lambda_i\eta_j + \gamma_i$, with $\gamma_i = -\lambda_i \times \beta_i$. Sometimes this is reffered to as *slope-intercept* (SI)parameterization as opposed to the *IRT* parameterization in (1) traditional cosidered for interpretation.

Traditional literature assumes that $\eta_j \sim \mathcal{N}(0,1)$ for $j = 1,\dots,N$, but there are situations in which such assumption can be too restrictive. To add more flexibility, we can extend the model in (1) via a DP prior as

$$\eta_j|G \sim G \quad G \sim DP(\alpha,G_0) \tag{2}$$

where α is the concentration parameter and G_0 the base measure. The DP process is often represented via the Chinese Restaurant Process representation, introducing a set of indicator variables z_j for $j = 1,\dots,N$ indicating the cluster assignment for the ability η_j. The prior in (2) becomes

$$(\eta_j|z_j = h) = \eta_h \quad \eta_h \sim \mathcal{N}(\mu_h,\sigma_h^2) \tag{3}$$

with typically hyperpriors on μ_h and σ_h^2.

4 Model comparison

We compare estimation of the parametric and nonparametric estimation of the parametric 2PL models via simulation. Typically parameters of the 2PL model are not identifiable, so constraints are either included in the model or one can post-process posterior samples to meet the constraints. We consider this last option and use sum-to-zero constraints on the item parameters, i.e. $\sum_{i=i}^{I}\beta_i = 0, \sum_{i=i}^{I}\log(\lambda_i) = 0$ and estimate the 2PL under IRT and SI parameterizations.

We simulate data from two different scenarios changing the distribution generating the latent abilities. We simulate responses from $N = 2,000$ individuals to $I = 20$ binary items. Values for the discrimination parameters $\{\lambda_i^0\}_{i=1}^{20}$ are sampled from a $Unif(0.5, 1.5)$, while values for difficulty parameters $\{\beta_i^0\}_{i=1}^{20}$ are taken as equally spaced between $(-3, 3)$. In particular we considered for the latent abilities η_j^0 for $j = 1, \ldots, 2000$:

1. **Unimodal scenario**. Latent abilities comes from a normal distribution with mean 0 and standard deviation 1.25.
2. **Bimodal scenario**. Latent abilities comes from a mixture of two normal distribution with means $\{-2, 2\}$ and common standard deviation 1.25.

We implement all the strategies in NIMBLE, choosing moderately vague priors for the item parameters, $\beta_i \sim \mathcal{N}(0,3), \gamma_i \sim \mathcal{N}(0,3), \log(\lambda_i) \sim \mathcal{N}(0.5, 0.5)$ for $i = 1, \ldots, I$. We assume normal latent abilities $\eta_j \sim \mathcal{N}(\mu_\eta, \sigma_\eta^2)$ for $j = 1, \ldots, N$, and placed a $\mathcal{N}(0,3)$ on μ_η and $Unif(0, 10)$ on the standard deviation σ_η in the parametric case, while in the nonparametric setting we choose $G_0 \equiv \mathcal{N}(0,3) \times Inv-Gamma(1.01, 2.01)$. We run the MCMC for $50,000$ iterations using a 10% burn-in of $5,000$ iterations, and check traceplots for convergence.

Table 1 reports the minimum effective samples size (ESS) per second relative to the strategies, computed by dividing the ESS for the computation time. As expected there is a loss in efficiency when moving from the parametric to the semiparametric specification, given that sampling from the Dirichlet Process requires more computational effort. Flexibility comes with a price, but also with a benefit for inference when abilities are not normal. While in the unimodal scenario results match, in the bimodal there are substantial differences.

	unimodal	simulation	bimodal	simulation
Model	parametric	bnp	parametric	bnp
IRT unconstrained	0.78	0.33	2.43	1.27
SI unconstrained	1.06	0.57	0.23	0.06

Table 1 Minimum ESS/seconds for different estimations strategies of the 2PL model parameters under the two simulated scenarios.

For example, Figure 1 compares the density estimates of the posterior mean latent abilities from the parametric and semiparametric models, computed taking the posterior means of the $\{\eta_j\}_{j=1}^{N}$. It can be notice that the parametric model detect just

one mode because of the underlying normal assumption, while the semiparametric specification recover the true density structure. Better estimation of the latent abilities helps to avoid bias in inference, for example when estimating item parameters or item characteristics curves (ICC).

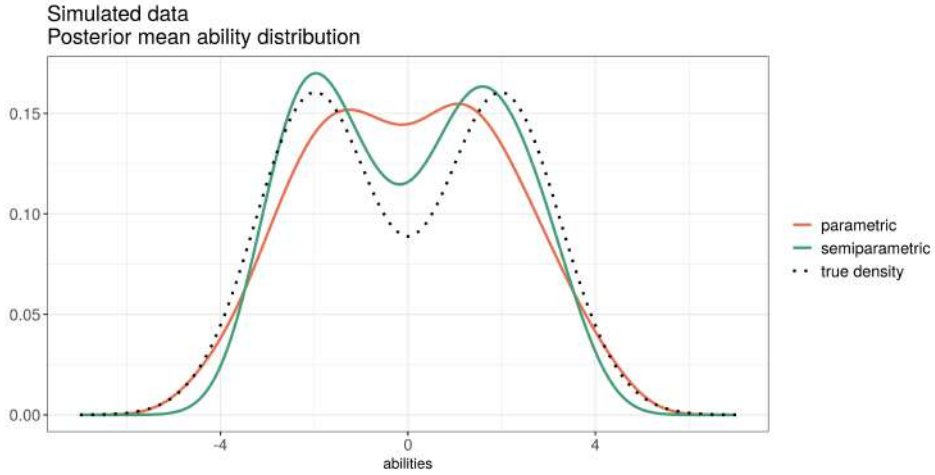

Fig. 1 Density estimates of the posterior mean latent abilities under the parametric and semiparametric 2PL models under the bimodal simulated scenario. Both models are estimated under the unconstrained IRT parameterizations, the most efficient from Table 1.

Bayesian modelling of Facebook communities via latent factor models

Modellazione Bayesiana di comunità Facebook tramite modelli a fattori latenti

Emanuele Aliverti

Abstract Network data are routinely collected in a variety of applications, ranging from marketing to social sciences. In this article I focus on the analysis of a large Facebook network involving thousands of public pages. The dependence structure is characterized trough a Bayesian latent factor model for network data, which allows to model the architecture of nodes' connectivity as a function of their position in a latent space. Inference proceeds via Variational Bayes leveraging a Coordinate Ascent routine. Results indicate good fit for the algorithm, while inference on the latent coordinates suggests the presence of different communities.

Abstract *Dati di rete vengono regolarmente raccolti in diversi campi applicativi. In questo articolo mi concentro su una grande rete Facebook composta da alcune migliaia di pagine pubbliche. La struttura di dipendenza è caratterizzata attraverso un modello Bayesiano a fattori latenti per dati di rete, che consente di modellare la connettività dei nodi in funzione della loro posizione in uno spazio latente. La stima procede tramite un approccio variazionale. I risultati indicano un buon adattamento del modello, mentre l'inferenza sulle coordinate latenti suggerisce la presenza di diverse strutture di comunità.*

Key words: Bayesian Inference, Factor Model, Network Data, Variational Bayes

1 Introduction

Network data are ubiquitous in many areas of science and industry. Some notable examples are social science [10], biology [9] and neuroscience [5, 2], where network analysis can provide valuable insight into the functionality of an entire system. In practice, it is interesting to study various aspects of network data, ranging from sim-

Emanuele Aliverti
Department of Statistical Sciences, University of Padova e-mail: aliverti@stat.unipd.it

ple descriptive statistics to the full specification of the network generating process and its dependence structure. In general terms, a network can be defined as a collection of n interconnected units (*nodes*), which can be conveniently expressed as an $(n \times n)$ *adjacency* matrix $\mathbf{Y}$ with elements y_{ij} characterising the connection (*edges*) from node i to node j. In this article I focus on binary undirected networks, leading to symmetric adjacency matrices. Therefore, it is sufficient to characterise the lower-triangular part of $\mathbf{Y}$, thereby letting $y_{ij} = y_{ji} = 1$ if there is and edge between the pair (i, j) with $i = 2, \dots, n$ and $j = 1, \dots, i-1$ and 0 otherwise. Specifically, I will focus on a large network involving $n = 22470$ public Facebook pages collected through the Facebook API in November 2017 [11]. A link between page i and page j is present if they share a mutual like relationship. My interest is on characterising the dependence structure of such network, to provide insights on the community structure underlying such Facebook community. Such an aim is accomplished via a Bayesian Latent Factor Model (LFM) for networks, which characterizes the probability to observe and edge between two Facebook pages as a function of their position in an H-dimensional latent space. The more similar two nodes are in the latent space, the more likely it is to observe a connection among them. Such a structure facilitates interpretation on the underlying community structure, reducing the dimensionality from $n(n-1)/2$ to nH free parameters. In addition, posterior inference is performed efficiently leveraging a scalable Variational Bayes algorithm.

2 Latent factor model

Let $\text{pr}(y_{ij} = 1 \mid \pi_{ij}) = \pi_{ij} \in (0,1)$, denote the population probability of an edge between node i and j, for each $i = 2, \dots, n$, $j = 1, \dots, i-1$. The LFM for networks [6] is specified as follows.

$$\begin{aligned} (y_{ij} \mid \pi_{ij}) &\sim \text{Bern}(\pi_{ij}) \\ \pi_{ij} &= \Phi(\eta_{ij}) \\ \eta_{ij} &= \beta_0 + w_i^{\intercal} w_j \end{aligned} \tag{1}$$

for each pair $i = 2, \dots, n$ and $j = 1, \dots, i-1$, with Φ denoting the Gaussian cumulative distribution function. The vector $(w_i) \in \mathbb{R}^H$ corresponds to the position of the node i in the H-dimensional latent space. Therefore, the quantity $\eta_{ij} \in \mathbb{R}$ can be interpreted as a weighted similarity among region i and j in the latent space, with more similar regions having larger similarities resulting in greater probability of being connected. See [7] for a recent overview and a comparison among the LFM and other latent variable methods for networks.

I seek simple specification of the prior distributions, leading to efficient computational algorithms. With this motivation in mind, the prior distributions for the coefficients and latent structures are specified as follows.

$$\beta_0 \sim \text{N}(0,1), \quad w_i \sim \text{N}_H(0, I_H) \quad i = 1, \dots, n \tag{2}$$

Conditional conjugacy is obtained leveraging the data-augmentation strategy of [1], introducing a set of latent continuous observations $z_{ij} \sim \mathrm{N}(\eta_{ij}, 1)$. This choice implies that the observed $y_{ij} = 1$ if $z_{ij} > 0$ and $y_{ij} = 0$ if $z_{ij} < 0$. Integrating out z_{ij} the specification of Equation (1) is obtained.

2.1 Bayesian inference via Variational Bayes

Combining the LFM with the data augmentation strategy of [1], the model can be revised in terms of a conditional conjugate exponential family. Beyond facilitating inference via Gibbs sampler, the availability of closed-form expressions for full conditional distributions also simplifies Bayesian estimation via Variation Bayes (VB) [3, 4].

Specifically, I focus on a Mean Field (MF) restriction, conducting approximate Bayesian inference via optimisation. Such a strategy aims at finding the closest distribution in KL divergence to the true posterior subject to the MF product restriction. In particular, the following restriction will be assumed for the variational family of distributions.

$$q(\beta_0, \mathbf{W}, \mathbf{z}) = q(\beta_0) q(\mathbf{W}) q(\mathbf{z}), \tag{3}$$

with $\mathbf{W} = \{w_i\}_{i=1}^{n}$, $\mathbf{z} = \{z_{ij}\}_{i=2,\dots n}^{j=1,\dots,i}$

Since the LFM falls within the class of conditionally conjugate exponential families, each full conditional distribution — available in closed form — is in the exponential family, being either multivariate Gaussian or truncated normal. This result is particularly useful since, under the MF factorisation in (3), it is possible to show [e.g. 4, Sec 2.4] that the optimal distributions $q^\star$ have closed form expressions. Indeed, the optimal distribution for each factor is in the same parametric (exponential) family of the corresponding full conditional distribution, with natural parameters replaced with variational expectations [8] which can be easily computed for both the Gaussian and the truncated Gaussian full conditionals. The optimal solution can be found iteratively, maximising each variational distribution on the basis of the current values of the remaining parameters, until convergence.

3 Results

The approach is applied to the Facebook network described in Section 1, focusing for simplicity on $H = 2$. Figure 1 reports the posterior mean of the latent coordinates w_i and the ROC curve, using the posterior predictive mean $\mathbb{E}[\pi_{ij} \mid \mathbf{Y}]$ for predicting the edge probabilities. Such a quantity can be easily obtained via Monte-Carlo integration, relying on an independent sample from the approximate posterior distribution. Results indicated a good performance for the estimated model, with an Area Under the ROC curve close to 0.84; see the right panel of Figure 1. In addition,

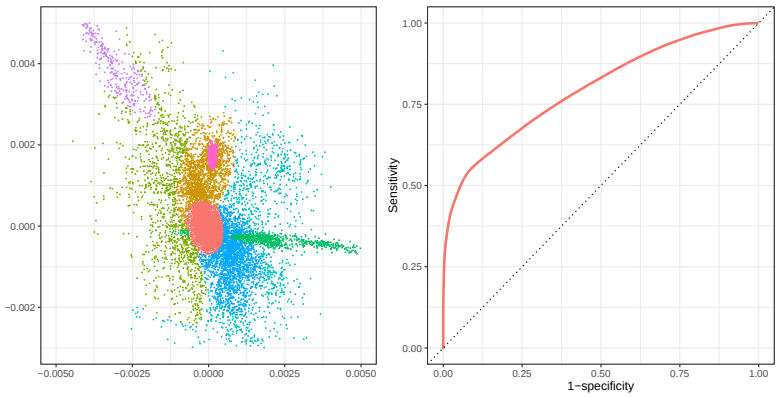

Fig. 1 Left panel: latent factors (w_{i1}, w_{i2}), $i = 1, \ldots, n$. Right panel: ROC curve.

the estimates for the latent positions (posterior means, left panel of Figure 1) indicate the presence of different communities. To improve visualisation, I performed a model-based clustering via Gaussian mixtures in the latent space. Results suggest the presence of different overlapping communities, which might correspond to Facebook pages referring to similar topics or discussing similar threads.

Bayesian nonparametric adaptive classification with robust prior information

Modello Bayesiano nonparametrico per classificazione adattiva con informazione a priori robusta

Francesco Denti, Andrea Cappozzo and Francesca Greselin

Abstract In a standard classification framework, a discriminating rule is usually built from a trustworthy set of labeled units. In this context, test observations will be automatically classified as to have arisen from one of the known groups encountered in the training set, without the possibility of detecting previously unseen classes. To overcome this limitation, an adaptive semi-parametric Bayesian classifier is introduced for modeling the test units, where robust knowledge is extracted from the training set and incorporated within the priors' model specification. A successful application of the proposed approach in a real-world problem is addressed.

Abstract Di solito, in un problema di classificazione, si costruisce una regola discriminante in base ad un insieme affidabile di unità etichettate. E' così possibile, quindi, attribuire le osservazioni di un dataset di test ad uno dei gruppi noti, presenti nel training set. Non vi è invece possibilità di rilevare classi mai viste prima. In molti contesti applicativi, tuttavia, può accadere che emergano nuove classi. Per rispondere a questa necessità, si introduce un classificatore bayesiano semi-parametrico, che estrae informazione robusta dal dataset di training, la incorpora come prior knowledge ed è in grado di includere nuove classi per modellare le unità del test set. Viene poi presentata un'applicazione dell'approccio proposto su dati reali.

1 Introduction and Motivation

The usual framework of supervised classification does not contemplate the possibility of having test units belonging to a class not previously observed in the learning phase. A classic hypothesis is that the training set contains samples for each and every group within the population of interest. Nevertheless, this strong assumption may not hold true in fields like biology, where novel species may appear and their detection is an important issue, or in social network analysis where communities continuously expand and evolve. Therefore, a classifier suitable for these situations needs to adapt to the detection of previously unobserved classes, accounting also for few extreme and outlying observations that may emerge in such evolving ecosystems. Unfortunately, standard supervised methods will predict class labels only within the set of groups previously encountered in the learning phase.
We propose a flexible procedure in a semi-parametric Bayesian framework for dealing with outliers and hidden classes that may arise in the test set. The learning process articulates in two phases. First, we infer the structure of the known components from the labeled set via standard robust procedures. Consequently, employing an Empirical Bayes rationale, the dynamic updating typical of Bayesian statistics is adopted to model the new, unlabeled dataset allowing for the detection of possibly infinite new components.
The rest of the paper is organized as follows: in Section 2 the main features of the novel model are presented. An application to the discrimination of wheat kernels varieties, under sample selection bias, is reported in Section 3. Section 4 summarizes the contributions and highlights future research directions.

2 The model

Consider a classification framework with $\{(\mathbf{x}_1,\mathbf{l}_1),\dots,(\mathbf{x}_N,\mathbf{l}_N)\}$ identifying the training set: $\mathbf{x}_n$ is a p-variate observation and $\mathbf{l}_n$ its associated group label, $\mathbf{l}_n \in \{1,\dots,G\}$ with G the number of unique observed classes. Correspondingly, let $\{\mathbf{y}_1,\dots,\mathbf{y}_M\}$ be the test set, where it is assumed, differently from the standard framework, that its associated (unknown) labels may not only belong to the set of previously observed G classes, but potentially more groups could be present within the unlabeled units. That is, there may be a number H of novel classes in the test such that the total number of groups in the population is $E = G+H$, with $H \geq 0$.
We assume that each observation in the test set is generated from a mixture of $G+1$ elements: G densities $f(\cdot|\boldsymbol{\Theta}_g)$ parametrized by $\boldsymbol{\Theta}_g$ and an extra term, called *novelty* component. In formulas:

$$\mathbf{y}_m \sim \sum_{g=1}^{G} \pi_g f(\cdot|\boldsymbol{\Theta}_g) + \pi_0 f_{nov}, \tag{1}$$

where π_g, $g = 1,\dots,G$ indicates the prior probability of observing class g (already present in the learning set), while π_0 is the probability of observing a previously

unseen class, such that $\sum_{g=0}^{G} \pi_g = 1$. Different specifications for the known components can be easily accommodated in the general formulation of (1): Gaussian distributions will be subsequently considered, in line with the application reported in Section 3. A Bayesian nonparametric approach is employed to model f_{nov}. In particular, we resort to the Dirichlet Process Mixture model [1, 4], imposing the following structure:

$$f_{nov} = \int f(\cdot|\boldsymbol{\Theta}^{nov}) G(d\boldsymbol{\Theta}^{nov}), \qquad G \sim DP(\gamma, H),$$

where $DP(\gamma, H)$ is the usual Dirichlet process with concentration parameter γ and base measure H. Note that we use the superscript *nov* to denote a parameter relative to the novelty part of the model. Adopting Sethuraman's Stick Breaking construction [7], we can express the likelihood as follows:

$$\mathscr{L}(\mathbf{y}|\boldsymbol{\pi}, \boldsymbol{\mu}, \boldsymbol{\Sigma}, \boldsymbol{\omega}) = \prod_{m=1}^{M} \left[\sum_{g=1}^{G} \pi_g \phi\left(\mathbf{y}_m | \boldsymbol{\mu}_g, \boldsymbol{\Sigma}_g\right) + \pi_0 \sum_{h=1}^{\infty} \omega_h \phi\left(\mathbf{y}_m | \boldsymbol{\mu}_h^{nov}, \boldsymbol{\Sigma}_h^{nov}\right) \right], \quad (2)$$

where $\phi(\cdot|\boldsymbol{\mu}, \boldsymbol{\Sigma})$ denotes the multivariate normal density, parametrized by its mean vector $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Sigma}$. There are two main reasons for employing a nonparametric prior in this context. First, adopting a DP as mixing measure allows an a priori unbounded number of hidden classes and/or outlying observations. Second, it reflects our lack of knowledge about the previously unseen components. The following prior probabilities for the parameters complete the Bayesian model specification:

$$\begin{aligned} \left(\boldsymbol{\mu}_g, \boldsymbol{\Sigma}_g\right) &\sim NIW\left(\hat{\boldsymbol{\mu}}_{gMCD}, \tilde{\lambda}_{tr}, \tilde{\nu}_{tr}, \hat{\boldsymbol{\Sigma}}_{gMCD}\right), \quad g = 1, \ldots, G \\ \left(\boldsymbol{\mu}_h^{nov}, \boldsymbol{\Sigma}_h^{nov}\right) &\sim NIW\left(\tilde{\boldsymbol{m}}, \tilde{\lambda}, \tilde{\nu}, \tilde{\boldsymbol{S}}\right), \quad h = 1, \ldots, \infty \\ \boldsymbol{\omega} &\sim SB(\gamma) \qquad \boldsymbol{\pi} \sim Dir(\tilde{\alpha}_0, \tilde{\alpha}_1, \ldots, \tilde{\alpha}_G). \end{aligned} \quad (3)$$

A detailed explanation of the quantities in (3) follows, where we incorporate the information contained in the training set for setting robust informative priors for the parameters of the known classes. Values $\tilde{\alpha}_1, \ldots, \tilde{\alpha}_G$ are the hyper-parameters of a Dirichlet distribution on the known classes. The learning set can be exploited to determine reasonable values of such hyper-parameters, setting $\tilde{\alpha}_g = n_g/N$ for $g = 1, \ldots, G$ with n_g the total number of observations belonging to the g-th group in the training set. The priors for the mean vectors and the covariance matrices of both known and hidden classes are assumed to follow a conjugate Normal-inverse-Wishart distribution. Robust hyperparameters $\hat{\boldsymbol{\mu}}_{gMCD}$ and $\hat{\boldsymbol{\Sigma}}_{gMCD}$, $g = 1, \ldots, G$ are obtained via the Minimum Covariance Determinant estimator (MCD) [6] computed group-wise in the training set. Subsets of sizes $\lceil 0.95 n_g \rceil$, $g = 1, \ldots, G$, over which the determinant is minimized, are employed in the application of Section 3. In this way, outliers and label noise that may be present in the labelled units will not bias the initial beliefs for the parameters of the known groups. Lastly, with $\boldsymbol{\omega} \sim SB(\gamma)$

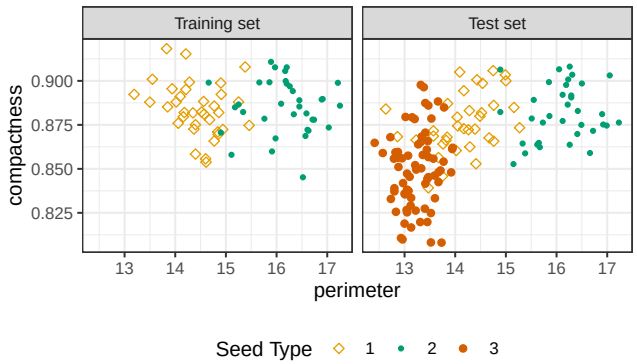

Fig. 1 Learning scenario (only `perimeter` and `compactness` variables displayed) for novelty detection of 1 unobserved wheat variety, seed dataset.

we denote the vector of Stick-Breaking weights, composed of elements defined by $w_k = u_k \prod_{l<k}(1-u_l)$, where $\forall k\ u_k \sim Beta(1,\gamma)$.
We remark that particular care is needed in choosing informative values for $\tilde{\lambda}_{tr}$ and $\tilde{\nu}_{tr}$, according to the problem at hand: inducing non-informative priors would jeopardize the robust extraction of information performed with the MCD estimator.
A blocked Gibbs sampler scheme [5] is employed for posterior computation, wherein the full conditionals for the model parameters are derived considering the following *complete likelihood*, obtained after proper reparameterization:

$$\mathscr{L}(\mathbf{y},\boldsymbol{\alpha},\boldsymbol{\beta},\mathbf{u}|\boldsymbol{\pi},\boldsymbol{\mu},\boldsymbol{\Sigma},\boldsymbol{\omega}) = \prod_{m=1}^{M}\Big[\pi_{\alpha_m}\mathbb{1}_{\{\alpha_m>0\cap\beta_m=0\}}\phi\left(\mathbf{y}_m|\boldsymbol{\mu}_{(\alpha_m,0)},\boldsymbol{\Sigma}_{(\alpha_m,0)}\right) + \\ + \pi_0\omega_{\beta_m}\mathbb{1}_{\{\alpha_m=0\cap\beta_m>0\}}\phi\left(\mathbf{y}_m|\boldsymbol{\mu}^{nov}_{(0,\beta_m)},\boldsymbol{\Sigma}^{nov}_{(0,\beta_m)}\right)\Big],$$

where $\alpha_m \in \{0,\dots,G\}$ and $\beta_m \in \{0,\dots,\infty\}$ are latent variables identifying the unobserved group membership for $\mathbf{y}_m$, $m = 1,\dots,M$. In detail, $\alpha_m > 0$ controls the assignation of $\mathbf{y}_m$ to one of the G training class ($\beta_m = 0$). In case $\mathbf{y}_m$ is recognized as a novel observation ($\alpha_m = 0$), it is assigned to one of the previously unseen mixture components constituting f_{nov}, according to $\beta_m > 0$.

3 Application

The methodology described in Section 2 is used to perform classification when a novelty component is present within the data units. The considered dataset contains 210 grains belonging to three different varieties of wheat. For every sample (70 units for each variety), seven geometric parameters are recorded postprocessing X-ray photograms of the kernel [3]. The obtained dataset is publicly available

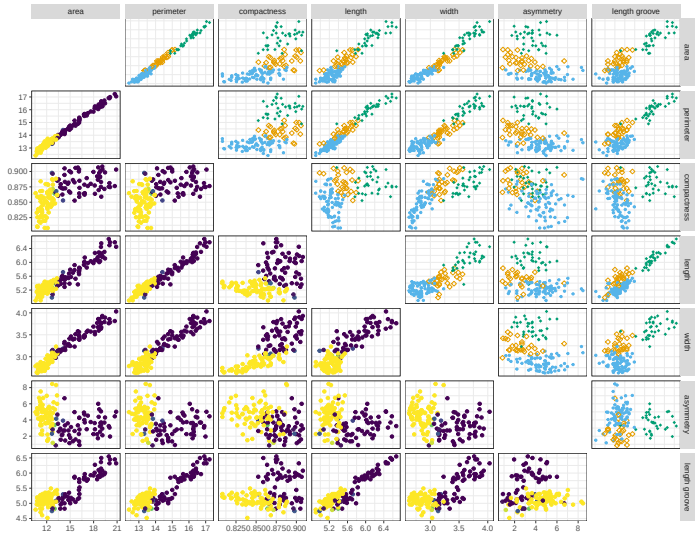

Fig. 2 Model results for experimental scenario H_3, seeds test set. Plots below the main diagonal represent the estimated posterior probability of being a novelty, according to formula (4): the brighter the color the higher the probability of belonging to f_{nov}. Plots above the main diagonal display the associated group assignments: the turquoise solid dots denote observations classified as novelties.

	$H_1: \tilde{\lambda}_{tr}=1, \tilde{\nu}_{tr}=50$			$H_2: \tilde{\lambda}_{tr}=10, \tilde{\nu}_{tr}=500$			$H_3: \tilde{\lambda}_{tr}=250, \tilde{\nu}_{tr}=1000$		
	T:1	T:2	T:3	T:1	T:2	T:3	T:1	T:2	T:3
C:1	1	35	0	27	0	3	26	0	3
C:2	34	0	70	1	35	0	0	35	0
C:New	0	0	0	7	0	67	9	0	67

involves the random selection of 70 training units from the first two cultivars, and a test set of 140 samples, including the entire set of 70 grains from the third variety: the resulting learning scenario is displayed in Figure 1. The aim of the experiment is therefore to employ the model described in Section 2 to detect the third unobserved variety, incorporating robust priors information retrieved from the training set. We employ three different hyperpriors specification ($H_1: \tilde{\lambda}_{tr}=1, \tilde{\nu}_{tr}=50$, $H_2: \tilde{\lambda}_{tr}=10, \tilde{\nu}_{tr}=500$, $H_3: \tilde{\lambda}_{tr}=250, \tilde{\nu}_{tr}=1000$) to investigate how the results change when different degrees of informativeness are adopted for the values extracted from the learning set. Model results for scenario H_3 are reported in Fig-

ure 2, where the posterior probability of being a novelty $PPN_m = \mathbb{P}[\mathbf{y}_m \sim f_{nov}|\mathbf{Y}]$, $m = 1,\dots,M$ are estimated according to the ergodic mean:

$$\hat{PPN}_m = \frac{\sum_{t=1}^{T} \mathbb{1}(\alpha_m^{(t)} = 0)}{T} \tag{4}$$

where $\alpha_m^{(t)}$ is the value assumed by the parameter α_m at the t-th iteration of the MCMC chain and T is the total number of iterations. The confusion matrices associated with the estimated group assignments for the three scenarios are reported in Table 1. When fairly and strongly informative priors for the training set information are adopted, the third group variety is effectively captured by the flexible process modeling the novel component. Notice that, whenever the novelty contains more than an extra class, its best partition can be recovered minimizing for example the Binder loss [2] or the Variation of Information [8], thus providing a way to automatically identify an infinite number of hidden classes, as well as anomalous and/or unique outlying patterns.

4 Conclusion

In the present work we have introduced an adaptive semi-parametric Bayesian classifier, capable of detecting an unbounded number of hidden classes in the test set. By means of robust procedures, prior knowledge for the known groups is reliably incorporated in the model specification. The methodology has been then effectively employed in the detection of a novel wheat variety in X-ray images of grain kernels. Future research directions will consider data-tailored extensions to the general "known classes + novelty" mixture framework introduced in this paper: a flexible specification for adaptive classification of functional data is being developed.

Choosing the right tool for the job: a systematic analysis of general purpose MCMC software

Scegliere lo strumento giusto: un'analisi sistematica di software MCMC di uso generale

Mario Beraha, Giulia Gualtieri, Eugenia Villa, Riccardo Vitali and Alessandra Guglielmi

Abstract We perform a throughout comparison of three of the most widely used software for Bayesian computation: JAGS, Stan and NIMBLE. We compare the performance of each software in several different settings, corresponding to four different class of models, each with three different priors and different sample sizes and dimensionality of the parameter space. By looking at several performance metrics, we are able to create a decision tree that should guide practitioners approaching Bayesian modelling into the choice of the right tool for the statistical problem under investigation.

Abstract *Confrontiamo tre dei software più utilizzati per il calcolo della distribuzione a posteriori in un modello bayesiano, e cioè JAGS, Stan e NIMBLE. In particolare confronteremo le prestazioni di ogni software in diversi esempi, corrispondenti a quattro distinte classi di modelli, ognuno con tre prior diverse e con dimensione campionarie e parametriche che variano. Dall'analisi di alcune metriche di prestazioni, saremo in grado di costruire un albero delle decisioni per guidare i ricercatori non esperti dell'argomento nella scelta dello strumento giusto per il problema statistico considerato.*

1 Introduction

It is well known that in the Bayesian setting, the posterior distribution, i.e. the conditional law of parameters given data, is not available in closed analytic form but under simple models. From 1990's, novel techniques that go by the name of Markov Chain Monte Carlo (MCMC) sampling have been developed to simulate draws from the posterior distribution of interest. However, despite the good theoretical properties of MCMC, deriving an efficient sampler can be demanding even for successful statisticians, due both to mathematical and implementation/computational issues.

One of the main reasons behind the success, in recent years, of the Bayesian framework among practitioners, is that a number of "probabilistic" programming languages have originated. This kind of software enables the user to specify the likelihood function as well as the prior distribution of parameters using an intuitive syntax and then automatically perform MCMC sampling from the posterior. Although united by the same target, each software exploits different numerical algorithms underneath, and also employs a different syntax, hence exhibiting different behaviours.

In this work, we investigate the *performance*, under different metrics, for three types of such general purpose software, i.e. JAGS, Stan and NIMBLE. In particular, given a class of Bayesian models, such as, for example, generalized linear models or accelerated failure time models, and the size of the dataset, we aim at providing practitioners guidance in choosing the right software, that is the most efficient, for MCMC sampling.

2 Overview of the software under investigation

JAGS stands for "Just another Gibbs Sampling"[4]. It is a program for the analysis of Bayesian models using Markov Chain Monte Carlo (MCMC), like OpenBUGS, it includes a shared C library for BUGS language interpretation and MCMC computation. BUGS proceeds by creating a graph where the nodes are the parameters in the model and data, and then it chooses the "best" sampler for each node among a list of candidates. Finally, the MCMC computation is done by updating a node at a time, in a Gibbs sampler fashion. See [2] for reference to the main ideas beneath BUGS (Bayesian inference Using Gibbs Sampling) software and to the project that started it in 1989.

NIMBLE [3] extends the BUGS language, hence the same sampling strategy of JAGS is employed. However, as we shall see, the choice of the sampler for each node can be different in the two languages and thus produce different results.

Stan [1], differently from JAGS which is able to choose the best sampling method basing on the implemented model, can use only two algorithms for MCMC sam-

pling: Hamiltonian Monte Carlo (HMC) and its adaptive variant called NUTS (No-U-Turn Sampler) which is the one set by default. Being HMC based on the computation of gradients of the log joint posterior distribution with respect to parameters, it is worth remembering that Stan does not allow the direct use of discrete random parameters, while discrete response variables are supported. This can represent a limitation of Stan with respect to BUGS languages.

3 Methodology

We consider four different classes of models: linear models, generalized linear models, linear mixed effects models and accelerated failure time models. We believe that in practical applications these classes cover most of the needs of practitioners.

For each model we consider three different priors on the parameters: an hierarchical prior, an extremely non informative prior and a simpler (though less flexible) non-hierarchical prior, that is chosen as the conjugate prior when available. Hence we end up with twelve different Bayesian models, where each model is fitted using the three software we consider, and for any of them we analyze the MCMC output and the computational performance.

Here, we report detail only on the example of the homoscedastic linear model, for lack of space. The likelihood is given by

$$Y_i = \mathbf{x}_i^T \boldsymbol{\beta} + \varepsilon_i, \quad \varepsilon_i \overset{\text{iid}}{\sim} \mathscr{N}(0, \sigma^2) \quad i = 1, ..., N$$

where $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)$ are the regression parameters, which may include the intercept, and $\mathbf{x}_i$ is a p–dimensional vector of covariates. We specify three priors:

Zellner's	**hierarchical**	**noninformative**
$\boldsymbol{\beta}\|\sigma^2 \sim \mathscr{N}_p(\boldsymbol{\beta}_0, \sigma^2 B_0)$	$\boldsymbol{\beta}\|\Sigma \sim \mathscr{N}_p(\boldsymbol{\beta}_0, \Sigma)$	$\beta_j \overset{\text{iid}}{\sim} \mathscr{N}(0,100)\ j = 1, \ldots, p$
$B_0 = c(X^T X)^{-1}$	$\Sigma \sim IW(S_0^{-1}, \eta_0)$	$\sigma \sim \mathscr{U}(0,100)$
$\sigma^2 \sim IG(\frac{\nu_0}{2}, \frac{\nu_0 \sigma_0^2}{2})$	$S_0^{-1} = \sigma^2 B_0$	
$c \sim \mathscr{U}(0, 10^6)$	$\sigma^2 \sim IG(\frac{\nu_0}{2}, \frac{\nu_0 \sigma_0^2}{2})$	

By $IG(a,b)$ we mean the inverse-gamma distribution with mean $b/(a-1)$, while $IW(S_0^{-1}, \eta_0)$ denotes the inverse-Wishart distribution, with mean $S_0^{-1}/(\eta_0 - p - 1)$ and $\mathscr{U}(a,b)$ is the uniform distribution on the real interval (a,b).

We briefly describe the second model we include here, namely the linear mixed effects model, with likelihood given by

$$Y_{ij} = \mathbf{x}_i^T \boldsymbol{\beta} + \mathbf{z}_i^T \boldsymbol{\gamma}_j + \varepsilon_{ij}, \quad \varepsilon_{ij} \overset{\text{iid}}{\sim} \mathscr{N}(0, \sigma^2) \quad i = 1, ..., N_j,\ j = 1, \ldots, n_{gr}$$

where n_{gr} is the number of groups, $\boldsymbol{\gamma}_j = (\gamma_{j1}, \ldots, \gamma_{jq})$ is the vector of random effects parameters, and $\mathbf{z}_i$ is a q–dimensional vector of covariates. Similarly to the case of the linear regression model we consider three priors, i.e. a hierarchical prior (with exchangeable marginal priors for all the parameters in $\boldsymbol{\beta}$ and for all parameters $\boldsymbol{\gamma}_1, \ldots, \boldsymbol{\gamma}_{n_{gr}}$), and two priors where all the components in the vectors $\boldsymbol{\beta}, \boldsymbol{\gamma}_1, \ldots, \boldsymbol{\gamma}_{n_{gr}}$ are independent (in one case with noninformative marginal priors).

For each class of models we have generated multiple datasets, with different sample sizes or different sizes of the parameters (i.e. varying p in the linear model case). Data were independently generated directly from the likelihood, having fixed a "true" value of the parameters.

The metrics we consider for assessing the performance of the software are (i) the convergence to the true values, (ii) the number of iterations to reach convergence, (iii) the amount of RAM required to run the MCMC, (iv) the effective sample size, (v) the total time elapsed. We believe that these metrics provide a throughout description of the performance of each software. Of course, the convergence of the chain, measured by $\hat{R}$ is a prerequisite for each software.

We run several times the MCMC chains for each model and each software, and average the results for each metric.

For each model, changing the prior and the dimensionality of the problem, we pick a winner based on the following criteria. First of all $\hat{R}$ should be close to 1, and we decided to exclude those software that presented $\hat{R} > 1.1$. Secondly, the effective sample size should be as large as possible, so that if one software chain shows a much larger effective sample size compared to the others, it would be elected winner. In case only these two metrics were close among different software, which was the case for most of the analysed scenarios, we would go on and choose the fastest software. Finally, in case of ties of total elapsed time, we would either declare a tie or choose the software that occupies fewer RAM, but just in case that the RAM usage exceeded 2GBs.

Based on the description above, we come up with a decision tree for each model, where the nodes represent the different priors and the dimensionality of the problem, while the leaves denote the software that we recommend to choose. Figure 1 reports two of such trees, for the linear model and the linear mixed effects model.

4 Discussion and conclusion

Despite an ad-hoc discussion should be made for each model, we try to summarize our insights so far as follows. In general, Stan is more sensitive to prior selection, since the gradient computation required in the NUTS algorithm is really complex and high computationally demanding. This is why, looking at the MCMC output obtained by Stan, we have better performances with non-informative priors, since it is easy to compute the gradient of uniform densities. For the same reason, using the conjugate prior in Stan does not imply higher computational efficiency.

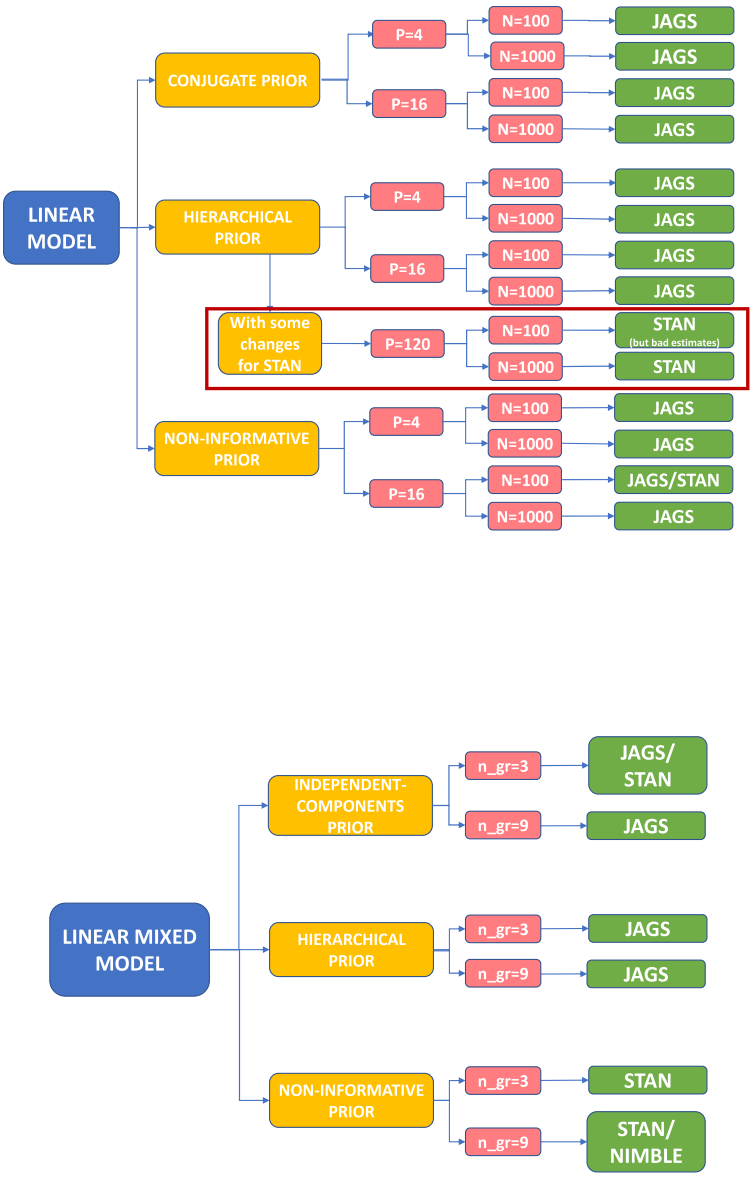

Fig. 1: The leaves denote the best choice of software for two classes of models. Top tree, linear model: p denotes the dimension of the regression parameters and N is the sample size. Bottom tree, linear mixed effects model: `n_gr` is the number of groups.

The importance of the parametric family assumed as the prior is also clear in the case of the most complex linear model (with the largest p), where, using the multivariate normal prior for $\boldsymbol{\beta}$, Stan was not able to move the chains from the initial points. In this case, the Stan manual suggests priors that are more efficient from a computational point of view, to be adopted with hyperparameters that give the prior belief available (e.g. via prior moments of the parameters). This proves that model specification is important when comparing software performance and may influence the performance itself.

It is also important to underline that, in more than one case, NIMBLE was not able to recognize conjugacy in the full conditionals, leading to an inappropriate choice of the sampling method and therefore in inefficiency when building the MCMC chains. As a general result, we have evidence that NIMBLE behaves similarly to JAGS but it is slightly less efficient in terms of effective sample size. However, when the number of data and/or parameters increases, we notice that NIMBLE becomes much faster, in terms of total elapsed time, than JAGS.

Concerning our advice in software selection, results from this procedure show to be in agreement for almost all tested models but the linear model, showing Stan as a general good choice, while JAGS should be used only for well-suited problems, namely with conjugate priors.

The most significant positive feature of Stan is its efficiency, namely the ability to create highly uncorrelated chains, thanks to the underlying algorithm. However, as a drawback, in some cases Stan requires more time to build the chains than other software, especially with specific priors. In these latter cases, such as the linear model and some examples of the linear mixed effects model, considering the ratio of effective samples size over time, one might favor JAGS over Stan, given that the total elapsed time in JAGS is much smaller.

However, when model complexity increases, under the same partial prior information (e.g. fixing the same prior moments of the parameters) if we choose the prior appropriately, Stan results again to be the most efficient software. This has clearly emerged from the analysis of the performance of the software for generalized linear models and accelerated failure time models.

Empirical Bayes estimation for mixture models

Stima empirico-bayesiana per modelli mistura

Catia Scricciolo

Abstract Mixture models are a useful tool for analysing complex data. The Bayesian approach to inference offers a vast choice of prior laws on the mixing measure, which induce priors on the mixture density. The posterior distribution of any summary of the mixing distribution can be derived. This note reviews the current status of mixture density estimation, focussing on recent results on posterior contraction rates for the mixing distribution in the 1-Wasserstein metric. Viewing the mixing measure as a genuine prior, the single mixing parameters can be estimated exploiting the relationship, formalized by Tweedie's formula, with the marginal density.
Abstract I modelli mistura costituiscono un utile strumento per l'analisi di dati complessi. L'approccio bayesiano all'inferenza offre una vasta gamma di leggi iniziali sulla distribuzione misturante che inducono misure di probabilità a priori sulla mistura. È possibile derivare la distribuzione finale di ogni sintesi della misturante. Questa nota fornisce una rassegna sullo stato dell'arte della stima di misture di densità, focalizzando l'attenzione su recenti risultati concernenti la velocità di convergenza nella metrica di Wasserstein della legge finale della distribuzione misturante. Considerando quest'ultima come una distribuzione a priori, i singoli parametri della mistura possono essere stimati sfruttando il legame con la densità marginale stabilito dalla formula di Tweedie.

Key words: Mixture Model, Tweedie's Formula, Wasserstein Metric

1 Introduction

Mixture models

$$p_G(\cdot) = \int k(\cdot \mid \theta)\, \mathrm{d}G(\theta),$$

where k denotes a known base density and G an unknown, nonparametric mixing distribution, provide a useful tool for analysing clustering and making inference about heterogeneity. They can also be a device for density approximation or

Catia Scricciolo
Università degli Studi di Verona, Via Cantarane, 24, 37129 Verona,
e-mail: catia.scricciolo@univr.it

estimation and for performing automatic model selection. Such models are fundamental in empirical Bayes compound decision settings [11] too, see Section 3. The problem is to estimate the mixing distribution G on the base of n independent and identically distributed (iid) observations $X_1, \ldots, X_n$, or $X_{1:n}$ for short, from p_G. When θ is a location parameter, $k(\cdot \mid \theta) = k(\cdot - \theta)$ is a location model and $p_G(\cdot) = \int k(\cdot - \theta)\,\mathrm{d}G(\theta)$ a convolution, therefore we have a deconvolution problem. An alternative approach to the classical nonparametric maximum likelihood estimation of G has been recently proposed in [3], where the problem is reformulated expressing the log-derivative of G as a regression spline. Inference on the mixing distribution G has been reasonably conducted with respect to Wasserstein metrics, which have lately appeared to be natural metrics for controlling the estimation of geometric and topological features of the sampling measure and its support.

Definition 1 (Wasserstein Metrics). Given $p \geq 1$, for any two probability measures G and G' with finite pth moments, the Wasserstein distance of order p is defined as

$$\mathscr{W}_p(G, G') := \inf_{\pi} \left\{ \int \|\theta - \theta'\|^p \,\mathrm{d}\pi(\theta, \theta') \right\}^{1/p},$$

where the infimum is taken over all joint distributions with marginals G and G'.

The Wasserstein distance $\mathscr{W}_p$ is an optimal transport metric, meaning that, if $G = \sum_{j=1}^N p_j \delta_{\theta_j}$ and $G' = \sum_{j=1}^N p_j \delta_{\theta'_j}$, then, for example, $\mathscr{W}_1(G, G') = \sum_{j=1}^N p_j \|\theta_j - \theta'_j\|$ quantifies the minimum cost for moving mass from one probability measure to another one. Besides, $\mathscr{W}_p$ can be endowed with an interesting interpretation: if $\mathscr{W}_p(G_n, G) \asymp \delta_n = o(1)$ and G has a finite number of support points, then there are atoms of G_n converging to those of G at rate δ_n and atoms of G_n, which are redundant, vanishing at a faster rate than δ_n. Lower bounds on the estimation rates with respect to $\mathscr{W}_p$ for the deconvolution problem have been recently obtained in [1] for super- and ordinary smooth kernels, see Table 1.

	Gaussian kernel	Laplace kernel
Super-smooth kernel	$(\log n)^{-1/2}$	
Ordinary smooth kernel		$n^{-1/5}$

Table 1 Optimal 1-Wasserstein $\mathscr{W}_1$ estimation rates for a super-smooth kernel (Gaussian) and for an ordinary smooth kernel (Laplace).

In Bayesian inference, mixture models can be a device for density approximation or, when the kernel k is known, a tool for model-based inference. Prior laws on the mixing distribution G induce prior measures on the mixture density p_G. A common choice for the prior law on G is the Dirichlet process (DP). For DP convolution mixtures, under smoothness conditions on the sampling density p_0 (being not necessarily a mixture p_{G_0}), the posterior distribution on p_G contracts at p_0 at a minimax-optimal rate (up to a log-factor), which automatically adapts to the regularity level of p_0, see [7, 17]. For clustering, nonparametric prior laws as the Pitman-Yor process, which includes the DP as a special case, may result in inconsistent estimates of the number of clusters and mixing components, see [8, 12]. Posterior contraction rates

in Wasserstein metrics $\mathscr{W}_p$ for the latent distribution in deconvolution problems have been studied by [10, 4, 14, 6]. For DP convolution mixtures of super-smooth kernels with decreasing rate β of the Fourier transform, the speed of convergence for the posterior distribution is, up to a log-factor, equal to the optimal rate $(\log n)^{-1/\beta}$, whereas for DP convolution Laplace mixtures, the best obtained rate $n^{-1/8}$ under no assumption on the mixing distribution is sub-optimal. This rate has been recently improved to the lower bound $n^{-1/5}$ by [13] using an approximation scheme based on mixtures of Gaussian-Laplace densities, but under the assumption of Lebesgue absolute continuity of the mixing measure. For finite mixtures, two cases can be distinguished, depending on whether the number of mixture components is or not known. In the former case, using a model-based prior specification, the mixture density as well as the mixing distribution can be estimated at a nearly parametric rate $n^{-1/2}(\log n)^{\kappa}$, see [6, 15]. In the latter case, as shown in Section 2, a mixture of finite mixtures model, with a prior on the number of components, allows to retrieve the parametric rate for estimating the mixture density and the mixing distribution. By Tweedie's formula, estimation of the mixture density is useful for estimation and prediction of the single mixing parameters expressing specific features of the underlying subpopulations in compound decision problems, see Section 3.

2 Mixture Models with a Prior on the Number of Components

When the sampling density p_0 is a finite kernel mixture, with an unknown number N_0 of components, a natural way to deal with this source of uncertainty is to put a prior on it. Let the true density be

$$p_0(\cdot) \equiv p_{G_0}(\cdot) = \sum_{j=1}^{N_0} p_j^0 k(\cdot \mid \theta_j^0),$$

with mixing distribution $G_0 = \sum_{j=1}^{N_0} p_j^0 \delta_{\theta_j^0}$ for weights $\mathbf{p}_{N_0}^0 := (p_1^0, \ldots, p_{N_0}^0)$ and support points $\boldsymbol{\theta}_{N_0}^0 := (\theta_1^0, \ldots, \theta_{N_0}^0)$. Let P_0 denote the probability measure corresponding to p_0. A mixture of finite mixtures (MFM) model, see [9], with a prior on the number of components, can be thus described:

- the number of components N is a random variable (rv) with distribution ρ,
- given N, the random vectors $\mathbf{p}_N := (p_1, \ldots, p_N)$ and $\boldsymbol{\theta}_N := (\theta_1, \ldots, \theta_N)$ are independent, with $\mathbf{p}_N \sim \tilde{\pi}_N$ and $\boldsymbol{\theta}_N \sim \pi_N$,
- given N and $G = \sum_{j=1}^{N} p_j \delta_{\theta_j}$, the rv's $X_1, \ldots, X_n$ are conditionally iid according to p_G.

The overall prior is $\Pi = \sum_{N \geq 1} \rho(N)(\tilde{\pi}_N \otimes \pi_N)$. This general specification allows for other prior laws on $\boldsymbol{\theta}_N$ than the Dirichlet distribution as in [5]. Assume that

i) there exists $K > 0$ such that $\|k(\cdot \mid \theta_1) - k(\cdot \mid \theta_2)\|_1 \leq K|\theta_1 - \theta_2|$ for all θ_1, θ_2;
ii) for $\varepsilon > 0$ small enough and $c_0 > 0$, $\tilde{\pi}_N(\{\mathbf{p}_N : \sum_{j=1}^{N} |p_j - p_j^0| \leq \varepsilon\}) > \varepsilon^{c_0 N}$;
iii) the prior distribution π_N for the atoms has a continuous and positive Lebesgue density (also denoted by π_N) on an interval containing the support of G_0;
iv) the prior probability $\rho(N) > 0$ for every $N \in \mathbb{N}$.

Condition i) requires that $k(\cdot \mid \theta)$ is globally Lipschitz continuous with respect to θ. Condition ii) is satisfied for a Dirichlet prior distribution $\tilde{\pi}_N = \mathrm{Dir}(\alpha_1, \ldots, \alpha_N)$, with parameters $\alpha_1, \ldots, \alpha_N$ such that, for constants $a, A > 0$, $D \geq 1$ and $0 < \varepsilon \leq 1/(DN)$, it is $A\varepsilon^a \leq \alpha_j \leq D$, $j = 1, \ldots, N$. Condition iv) requires that every possible number of components N is assigned a priori a positive probability.

Proposition 1. *Under assumptions i)–iv) and B(1) of [6],*

- $\Pi(N = N_0 \mid X_{1:n}) \to 1$ P_0^∞*-almost surely,*
- *for* $M > 0$ *large enough,* $\Pi(G : \mathscr{W}_1(G, G_0) > M(n/\log n)^{-1/2} \mid X_{1:n}) \to 0$ *in* P_0^n*-probability.*

Proof. Apply Proposition 1 and Lemma 1 in [15] and use relationship (20) of Theorem 6.3 in [6] to conclude. □

Proposition 1 simplifies the proof of Theorem 3.1 in [5] and extends it to a larger class of prior distributions on the mixing weights.

3 Empirical Bayes Estimation of the Single Mixing Parameters

Mixture models are also fundamental in empirical Bayes compound decision problems having the following hierarchical structure, as illustrated in Figure 1:

$$\text{for each } i = 1, \ldots, n, \qquad \begin{aligned} &\theta_i \sim G \ \text{ independently,} \\ &X_i \mid \theta_i \sim k(\cdot \mid \theta_i), \end{aligned}$$

which allows for "borrowing strength" across different populations. Consider, for

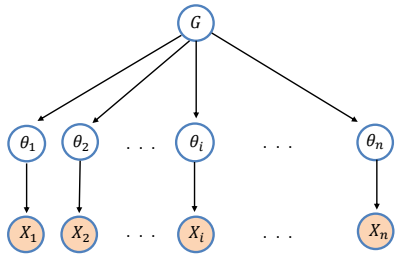

Fig. 1 Empirical Bayes compound decision problem: the parameters θ_i are sampled independently from G and the observation X_i is made within the ith group.

example, a model that allows for different disease rates in n cities, where n_i people are selected from the ith city and we observe how many people X_i have the disease being studied. We can think of the probability of disease as a random draw from some distribution G and it is of interest to estimate the parameters θ_i for each city or the overall disease rate $\int \theta \, \mathrm{d}G(\theta)$. We want to construct estimates of the θ_i's. The optimal prediction of the θ_i's, under the squared error loss, is given by the Bayes rule $\varphi_G(x) := \mathbb{E}(\theta \mid X = x)$. Clearly, $\hat{\theta}_i := \varphi_G(X_i)$ is an estimator of θ_i. For any kernel of the "Laplacian" type $k(x \mid \theta) = e^{\theta x} f(x) h(\theta)$, the following "extraordinary Bayesian estimation formula", see [2], attributed to M.C.K. Tweedie [11], holds

$$\varphi_G(x) = \frac{\mathrm{d}}{\mathrm{d}x}\left(\log \frac{p_G(x)}{f(x)}\right) = \frac{f(x)}{p_G(x)} \times \frac{\mathrm{d}}{\mathrm{d}x}\left(\frac{p_G(x)}{f(x)}\right).$$

The "Laplacian" type kernel includes the exponential family $k(x \mid \theta) = e^{\theta x - \psi(\theta)} f(x)$ as a special case. In particular, for a Gaussian kernel $k(x \mid \theta) = \phi_{\theta,\sigma}(x)$, where $\phi_{\theta,\sigma}$ is the density of a normal $\mathcal{N}(\theta, \sigma^2)$, we have

$$\varphi_G(x) = x + \sigma^2 l'(x), \qquad \text{where } l'(x) := \frac{\mathrm{d}}{\mathrm{d}x} \log p_G(x) = \frac{p'_G(x)}{p_G(x)}.$$

The estimator $\hat{\theta}_i$ takes the form

$$\hat{\theta}_i = X_i + \sigma^2 l'(X_i) = \text{unbiased estimator + Bayes correction.} \tag{1}$$

As remarked by [2], the crucial advantage of Tweedie's formula is that it works directly with the marginal density $p_G(x)$. All observations $x_1, \ldots, x_n$ can then be used to obtain an estimate $\widehat{l'_n}(x)$ of $l'(x)$ yielding an empirical Bayes version of (1)

$$\hat{\theta}_i^{\mathrm{EB}} = X_i + \sigma^2 \widehat{l'_n}(X_i).$$

The "Laplacian" type kernel does not comprise the location Laplace model. Nonetheless using the representation of the Laplace density as a scale mixture of normals $e^{|x-\theta|}/2 = \int_0^{+\infty} (\phi_{\theta,\sqrt{\sigma}}(x) e^{-\sigma/2}/2)\,\mathrm{d}\sigma$ and Tweedie's formula for the Gaussian kernel, which yields $\int \theta \phi_{\theta,\sqrt{\sigma}}(x)\,\mathrm{d}G(\theta) = [x + \sigma l'(x)] p_G^{\mathrm{N}}(x)$ with $p_G^{\mathrm{N}}(x) := (G * \phi_{\theta,\sqrt{\sigma}})(x)$ and $l'(x) := (\mathrm{d}/\mathrm{d}x) \log p_G^{\mathrm{N}}(x)$, we have

$$\varphi_G(x) = \frac{1}{p_G^{\mathrm{L}}(x)} \int \frac{\theta}{2} e^{-|x-\theta|}\,\mathrm{d}G(\theta) = x + \frac{1}{p_G^{\mathrm{L}}(x)} \int_0^{+\infty} \frac{\sigma}{2} e^{-\sigma/2} \frac{\mathrm{d}}{\mathrm{d}x} p_G^{\mathrm{N}}(x)\,\mathrm{d}\sigma \tag{2}$$

and the corresponding estimator for θ_i is

$$\hat{\theta}_i = X_i + \frac{1}{p_G^{\mathrm{L}}(X_i)} \int_0^{+\infty} \frac{\sigma}{2} e^{-\sigma/2} \frac{\mathrm{d}}{\mathrm{d}x} p_G^{\mathrm{N}}(x)\Big|_{x=X_i} \mathrm{d}\sigma.$$

Since the sampling density p_G^{L} is a location mixture of Laplace densities and, for every x and σ, the density $p_G^{\mathrm{N}}(x)$ is a linear functional of the mixing distribution G, if G has Lebesgue density, then $p_G^{\mathrm{N}}(x)$ can be efficiently estimated by

$$\widehat{p_n^{\mathrm{N}}}(x) = \frac{1}{n} \sum_{i=1}^{n} \phi_{X_i,\sqrt{\sigma}}(x) \left(1 - \frac{1}{\sigma} + \frac{(x - X_i)^2}{\sigma^2}\right),$$

see [16] for the details. For any estimator $\widehat{p_n^{\mathrm{L}}}(x)$ of $p_G^{\mathrm{L}}(x)$, an empirical Bayes version of (2) is given by

$$\widehat{\varphi_G}(x) = x + \frac{1}{\widehat{p_n^{\mathrm{L}}}(x)} \int_0^{+\infty} \frac{\sigma}{2} e^{-\sigma/2} \frac{\mathrm{d}}{\mathrm{d}x} \widehat{p_n^{\mathrm{N}}}(x)\,\mathrm{d}\sigma,$$

which yields

$$\hat{\theta}_i^{\mathrm{EB}} = X_i + \frac{1}{\widehat{p_n^{\mathrm{L}}}(X_i)} \int_0^{+\infty} \frac{\sigma}{2} e^{-\sigma/2} \frac{\mathrm{d}}{\mathrm{d}x} \widehat{p_n^{\mathrm{N}}}(x) \Big|_{x=X_i} \mathrm{d}\sigma.$$

4 Concluding Remarks

We have shown that, a mixture of finite mixtures prior allows to estimate the mixing distribution of a finite kernel mixture with an unknown number of components N_0 at a nearly parametric rate, as if N_0 were known and this information could be used for the prior specification. Estimating the mixture density is also useful for estimation and prediction of the single mixing parameters or support points of the mixing distribution, which express specific features of the underlying subpopulations in compound decision problems. An empirical Bayes estimator of the single mixing parameters for Laplace convolution mixtures is proposed.

Improving ABC via Large Deviations Theory
Migliorare ABC *tramite la teoria delle Grandi Deviazioni*

Cecilia Viscardi, Michele Boreale and Fabio Corradi

Abstract *Sample degeneracy* in Approximate Bayesian Computation (ABC) is caused by the difficulty of simulating pseudo-data matching the observed data. In order to mitigate the resulting waste of computational resources and/or bias in the posterior distribution approximation, we propose to weight each parameter proposal by treating the generation of matching pseudo-data, given a "poor" parameter proposal, as a *rare event* in the sense of Sanov's Theorem. We experimentally evaluate our methodology through a proof-of-concept implementation.
Abstract *Il problema della* degenerazione del campione *in metodi ABC deriva dalla difficoltà di generare dati simili a quelli osservati. Al fine di evitare i conseguenti sforzi compuatazionali e/o distorsioni nell'approssimazione della distribuzione a posteriori, proponiamo di pesare ciascun parametro trattando la simulazione di dati uguali a quelli osservati come un evento raro nel senso del Teorema di Sanov. Si riportano i risultati di una valutazione empirica della metodologia proposta.*

Key words: ABC, Large Deviations, Sanov's Theorem, Sample Degeneracy.

1 Approximate Bayesian Computation and sample degeneracy

Let $x^n \in \mathscr{X}^n$ be a vector of observed data, which will be assumed to be drawn from a probability distribution in the family $\mathscr{F} \stackrel{\triangle}{=} \{P(\cdot|\theta) : \theta \in \Theta\}$. Suppose that our aim is to provide information about the uncertainty on θ by deriving the posterior distribution $\pi(\theta|x^n) \propto \pi(\theta)P(x^n|\theta)$ via Bayes' Theorem. When the likelihood function is analytically and numerically intractable, Approximate Bayesian Computation (ABC) allows for simulated inference by providing a conversion of samples from the prior into samples from the posterior distribution. This relies on compar-

Authors'affiliation: University of Florence - Department of Statistics and Computer Science (DiSIA) - e-mail: cecilia.viscardi@unifi.it, michele.boreale@unifi.it, fabio.corradi@unifi.it.

isons between the observed data and the pseudo-data generated from a *simulator*[1]. Algorithm 1 displays the rejection sampling scheme (R-ABC), whose origins can be traced back to [7, 4].

Algorithm 1 R-ABC

1: **for** $s = 1,...,S$ **do**
2: Draw $\theta^{(s)} \sim \Pi$
3: Generate $y \sim P(\cdot|\theta^{(s)})$
4: Accept $(\theta^{(s)}, s_y^{(s)})$ if $d(s_y^{(s)}, s_x) < \varepsilon$
5: **end for**

Algorithm 2 IS-ABC

for $s = 1,...,S$ **do**
2: Draw $\theta^{(s)} \sim q$
Generate $y \sim P(\cdot|\theta^{(s)})$
4: Set the IS weight for $\theta^{(s)}$ to

$$\omega_s = K_\varepsilon\big(d(s_y, s_x)\big) \cdot \frac{\pi(\theta^{(s)})}{q(\theta^{(s)})}$$

end for

Samples resulting from Alg.1 are not from the exact posterior distribution since a twofold approximation is introduced by: summarizing data through a statistic $s(\cdot)$ — i.e. a function from the sample space $\mathscr{X}^n \subseteq \mathbb{R}^n$ to a lower-dimensional space $\mathscr{S}$— and assessing similarity via a distance function $d(\cdot,\cdot)$ and a tolerance threshold $\varepsilon > 0$.

Abbreviating $s(x^n)$ and $s(y^n)$ respectively as s_x and s_y, the output of the Alg.1 is a sample of pairs $(\theta^{(s)}, s_y^{(s)})$ from the following *approximated* joint posterior distribution

$$\tilde{\pi}(\theta, s_y|s_x) \propto \pi(\theta)\, P(s_y|\theta)\, \mathbb{1}\{d(s_y, s_x) \leq \varepsilon\} \tag{1}$$

where $\mathbb{1}\{d(s_y, s_x) \leq \varepsilon\}$, the indicator function assuming value 1 if $d(s_y, s_x) \leq \varepsilon$ and 0 otherwise, corresponds to the acceptance step. Marginalizing out s_y in (1), that is ignoring the simulated summary statistics, the output of the algorithm becomes a sample from the following approximated marginal posterior distribution

$$\tilde{\pi}(\theta|s_x) \propto \int_{\mathscr{S}} \pi(\theta)\, P(s_y|\theta)\, \mathbb{1}\{d(s_y, s_x) \leq \varepsilon\}\, ds_y = \pi(\theta) \cdot \Pr\big(d(s_Y, s_x) \leq \varepsilon|\theta\big). \tag{2}$$

The probability $\Pr\big(d(s_Y, s_x) \leq \varepsilon|\,\theta\big)$, where s_Y indicates $s(Y^n)$, is called the ABC *approximated likelihood.* As $\varepsilon \to 0$ the ABC likelihood converges to the true likelihood (see [3, Appendix A, p. 832]) and, whenever sufficient summary statistics for θ are chosen, $\tilde{\pi}(\cdot|s_x)$ converges to the true posterior $\pi(\cdot|x^n)$ (see [6, Ch. 1]). In practice the indicator function in (1) is often replaced by a kernel function $K_\varepsilon(\cdot)$ (e.g. triangular, Epanechnikov, Gaussian etc.) defined on the compact support $[0, \varepsilon]$ and providing a continuous decay from 1 to 0 (see e.g.[1]).

In the ABC literature a great variety of methods to sample from $\tilde{\pi}(\theta, s_y|s_x)$ have been proposed [2]. An example, is the importance sampling scheme IS-ABC reported as Alg. 2. Like the standard importance sampling, it suffers from *sample degeneracy*

[1] A simulator can be thought of as computer program taking as input a parameter value (or a vector thereof) $\theta^* \in \Theta$ and returning a sample from the distribution $P(\cdot|\theta^*)$.

[2] We refer the reader to [6, Ch 4] for an overview.

– i.e. only a small fraction of the proposed pairs has relatively high weights when the instrumental density $q(\cdot)$ is far from the target. Unlike the standard importance sampling, the IS-ABC implicitly involves a rejection when $\omega_s = 0$ — i.e. whenever a distance $d(s_y^{(s)}, s_x) > \varepsilon$ is observed [3]. Since they depend on the random variable s_Y through the distance $d(s_Y, s_x)$, when θ^* is such that $\Pr(s_Y = s_x|\theta^*)$ is close to zero, the importance weights will cause a huge number of rejections before a distance smaller than ε will be observed. This further aggravates the *sample degeneracy* issue. More sophisticated sampling schemes (e.g. MCMC-ABC, SMC-ABC, SIS-ABC, etc.) have been proposed to handle the issue of finding a good importance distribution, $q(\theta)$, but they completely ignore the effect of the kernel $K_\varepsilon(\cdot)$. In the next two sections we discuss how to define a kernel function $K_\varepsilon(\cdot)$ that improves the efficiency of ABC sampling schemes by avoiding rejections at all.

2 Large Deviations Theory in ABC

When a "poor" parameter proposal is given as an input to the generative model, simulating pseudo-data y^n such that $d(s_y, s_x) \leq \varepsilon$ can be treat as a *rare event*. This often leads to a shortage of accepted values mostly in regions of Θ with a low but positive (true) posterior density, in turn resulting in a bad approximation in the tails of the posterior distribution. A possible approach to mitigate those issues is to provide a finer estimate for the ABC likelihood allowing to avoid rejections at all. To this aim, we resort to *Large Deviations Theory* (LDT).

Let x^n be a sequence of n symbols drawn from $\mathscr{X}$ according to $P_\theta \stackrel{\triangle}{=} P(\cdot|\theta)$, say $x^n = (x_1, ..., x_n)$. The empirical distribution of x^n, written P_{x^n}, is the probability distribution on $\mathscr{X}$ defined by

$$P_{x^n}(r) \stackrel{\triangle}{=} \frac{|\{i : x_i = r\}|}{n} \quad \forall r \in \mathscr{X}. \tag{3}$$

Given a large n, observing a sequence whose empirical distribution is far from P_θ is a rare event, and its probability obeys to a fundamental result in LDT, Sanov's theorem (see [2, Th.11.4.1]).

Theorem 1 (Sanov's Theorem). *Let $\{X_i\}_{i=1}^n$ be i.i.d. random variables on $\mathscr{X}$, with each $X_i \sim P_\theta$. Let $\Delta^{|\mathscr{X}|-1}$ be the simplex of probability distributions over $\mathscr{X}$ and let $E \subseteq \Delta^{|\mathscr{X}|-1}$. Then*

$$\Pr\left(P_{X^n} \in E \,|\, \theta\right) \leq (n+1)^{|\mathscr{X}|} 2^{-nD(P^*||P_\theta)}. \tag{4}$$

where $D(\cdot||\cdot)$ is the Kullback-Leibler divergence and $P^* = \operatorname{argmin}_{P \in E} D(P||P_\theta)$ is the information projection of P_θ onto E. Furthermore, if E is the closure of its interior

[3] Note that Alg. 1 is a special case of the Alg.2 where the marginal importance distribution, $q(\theta)$, is the prior distribution and the resulting importance weights are $\omega_s \in \{0, 1\}$.

$$\lim_{n\to\infty}\frac{1}{n}\log\Pr(P_{X^n}\in E\,|\,\theta)=-D(E||P_\theta)=-D(P^*||P_\theta).$$

In order to show how to make use of the Sanov's result in the approximated likelihood computation, from now on we will assume: a) $\varepsilon>0$ as a threshold; b) empirical distributions as summary statistics; c) the Kullback-Leibler divergence as distance function; d) the empirical distribution P_{x^n} to be full support. The IS-ABC generates pairs $(P^{(s)}_{y^m},\theta^{(s)})$ with $s\in\{1,...,S\}$. Each $P^{(s)}_{y^m}$ is an empirical distribution resulting from a sequence of i.i.d. random variables, $Y^m=\{Y_j\}_{j=1}^m$, distributed according to $P\big(\cdot\,|\,\theta^{(s)}\big)$. We want to stress that the length of the simulated sequence, m, need not be equal to n, the length of the observed data sequence.

Under our assumptions, each $\theta^{(s)}$ is accepted or rejected depending on the divergence $D(P_{y^m}||P_{x^n})$. Thus, we can define the following acceptance region:

Definition 1 (Acceptance region). Let $\Delta^{|\mathscr{X}|-1}$ be the simplex of probability distributions over $\mathscr{X}$ and let P_{x^n} be the empirical distribution of the observed sequence x^n. The *acceptance region* $\mathscr{B}_\varepsilon(P_{x^n})$, shortly $\mathscr{B}_\varepsilon$, is defined for any $\varepsilon\geq 0$, as

$$\mathscr{B}_\varepsilon\stackrel{\triangle}{=}\big\{P\in\Delta^{|\mathscr{X}|-1}:D(P||P_{x^n})\leq\varepsilon\big\}.$$

Sanov's result, for m large enough, allows to approximate the probability of simulating pseudo-data whose summary statistic, P_{y^m}, is in the acceptance region even when a "poor" parameter in proposed:

$$\Pr\big(P_{Y^m}\in\mathscr{B}_\varepsilon\,|\,\theta^{(s)}\big)\approx 2^{-mD(\mathscr{B}_\varepsilon||P_{\theta^{(s)}})}. \tag{5}$$

Unfortunately, the computation of the probability in (5) is still not feasible when the model $\mathscr{F}=\{P_\theta:\theta\in\Theta\}$ is unknown, as we do not know how to compute $D(\mathscr{B}_\varepsilon||P_{\theta^{(s)}})$. However, one we can prove that

$$\lim_{m\to\infty}D(\mathscr{B}_\varepsilon||P_{Y^m})=D(\mathscr{B}_\varepsilon||P_\theta)\quad a.s. \tag{6}$$

According to (5) and (6) we propose the following kernel function:

$$K_{\varepsilon,m}\big(P_{y^m}\big)=\begin{cases}1 & \text{if } D(P_{y^m}||P_{x^n})\leq\varepsilon\\ 2^{-mD(\mathscr{B}_\varepsilon||P_{y^m})} & \text{if } D(P_{y^m}||P_{x^n})>\varepsilon\end{cases} \tag{7}$$

By resorting to this kernel the joint and the marginal posterior distributions are characterized by the following equations:

$$\tilde{\pi}(\theta,P_{y^m}|P_{x^n})\propto\pi(\theta)\,K_{\varepsilon,m}\big(P_{y^m}\big)\;P_\theta(P_{y^m}) \tag{8}$$

$$\tilde{\pi}(\theta|P_{x^n})\propto\pi(\theta)\sum_{P_{y^m}\in\mathscr{P}^m}K_{\varepsilon,m}\big(P_{y^m}\big)\;P_\theta(P_{y^m}) \tag{9}$$

where $\mathscr{P}^m\subset\Delta^{|\mathscr{X}|-1}$ denotes the set of the empirical distributions with denominator m. Accordingly, the ABC likelihood is defined as follows

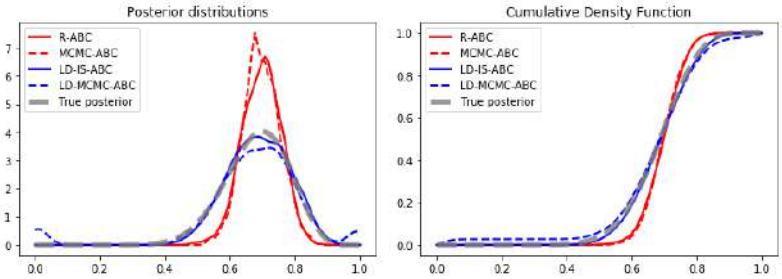

Fig. 1 Parameter posterior distributions (LHS) and posterior cumulative density functions (RHS) derived through IS and MCMC schemes with the uniform kernel and with the proposed kernel.

$$\tilde{\mathscr{L}}_{\varepsilon,m}(\theta;P_{x^n}) \stackrel{\triangle}{=} \sum_{P_{y^m}\in\mathscr{P}^m} K_{\varepsilon,m}\left(P_{y^m}\right) P_\theta\left(P_{y^m}\right). \tag{10}$$

Note that, now Alg.2 gives a positive weight to each $\theta^{(s)}$. More precisely, the weight equals 0 only when $D(\mathscr{B}_\varepsilon||P_{y^m}) = \infty$. In the next section we empirically demonstrate the improvements achieved by resorting to the proposed kernel.

3 A toy example

Let x^{20} be a sample from i.i.d. Bernoulli random variables with parameter θ. Suppose that x^{20} has empirical distribution $P_{x^n} = [0.3, 0.7]$. Assuming an uniform prior distribution, the posterior distribution, $\pi(\theta|x^{20})$, is a Beta distribution with parameters $\alpha = 15$ and $\beta = 7$.

We ran $S = 10000$ iterations of IS-ABC both with the uniform kernel and the proposed kernel. Note that in the first case the algorithm corresponds to a R-ABC. We also implemented the MCMC-ABC sampling scheme (see [6, Ch. 4]). For the sake of simplicity we adopt the abbreviation LD, standing for Large Deviations, to indicate that the employed kernel function is (7).

Fig.1 shows the posterior distributions and cumulative density functions (CDF) approximated by each algorithm. As it is apparent, the LD algorithms (blue lines) approximate better the true posterior (dashed grey line). Looking at the CDF's, we can see that using the uniform kernel (red lines) results in a worse approximation in the tails.

We evaluate the posterior mean point estimates and the posterior density estimates through the Squared Error and the Integrated Squared Error respectively. We also consider the Effective Sample Size as a measure of the degree of sample degeneracy. From Tab.1, we can see that, despite the quality of the point estimations is almost the same, the proposed kernel function leads to clear improvements in terms of density estimations and *ESS*, both for the IS-ABC and for the MCMC-ABC.

Table 1 Squared Errors, Integrated Squared Errors and Effective Sample Sizes with $\varepsilon = 0.01$, $m = 100$.

Algorithm	*SE*	*ISE*	*ESS*
R-ABC	0.0002	0.6428	1279
LD-IS-ABC	0.0003	0.0096	3060
MCMC-ABC	0.0002	0.8597	655
LD-MCMC-ABC	0.0002	0.041	1929

4 Conclusions

We have put forward an approach to address sample degeneracy in ABC. Our proposal consists in the definition of a convenient kernel function which, via Large Deviations Theory, takes into account the probability of rare events. Being defined on a non-compact support, the proposed kernel allows to avoid rejections, thus mitigating the effects of the sample degeneracy. We have also evaluated our methodology on a simple example, showing that it provides a better approximation of the posterior density and increases the Effective Sample Size.

Learning Bayesian Networks for Nonparanormal Data

Apprendimento di reti bayesiane per dati non parametrici

Abstract In the literature, structural learning procedures for selecting the directed acyclic graph of a Bayesian network are increasingly explored and specified according to the analyzed data typology. With respect to data drawn from a Gaussian Copula model, the Rank PC algorithm, based on Spearman rank correlation, has been introduced. Moreover, we recently proposed a modified version of the well known Grow-Shrink algorithm, the Copula Grow-Shrink one, based on the Spearman rank correlation and the Copula assumption. Here, we show a simulation study to verify the robustness of our Copula Grow-Shrink algorithm and we discuss the performance results in comparison with the baseline and the Rank PC algorithm.

Abstract *In letteratura, le procedure di apprendimento strutturale per la stima di un grafico diretto aciclico di una rete bayesiana sono sempre più esplorate e dettagliate in base alla tipologia di dati analizzati. Per quanto riguarda i dati derivanti da un modello di copula gaussiana l'algoritmo Rank PC, basato sulla correlazione di Spearman, è stato proposto in letteratura. Inoltre, abbiamo recentemente proposto una versione modificata del noto algoritmo Grow-Shrink, l'algoritmo Copula Grow-Shrink, basato sulla correlazione tra ranghi di Spearman e sull'assunzione di Copula. Qui, mostriamo uno studio di simulazione per verificare la solidità del nostro algoritmo Copula Grow-Shrink e discutiamo i risultati delle prestazioni rispetto agli algoritmi Grow-Shrink e Rank PC.*

1 Introduction

Statistical multivariate data modeling is increasingly carryed out through Bayesian networks, (BN, [2]) that depict the multivariate probability distribution of a set of

variables by a graphical representation of independencies encoded in a directed acyclic graph (DAG). A DAG is a finite set of nodes, standing for random variables, and directed edges, arranged never producing cycles, that point out direct relevance of one variable to another. In a DAG, a parent node has an outcoming arrow pointing to another node namely child; every node is associated with a conditional distribution given its parents and the joint distribution can be factorized according to the DAG.

In this context, a common issue concerns the DAG structural elicitation. When the dependencies are unknown or partially known, DAG structure has to be estimated directly from data. Most often, researchers wish to maximize the learning power respecting the typology of managed data. For nonparanormal data some structural learning algorithms have been discussed in the literature; we recently proposed the Copula Grow-Shrink [1], a modified version of the Grow-Shrink algorithm, based on the recovery of the Markov blanket of the nodes and on the Spearman correlation. The paper, aiming at evaluating the robustness of the our proposal, is organized as follows: nonparanormal graphical models are briefly recalled in Section 2; the Grow-Shrink and the Copula Grow-Shrink algorithms are discussed in Section 3; the simulation study and preliminary results are addressed in Section 4.

2 Nonparanormal Graphical models and their estimations

Nonparanormal data modeling by graphical models has been studied in the literature. Generally speaking, a nonparanormal graphical model is a semiparametric extentions of a Gaussian graphical model useful when the analysed continuous variables follow a Gaussian graphical model only if trasformed by unknown smooth monotone functions preserving the dependencies structure of the underlying multivariate normal distribution. According to [7]:

> Definition 1. Let $f = (f_v)_{v \in V}$ a collection of strictly increasing functions $f_v : R \to R$ and $\Sigma \in R^{V \times V}$ be a positive definite correlation matrix. The nonparanormal distribution NPN(f, Σ) is the distribution of the random vector $(f_v(Z_v))_{v \in V}$ for $(Z_v)_{v \in V} \sim N(0, \Sigma)$.

> Definition 2. The nonparanormal graphical model NPN(G) associated with a DAG G is the set of all distributions NPN(f, Σ) that are Markov with respect to G.

The function f_v realizes a deterministic transformation on Z_v preserving the same dependence structure of the underlying latent multivariate normal distribution also in the nonparanormal model.
If $X \sim NPN(f, \Sigma)$ and $Z \sim N(0, \Sigma)$, for any triple of pairwise disjoint set $A, B, S \subset V$, then $X_A \perp\!\!\!\perp X_B | X_S \Leftrightarrow Z_A \perp\!\!\!\perp Z_B | Z_S$.
For two nodes (u, v) and a separating set S we have $X_u \perp\!\!\!\perp X_v | X_S \Leftrightarrow \rho_{uv|S} = 0$.

A trigonometric transformation on Spearman rank correlation (r) produces latent Normal correlation coefficients accurate estimators. Reference [5] show that if (X,Y) are bivariate normal with $Corr(X,Y) = \rho$, it yelds:

$$P(|2sin(\frac{\pi}{6}\widehat{r}) - \rho|) > \varepsilon) \leq 2exp(-\frac{2}{9\pi^2}n\varepsilon^2) \tag{1}$$

Since $\widehat{r}$ depends on the observations *via* their ranks that are preserved under strictly increasing functions, (1) still holds for nonparanormal graphical models with Pearson correlation $\rho = \Sigma_{xy}$ in the underlying latent bivariate normal distribution. On the basis of the previous result ρ is estimated as:

$$\hat{\rho} = 2\sin(\frac{\pi}{6} \cdot \hat{r}) \tag{2}$$

The same transformation still holds for the partial correlation coefficients.

3 Bayesian Netoworks Structural Learning

Bayesian netoworks structural learning methods are mainly *scoring and searching* techniques or *constraint-based* algorithms; they estimate and depict the unknown independencies relations among variables by a DAG. The most spread algorithm is the PC algorithm [9] that proceeds along three steps: (i) the skeleton identification by testing marginal and conditional independencies by Pearson correlation test for Gaussian data, (ii) the v-structures identification standing for conditional dependence between two nodes given a third and (iii) the orientation of the remaining links without producing additional v-structures and/or directed cycles. If variables are not Gaussian, a PC algorithm rank version named Rank PC (RPC) algorithm is available [7]. RPC algorithm tests conditional independence between two variables given a separating set by computing the rank-based partial correlation estimates (Eq. 2). The RPC algorithm consistency is proved by [7], under some non-strict assumptions. It is shown that RPC works at the same strength of PC algorithm for normal data but considerably better for non-normal data under the *strong* assumption of joint distribution following a normal copula model. The RPC algorithm could be implemented using the `pcalg R` package [4].
A competitive algorithm to these common choices is the Grow-Shrink algorithm (GS, [6]) based on the intuitive concept of the Markov blanket (MB) of a variable, *i.e.* the set of all parents, children and parents of children of the variable of interest, say X. Moreover, the MB(X) d-separates variable X from any other variable outside its Markow blanket. The GS algorithm focuses on the recovery of the MB(X) based on pairwise independence tests by two phases: the growing phase, where, from MB(X) empty set denoted by S, the procedure adds variables to S as long as they are associated with X given the current contents of S; the shrinking phase identifies and removes variables not really belonging to MB(X) eventually added to S. Our Copula GS algorithm (CGS) [1] has the same logical structure as GS but the

marginal and partial correlations coefficients used in the statistical test for independence are computed trough (2). The GS is implemented in `bnlearn R` package [8] so that our proposal is developed in `R` as well.

4 Main Results and Conclusions

With the aim to explore the robustenss, a simulation study has been carried out. According to the procedure in [3] and to the simulation plan in [7], we simulated 200 random DAGs with sparsity parameter $s = 0.3$ and we sampled from a Gaussian Copula distribution faithful to them. Considered sample sizes are $n = 50$ and $n = 1000$. On every training set, we performed the structural learning GS, CGS and RPC algorithms with a significance level of 0.05. Algorithm performances have been compared in terms of sensitivity, specificity and precision.
In details, the diagnostic measure *true positive rate* (TPR) is the proportion of edges correctly estimated on the true edges; the closer the value is to 1, the better is the sensitivity. The *false positive rate* (FPR) is the proportion of edges incorrectly found over the number of true gaps; the closer the value is to 0, the better is the specificity. The *true discovery rate* (TDR) is the proportion of edges correctly found on the total number of estimated edges; the closer the value is to 1, the better is the precision. The performance measure distributions from simulations are displayed in the following boxplot (see Figures 1 e 2).

For small sample size $n = 50$ (see Figure 1) the sensitivity of CGS algorithm outperforms the GS and the RPC ones denoting a better capacity to catch the real structure. The specificity of CGS is still better with respect to GS and only slightly more variable in comparison to RPC. Also in terms of TDR, the CGS outperforms the GS and works the same as the RPC. For large sample size $n = 1000$ (see Figure 2) the CGS outperforms the GS and works slightly better than the RPC in terms of specificity and precision but gains a stronger sensitivity.
According to these simulation results the algorithm we propose represents a better choice to estimate a DAG in case of nonparanormal data. Since $1 - TPR$ is equal to the False Negative Rate (FNR), it means that the CGS algorithm prevents from bias in the model due to the absence of a "true" arc. We argue that, as the RPC one, also the CGS algorithm reduces the risk of an overparametrization of model since the FPR is smaller than that of GS for both sample sizes.

Measuring well-being combining different data sources: a Bayesian networks approach

Misurare il benessere combinando diverse fonti di dati: un approccio basato sulle reti bayesiane

F. Cugnata, S. Salini, E. Siletti

Abstract In this paper we focus on a Bayesian networks approach to combine traditional survey and social networks data to evaluate subjective well-being. Bayesian networks permit to use data with not the same geographical levels, provincial and regional, and with different time frequencies, quarterly and annual. Moreover, we remark that in this proposal we combine both categorical and continuous data. The application, referred to Italy from 2012 to 2017, has been performed using ISTAT's survey data, some covariates, from official statistics or related to the considered time period, and a composite index of well-being obtained by Twitter data.

Abstract *In questo lavoro ci focalizziamo su un approccio basato sulle reti bayesiane che, combinando dati provenienti da sondaggi tradizionali e da social networks, permette di valutare il benessere soggettivo. Le reti bayesiane consentono di utilizzare dati con livelli geografici non uguali, provinciali e regionali, e con frequenze temporali diverse, trimestrali e annuali. Inoltre, sottolineiamo che in questa proposta combiniamo dati sia categorici che continui. L'applicazione, riferita all'Italia dal 2012 al 2017, è stata eseguita utilizzando i dati provenienti da sondaggi ISTAT, alcune covariate, provenienti da statistiche ufficiali o relative al periodo considerato, e un indice composito di benessere ottenuto dai dati Twitter.*

1 Introduction and background

Following the Stiglitz Commission's suggestions, which in summary advised to build a complementary system focused on social well-being, suitable for measuring sustainability, and which takes into account also subjective assessment [17], new measures have been proposed. In these new indices, the subjective dimensions are traditional investigated by ad hoc surveys, nevertheless these data are not free of issues, we briefly remember those related to the survey structure or plan, which despite all the efforts made [11], still show some methodological drawbacks [4, 5], and those according their poor geographical disaggregation or low time frequency.

Moreover, an objective evaluation of the indices currently proposed cannot fail to note a limited and undersized presence of the subjective and perceived dimension. Trying to fill this information gap, since 2012, with the aim of finding complementary info, a new subjective and perceived Italian well-being index deepening social networks data has been proposed (Subjective Well-being Index - SWBI, [8]). This composite index, providing a measure across the same domains considered by the New Economic Foundation for its Happy Planet Index [14], is the result of a human supervised sentiment analysis (Integrated Sentiment Analysis - iSA, [2]) on Twitter data. Recently, [9] suggest to use SWBI to provide a measurement of subjective well-being available at Italian sub-national levels and at different moments of time.

However, despite social networks data has been defined the largest available focus group in the world [12, 7], they permit to cover several topics, are continuously updated, and are free or cheap, it is undeniable that also these data are not free of disadvantages. Even if the social media users are always increasing [1], not all are users; hence, one of the main issue concerns sampling bias. To not renounce such an intense source of information, scholars are still working to the solution for these issues. Especially, [10] suggested a new Italian well-being measure mashing-up official statistics with Twitter data using a weighting procedure combined with a Small Area Estimation (SAE) model to consider precisely sampling bias.

Following in this practice, with this contribute we combine, in a Bayesian networks (BNs) approach, traditional survey and social networks data to evaluate subjective well-being. Adopting this approach we can use both categorical and continuous data with different geographical area levels and time frequencies. Section 2 reports a brief presentation of BN, while in section 3 there is a first example referring to Italian data from 2012 to 2017.

2 Method

BN are both mathematically rigorous and intuitively understandable data analytic tools. They implement a graphical model structure, known as a directed acyclic

[1] "Digital in 2019", `http://wearesocial.com`: from Jan 2018 to Jan 2019 the world growth is +9.1% for the Internet accesses and +9% for the social media active accounts.

graph (DAG), that is popular in statistics, machine learning and artificial intelligence. They enable an effective representation and computation of a joint probability distribution (JPD) over a set of random variables.

The DAG's structure is defined by a set of nodes, representing random variables and plotted by labeled circles, and a set of arcs, representing direct dependencies among the variables and plotted by arrows. Thus, an arrow from X_i to X_j indicates that a value taken by variable X_j depends on the value taken by variable X_i. Node X_i is then referred to as a "parent" of X_j and, similarly, X_j is referred to as the "child" of X_i. An extension of these genealogical terms is often used to define the sets of "descendants", i.e., the set of nodes from which the node can be reached on a direct path. The DAG guarantees that there is no node that can be its own ancestor (parent) or its own descendent. Such a condition is of vital importance to the factorization of the joint probability of a collection of nodes. Although the arrows represent direct causal connection between the variables, under causal Markov condition, the reasoning process can operate on a BN by propagating information in any direction. A BN reflects a simple conditional independence statement, namely that each variable, given the state of its parents, is independent of its non-descendants in the graph. This property is used to reduce, sometimes significantly, the number of parameters that are required to characterize the JPD. This reduction provides an efficient way to compute the posterior probabilities given the evidence in the data [13, 15]. In addition to the DAG structure, which is often considered to be the qualitative part of the model, one estimates the quantitative parameters applying the Markov property, where the conditional probability distribution at each node depends only on its parents.

More formally, BNs are defined by a network structure, a DAG $G = (\mathbf{V};A)$, in which each node $v_i \in \mathbf{V}$ corresponds to a random variable X_i; a global probability distribution, $\mathbf{X}$, which can be factorised into smaller local probability distributions according to the arcs $a_{ij} \in A$ in the graph. The main role of the network structure is to express the conditional independence relationships among the variables in the model through graphical separation, thus specifying the factorisation of the global distribution:

$$\prod_{i=1}^{p} P(X_i|\Pi_{X_i}) \qquad \text{where } \Pi_{X_i} = \text{parents of } X_i.$$

The choice of the probability distribution $P(X)$ should such that the BN can be learned efficiently from data. This distribution is flexible, so the assumptions should not be too strict, and it is easy to query to perform inference [16]. The three most common choices in the literature, are:

- Discrete BNs (DBNs): X and $X_i|\Pi_{X_i}$ are multinomial;
- Gaussian BNs (GBNs): X is multivariate normal and $X_i|\Pi_{X_i}$ are normal;
- Conditional Linear Gaussian BNs (CLGBNs): X is a mixture of multivariate normal and $X_i|\Pi_{X_i}$ are either multinomial, normal or mixtures of normal.

It has been proved that exact inference is possible in these three cases, hence their popularity. In this work we consider CLGBNs: some variables are categorical

and some other are numerical. BNs have already been used to the analysis of multidimensional well-being [1], taking into account the correlation among dimensions. The same authors applied also multivariate statistical techniques to ISTAT's BES index [3]. Moreover, [18] employed BNs in the context of subjective well being, focusing on the ability to predict it by material living conditions and deprivation, using the European Quality of Life Study data (2011) in four Central European countries. This proposal combines, in a BNs approach, well-being data from social networks [8] and surveys.

3 Application: Data and Preliminary Results

As survey data we consider some variables from the "Aspect of daily life" report. This ISTAT sample survey collects fundamental details on Italian individual and household daily life, focusing on several thematic areas on different social aspects useful to study well-being, this data are adopted also for the subjective dimension in the ISTAT's well-being index BES (Benessere Equo e Sostenibile). This is an annual survey that consider people aged 14 and over, and data, with a regional aggregation, are available free of charge (http://dati.istat.it/).

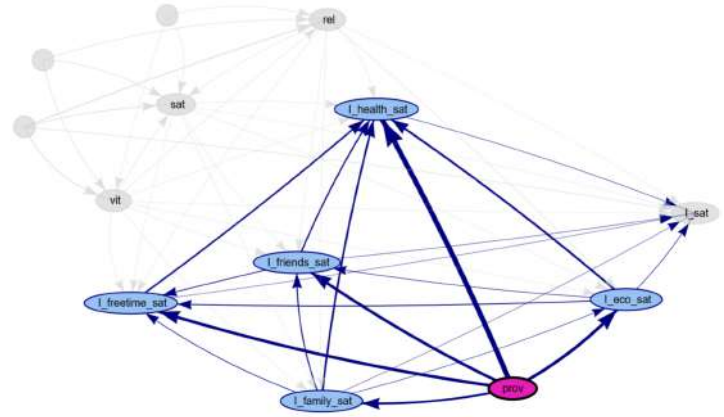
The considered variable are: (`I_sat`) the average rating of *satisfaction with life as a whole* (with a 1 to 10 scale), the percentage of people very or fairly satisfied with the *economic situation* (`I_eco_sat`), with *health* (`I_health_sat`), with *family relationships* (`I_family_sat`), with their *friendships* (`I_friends_sat`), and with their *free time* (`I_freetime_sat`).

Moreover we consider, as covariate, other social and demographic data and some variables related to the considered time period:

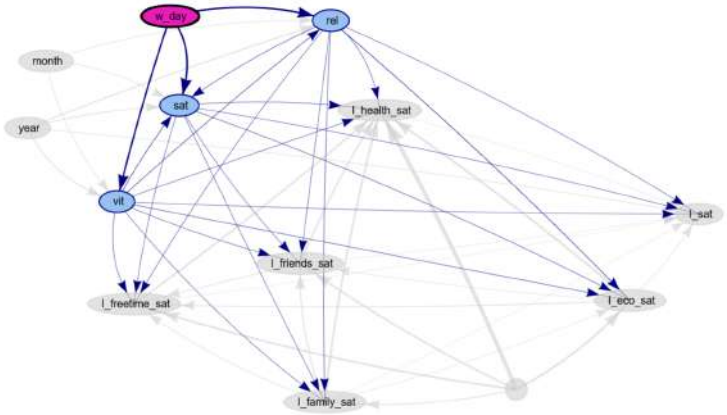
- the quarterly regional *unemployment rate* (`t_unemployment`), *number of inactive people* (`inactives`), *number of employed people* (`employed`), and *labor force* (`laborforce`);
- the quarterly provincial *broadband coverage* proportion (`broadband`);
- the annual regional *percentage of trusting people* (`trust`);
- the *week day* (`w_day`), *month* (`month`), and the *year* (`year`).

Focusing on SWBI, it is defined by eight domains, all measured in a scale $0-100$, according to the *personal well-being*, the *social well-being*, and the *well-being at work*, with daily frequency for all the Italian provinces, we consider:

- *Life satisfaction* (`sat`): having positive assessment of the overall life satisfaction;
- *Vitality* (`vit`): having energy, feeling well-rested and healthy, and being active;
- *Resilience and self-esteem* (`res`): a measure of individual psychological resources, optimism, and the ability to deal with stress;
- *Trust and belonging* (`tru`): trusting other people, feeling treated fairly and respectfully while experiencing sentiments of belonging;
- *Relationships* (`rel`): the degree and quality of interactions in close relationships with family, friends and others who provide support;



(a)



(b)

Fig. 1 Bayesian network obtained with the Hill-Climbing algorithm with BIC score functions. Line widths are proportional to the strength of each arc.

- *Quality of job* (`wor`): feeling satisfied with job, with work-life balance, and evaluating the emotional experiences of work, and work conditions.

The data are integrated at daily level using for annual and quarterly data repeated values.

A preliminary analysis was performed taking into account six survey variables (`I_sat`, `I_eco_sat`, `I_health_sat`, `I_family_sat`, `I_friends_sat`, and `I_freetime_sat`), three SWBI variables (`sat`, `vit` and `rel`), and four covariates. The analysis was performed using the R statistical language, using the `bnlearn` [16] and the `BNViewer` library [6]. In this plot it is possible to highlight

some nodes (in purple), their children (blue), the other descendants (gray); nodes not descendent are transparent (empty gray). Fig.1 shows the BN obtained with the Hill-Climbing algorithm with the BIC score functions. Line widths are proportional to the strength of each arc. Fig.1(a) highlights the descendent nodes of the day of week. As expected, the day of week has a direct impact on the indexes obtained by Twitter data, `sat`, `vit` and `rel`. These measures have, in turn, an effect on the ISTAT's satisfaction indices. Fig.1(b) highlights the descendent nodes of the province. This variable has a direct impact on the ISTAT survey data.

In the next future, we will focus on developing the analysis considering also the other variables. In addition, further research will be devoted to investigate how the BNs approach might be helpful for the assessment of hypothetical scenarios.

Penalising the complexity of extensions of the Gaussian distribution

Penalizzazione della complessità relativa alle estensioni della distribuzione normale

Diego Battagliese and Brunero Liseo

Abstract The Gaussian distribution has ever been the most popular and usable device in the field of statistics. Even in the context of penalised complexity (PC) priors, the normal density has a particular meaning, especially because we can consider it as a base model which could be extended both in terms of tail thickness and skewness. We derive the numerical PC prior for the shape parameter of the skew-normal density and the analytical PC prior for the degrees of freedom of the t-distribution. We also perform an approximation of the Kullback-Leibler divergence (KLD) in the the skew-normal model.

Abstract *La distribuzione normale ha sempre ricoperto un ruolo fondamentale in statistica. Anche nel caso delle PC prior essa riveste un ruolo importante, giacché può essere estesa sia per via di una componente di curtosi sia per una di asimmetria. Qui deriviamo la PC prior numerica per il parametro di forma di una normale asimmetrica e l'espressione analitica della PC prior per i gradi di libertà di una t di Student. Inoltre, proponiamo un'approssimazione della KLD quando l'estensione è in termini di asimmetria.*

Key words: PC priors, Skew-normal distribution, Student t-distribution, Kullback-Leibler divergence.

1 Introduction

In many practical statistical works, datasets reveal departures from symmetry, hence something more flexible than the normal model is needed. The skew-normal distribution [1] extends the normal one by introducing in the cumulative distribution function a perturbation parameter that accounts for skewness. The probability density function of a scalar skew-normal random variable X is of the form

$$f(x;\mu,\sigma,\lambda) = \frac{2}{\sigma}\,\phi\Big(\frac{x-\mu}{\sigma}\Big)\,\Phi\Big(\lambda\frac{x-\mu}{\sigma}\Big), \quad x\in\mathbb{R}, \quad \lambda\in(-\infty,+\infty), \tag{1}$$

where $\phi(\cdot)$ and $\Phi(\cdot)$ are the standard Gaussian pdf and CDF respectively . Also the t-distribution extends the Gaussian in terms of robustness. Penalised complexity priors have been proposed in [4] and are based on the KLD between the simpler and the complex models. For a review of the principles behind the construction of a Penalised Complexity prior, see [4].

2 PC prior for the shape parameter in the skew-normal model

We can look at the skew-normal model as a flexible version of the normal distribution, where the latter represents the base model. In fact, for a particular value of λ, i.e. $\lambda = 0$, the density in (1) boils down to the normal density as $\Phi(0) = 1/2$. An important feature of the PC prior for λ is the invariance with respect to the location and scale parameters.

Proposition 1 (Invariance wrt location-scale) *Let $X_1 \sim SN(\mu,\sigma^2,\lambda)$ and $Y_1 \sim N(\mu,\sigma^2)$ be the skew-normal and normal densities respectively, with the same location and scale parameters. Furthermore, let $X_2 \sim SN(0,1,\delta)$ and $Y_2 \sim N(0,1)$ be the standard versions of the above densities. The Kullback-Leibler divergence between X_1 and Y_1 does not differ from the one between X_2 and Y_2.*

$$\int_{\mathscr{X}} \frac{2}{\sigma}\frac{1}{\sqrt{2\pi}}\exp\Big\{-\frac{1}{2}\Big(\frac{x-\mu}{\sigma}\Big)^2\Big\}\Phi\Big(\lambda\frac{x-\mu}{\sigma}\Big)\log\Big\{2\Phi\Big(\lambda\frac{x-\mu}{\sigma}\Big)\Big\}dx, \tag{2}$$

can be written as

$$\int_{\mathscr{T}} 2\frac{1}{\sqrt{2\pi}}\exp\Big(-\frac{1}{2}t^2\Big)\Phi\Big(\lambda t\Big)\log\Big\{2\Phi\Big(\lambda t\Big)\Big\}dt, \tag{3}$$

where $t = \frac{x-\mu}{\sigma}$ and $dt = \frac{dx}{\sigma}$.

In other words, the resulting PC prior for λ does not depend on μ and σ. Suppose $X \sim SN(0,1,\lambda)$, the distance in terms of δ is

$$d(\delta) = \sqrt{2\mathrm{KLD}(\delta)} = \sqrt{2\int_{\mathscr{X}} 2\;\phi(x)\;\Phi\{\lambda(\delta)x\}\log[2\;\Phi\{\lambda(\delta)x\}]\;dx}, \tag{4}$$

where $\delta = \delta(\lambda) = \frac{\lambda}{\sqrt{1+\lambda^2}}$, $\delta \in (-1,1)$. The distance function in (4) is symmetric around 0, as well as the KLD. The minimum is at 0, where $d(0) = 0$, while the maximum is attained at the boundary values. The distance is exponentially distributed. We must be careful in making the change of variable to get the prior for δ, because we have to handle each monotone curve separately. In particular, the function $d(\delta)$ is monotone on $(-1,0)$ and on $(0,1)$. Then, the pdf for δ is

$$\pi(\delta) = \begin{cases} \sum_{i=1}^{2} \pi\{d_i(\delta)\} \left| \frac{\partial d_i(\delta)}{\partial \delta} \right| & \text{if } d(\delta) \in \Theta \\ 0 & \text{otherwise,} \end{cases} \tag{5}$$

where $\Theta = (0,\infty)$ and we make use of Leibniz's Rule to numerically compute the derivative of the distance. The PC prior for δ is

$$\pi^{PC}(\delta|\theta) = \frac{\theta}{2} e^{-\theta\sqrt{2\mathrm{KLD}(\delta)}} \frac{|\mathrm{KLD}'(\delta)|}{\sqrt{2\mathrm{KLD}(\delta)}}, \tag{6}$$

where θ regulates the shrinkage of the prior mass towards the base model. The higher θ the more the shrinkage.

2.1 Approximation of the KLD

The prior above has not a closed form. To this aim we perform an approximation of the KLD based on the moments of the skew-normal distribution. The approximation works pretty good, but not so good on the tails, especially when the parameter θ is small as the probability mass spreads out at the boundaries. Here, we approximate the logarithm of the normal CDF by means of a quintic polynomial regression. The amazing fact is that the intercept α gets closer and closer to $-\log 2$ as we increase the degree of the polynomial regression, and this is crucial to have the $\mathrm{KLD}(\lambda = 0) = 0$. It is not convenient to consider more moments as the quintic approximation seems to work very well. Given $Y \sim SN(\lambda)$, the KLD can be written as

$$\mathbb{E}_Y[\log\{2\Phi(\lambda Y)\}] = \log 2 + \mathbb{E}_Y(\alpha + \beta\lambda Y + \xi\lambda^2 Y^2 + \gamma\lambda^3 Y^3 + \varepsilon\lambda^4 Y^4 + \eta\lambda^5 Y^5), \tag{7}$$

where α, β, ξ, γ, ε and η are the coefficients of the polynomial regression. So, the KLD can be approximated by the first five moments of the skew-normal distribution

$$\log 2 + \alpha + \beta\lambda\sqrt{\frac{2}{\pi}}\delta + \xi\lambda^2 + \gamma\lambda^3\sqrt{\frac{2}{\pi}}(3\delta - \delta^3) + 3\varepsilon\lambda^4 + \eta\lambda^5\sqrt{\frac{2}{\pi}}(15\delta - 10\delta^3 + 3\delta^5). \quad (8)$$

In this way, we would be able to derive an analytical PC prior for λ or δ.

2.2 Bayesian inference for the skew-normal model

We check out the frequentist properties of our PC prior and we compare it to the Jeffreys' prior in [3], in order to see if there could be a certain value of the parameter θ that can be interpreted as objective. We perform a simulation study for different values of the shape parameter, for various sample sizes and for several values of the shrinkage parameter, θ. For any combination we calculate the MSE of the posterior median, the coverage probabilities and the Bayes factor. The posterior median is a reasonable choice, especially for samples where the MLE is infinite, because this entails the non finiteness of the posterior mean, see [2]. The simulation study confirms that large values of θ are quite useless, in the sense that they produce more biased estimates, especially in samples where the true $\lambda \neq 0$. A large value of θ works well only when the true $\lambda = 0$. Anyhow, the gap with respect to a small value of θ vanishes for large sample sizes. In the current work we are interested to find a particular θ that can be interpreted as objective. The simulation study shows that for θ approximately equal to 0.5, the PC prior approaches the estimates produced by the Jeffreys' prior. So, if we had to choose a noninformative value for θ we would say approximately 0.5.

2.3 Bayesian hypothesis testing

We use our PC prior for a Bayesian hypotheses test and we compare it to the Jeffreys' prior in [3], namely a $t(\lambda|\mu = 0, \sigma = \pi/2, \nu = 1/2)$. The proposition stated in Sect. 2 is very important as it allows us to write the Bayes factor in a simplified manner, i.e. without considering the joint prior distribution over the location and scale parameters. The Bayes factor for testing

$$H_0 : \lambda = 0 \qquad \text{vs} \qquad H_1 : \lambda \neq 0$$

can be written as

$$\mathrm{BF}_{01}(x) = \frac{\prod_{i=1}^{n} 2\phi(x_i)\Phi(\lambda x_i)|_{\lambda=0}}{\int_{-\infty}^{\infty} \prod_{i=1}^{n} 2\phi(x_i)\Phi(\lambda x_i)\pi^{PC}(\lambda|\theta)d\lambda}. \quad (9)$$

We use a uniform importance distribution. Indeed by using a standard Monte Carlo we would draw directly from the PC prior for λ and consequently we could obtain samples that produce negligible values of the likelihood function, for instance if the parameter θ is small and the asymmetry is close to 0. However, choices of small or large θ are suboptimal, in terms of convergence of the Bayes factor towards the true model. If we draw from a PC prior with a parameter θ too small, it is more likely to get extreme values of λ. Then, the marginal likelihood will be close to 0, as long as λ and x_i will have opposite signs. Suppose to draw values of λ from a PC prior with $\theta \to 0$, then for a generic x_i

$$\text{if} \begin{cases} \lambda \to \infty \begin{cases} x_i & \text{is positive} \implies \text{BF}_{01} \approx 0.5 \\ x_i & \text{is negative} \implies \text{BF}_{01} \approx \infty \end{cases} \\ \lambda \to -\infty \begin{cases} x_i & \text{is positive} \implies \text{BF}_{01} \approx \infty \\ x_i & \text{is negative} \implies \text{BF}_{01} \approx 0.5 \end{cases} \end{cases}.$$

On the other hand, the Bayes factor gives no evidence for the true model when the PC prior has a large θ. It doesn't matter what the true model is, and for $\theta \to \infty$ it will be exactly equal to 1. For $\theta \to \infty$ the PC prior becomes a Dirac centered at 0. Then

$$\text{BF}_{01}(x) = \frac{f(x|\lambda)|_{\lambda=0}}{\int_{-\infty}^{\infty} f(x|\lambda)\mathbb{I}_{\{\lambda=0\}} d\lambda} = 1, \tag{10}$$

where $\mathbb{I}_{\{\lambda=0\}}$ denotes the Dirac distribution and $f(x|\lambda)$ is the likelihood function. Simulations seem to favor a $\theta = 2$. The comparison with the Jeffreys' prior encourages the use of our prior.

3 PC prior for the degrees of freedom of the *t*-distribution

For the Gaussian base model, the Kullback-Leibler divergence can be resorted in terms of entropy and second moment of the more complex model. We use the following result

Theorem 1 (Alternative KLD for the Gaussian base model) *Suppose to have a standard normal variate whose density function is f, and a random variable, Y, with a more flexible distribution, g. Then, the KLD between any model that is built up by adding a component to the standard normal base model and the standard normal distribution itself can be expressed as*

$$\text{KLD}(g\|f) = -H(Y) + \frac{1}{2}\left\{\mathbb{E}(Y^2) + \log(2\pi)\right\}, \tag{11}$$

where $H(\cdot)$ stands for the entropy.

Proof.

$$\begin{aligned}\mathrm{KLD}(g\|f) &= \int g \log\left(\frac{g}{f}\right) dy \\ &= \int g \log g \, dy - \int g \log\left\{\frac{1}{\sqrt{2\pi}} \exp\left(-\frac{1}{2}y^2\right)\right\} dy \\ &= -H(Y) - \left\{-\frac{1}{2}\int y^2 g \, dy + \log\left(\frac{1}{\sqrt{2\pi}}\right)\right\} \\ &= -H(Y) + \frac{1}{2}\mathbb{E}(Y^2) + \log(\sqrt{2\pi}).\end{aligned}$$

□

We exploit the theorem above to derive the PC prior for the degrees of freedom, ν, of a t-distribution. The base model for the t-distribution is the Gaussian, which occurs when $\nu = \infty$. In [4] there is an approximation of the KLD, whilst Theorem 1 allows us to derive an analytical expression for the KLD and consequently for the PC prior. In addition, once again the prior is invariant with respect to the location-scale structure. Therefore

$$\mathrm{KLD}(\nu) = -\frac{\nu+1}{2}\left\{\Psi\left(\frac{\nu+1}{2}\right) - \Psi\left(\frac{\nu}{2}\right)\right\} - \log\left\{\sqrt{\nu}\, B\left(\frac{\nu}{2}, \frac{1}{2}\right)\right\} + \frac{1}{2}\frac{\nu}{\nu-2} - \log\left(\frac{1}{\sqrt{2\pi}}\right), \quad (12)$$

where Ψ is the digamma function and B is the beta function.
The resulting prior is defined only for $\nu > 2$ since the second moment of the Student t-distribution exists only for more than two degrees of freedom. Then

$$\pi(\nu) = \theta e^{-\theta\sqrt{\mathrm{A}(\nu)}} \frac{\left|\frac{1}{4}\left\{-\frac{2}{\nu} - \frac{4}{(\nu-2)^2} + (\nu+1)\Psi^{(1)}\left(\frac{\nu}{2}\right) - (\nu+1)\Psi^{(1)}\left(\frac{\nu+1}{2}\right)\right\}\right|}{\sqrt{\mathrm{A}(\nu)}}, \quad (13)$$

where $A(\nu) = 2\mathrm{KLD}(\nu)$ and $\Psi^{(1)}$ is the trigamma function.

Predictive discrepancy of credible intervals for the parameter of the Rayleigh distribution

Una misura predittiva di discrepanza tra intervalli di credibilità per il parametro della distribuzione di Rayleigh

Fulvio De Santis and Stefania Gubbiotti

Abstract The two most commonly used methods for Bayesian set estimation of an unknown one-dimensional parameter are equal-tails and highest posterior density intervals. The resulting estimates may be numerically different for specific observed samples but they tend to become closer and closer as the sample size increases. In this article we consider a pre-posterior measure of the progressive overlap between these two types of intervals and relationships with the skewness of the posterior distribution. We illustrate the implementation of the method for the Rayleigh model that is often used in the context of reliability and survival analysis.

Abstract *In ambito bayesiano la stima intervallare di un parametro scalare viene comunemente effettuata mediante intervalli di credibilità "equal-tails" e "highest posterior density". Le stime ottenute per particolari campioni osservati possono essere numericamente differenti ma tendono a coincidere all'aumentare della numerosità campionaria. In questo lavoro viene considerata una misura predittiva della discrepanza tra questi due tipi di intervalli, in relazione all'asimmetria della distribuzione a posteriori. La metodologia proposta viene illustrata per il parametro di un modello di tipo Rayleigh che viene solitamente applicato nell'analisi della affidabilità e della sopravvivenza.*

1 Introduction

Equal-tails (ET) and highest posterior density (HPD) intervals are the two most widely used methods for Bayesian set estimation of a scalar parameter. Let us assume that the posterior distribution of the parameter is a density function with a unique mode internal to the parameter space. In many common models ET and HPD intervals do not coincide and show complementary properties and drawbacks. ET intervals are (a) easy to obtain, (b) invariant under (monotonic) parameter transformation; (c) not of minimal length among credible intervals of given credibility level. HPDs are, typically, (a) not easy to compute, (b) not invariant under parameter transformation but (c) of minimal length among intervals of given credibility. Despite the differences, numerical values of the bounds of ETs and HPDs tend to be extremely close for sufficiently large sample sizes, as a consequence of the progressive normalization of the posterior density. Dealing with credible intervals the following two questions may typically arise:

- how do we measure the discrepancy between ET and HPD intervals?
- how do we determine a sample size sufficiently large to guarantee that ET and HPD intervals are close enough?

In this article we propose a method for determining the minimal sample size such that we have good chances of obtaining an ET interval fairly close to the HPD set. We consider a measure of discrepancy between ET and HPD intervals based on probability tails of HPDs originally proposed by [2] and the corresponding preposterior criterion for the selection of the sample size. For illustration we consider the Rayleigh model, often used in reliability and survival analysis (see [1]).

2 Methodology

Assume that $\boldsymbol{X_n} = (X_1, X_2, \ldots, X_n)$ is a random sample from $f_n(\cdot|\theta)$, where $\theta \in \Theta$ is an unknown scalar parameter and $\pi(\theta)$ its prior density. Given an observed sample $\boldsymbol{x_n} = (x_1, x_2, \ldots, x_n)$, let $\pi(\theta|\boldsymbol{x_n})$ be the posterior density of θ with a unique mode $\tilde{\theta}(\boldsymbol{x_n})$, not on the boundary of Θ. Let $C^E_{1-\gamma}(\boldsymbol{x_n}) = [\ell^E_n(\boldsymbol{x_n}), u^E_n(\boldsymbol{x_n})]$ and $C^H_{1-\gamma}(\boldsymbol{x_n}) = [\ell^H_n(\boldsymbol{x_n}), u^H_n(\boldsymbol{x_n})]$ denote the ET and HPD $(1-\gamma)$-credible intervals, respectively. More specifically, $C^E_{1-\gamma}(\boldsymbol{x_n})$ is defined by setting $\ell^E_n(\boldsymbol{x_n}) = q_{\frac{\gamma}{2}}(\boldsymbol{x_n})$ and $u^E_n(\boldsymbol{x_n}) = q_{1-\frac{\gamma}{2}}(\boldsymbol{x_n})$, where $q_\varepsilon(\boldsymbol{x_n})$ is the ε-quantile of $\pi(\theta|\boldsymbol{x_n})$; the HPD bounds are found as roots of the inequality $\pi(\theta|\boldsymbol{x_n}) \geq k_\gamma$, where k_γ is the constant such that $\mathbb{P}[\Theta \in C^H_{1-\gamma}(\boldsymbol{x_n})|\boldsymbol{x_n}] = 1-\gamma$. If $\pi(\theta|\boldsymbol{x_n})$ is symmetric with respect to its mode, $\tilde{\theta}(\boldsymbol{x_n})$, $C^E_{1-\gamma}$ and $C^H_{1-\gamma}$ coincide. If $\pi(\theta|\boldsymbol{x_n})$ is skewed, $C^E_{1-\gamma} \neq C^H_{1-\gamma}$. The degree of posterior skewness depends on the basic inputs of Bayesian analysis: the likelihood (i.e. model and observed data) and the prior distribution. However, under standard regularity conditions, as n increases, both likelihood and posterior tend to normalize

(Bayesian Central Limit Theorem) and any measure of discrepancy between $C^E_{1-\gamma}$ and $C^H_{1-\gamma}$ becomes more and more negligible.

A way to quantify the discrepancy between $C^E_{1-\gamma}$ and $C^H_{1-\gamma}$ proposed in [2] is based on the differences between their respective tail-probabilities:

$$|F_n(\ell^H_n|\boldsymbol{x_n}) - \gamma/2| + |1 - F_n(u^H_n|\boldsymbol{x_n}) - \gamma/2| = |2F_n(\ell^H_n|\boldsymbol{x_n}) - \gamma|, \tag{1}$$

where $F_n(\cdot|\boldsymbol{x_n})$ is the posterior cumulative distribution function (cdf) of Θ and where the equality follows recalling that $F_n(u^H_n|\boldsymbol{x_n}) - F_n(\ell^H_n|\boldsymbol{x_n}) = 1-\gamma$. The quantity in (1) takes values in $[0,\gamma)$. A relative measure of discrepancy is then given by

$$T_n = \frac{|2F_n(\ell^H_n|\boldsymbol{x_n}) - \gamma|}{\gamma}. \tag{2}$$

The values of T_n depend on the overall skewness of the posterior density: the smaller the skewness of $\pi(\theta|\boldsymbol{x_n})$, the smaller the values of T_n.

Before observing the data, the values of T_n can be summarized by its expected value, computed with respect to the sampling distribution of the data $f_n(\cdot|\theta)$. More specifically, let $e^T_n = \mathrm{e}_d[T_n(\boldsymbol{X_n})]$ be the expected value of $T_n(\boldsymbol{X_n})$ computed with respect to $f_n(\cdot|\theta_d)$, where θ_d is a hypothetically true value of θ. We assume that, as n increases, the random sequence $(T_n(\boldsymbol{X_n}),\ n \in \mathbb{N})$ converges in probability to zero – with respect to $f_n(\cdot|\theta_d)$ – and that the numerical sequence $(e^T_n, n \in \mathbb{N})$ converges to zero. If we want to obtain a small discrepancy between HPD and ET intervals, we select the minimum n such that e^T_n is sufficiently small, i.e.

$$n^\star = \min\left\{n \in \mathbb{N} :\ e^T_n < \lambda\right\}, \tag{3}$$

where $\lambda \in (0,1)$ is a chosen threshold.

3 Example: Rayleigh model

In order to illustrate the ideas sketched above we consider the Rayleigh model. Let $X_i|\theta \sim Rayleigh(\theta)$. Given an observed sample $\boldsymbol{x_n} = (x_1,...,x_n)$, the likelihood function is $L(\theta;\boldsymbol{x_n}) = \theta^{-2n}\left(\prod_{i=1}^n x_i\right)\exp\left\{-\frac{s^2}{2\theta^2}\right\}, x_i \geq 0, \theta > 0,$ where $s^2 = \sum_{i=1}^n x_i^2$. Following [1] let us consider a conjugate square root inverse gamma prior for θ, i.e. $\theta \sim SqInvGa(\alpha/2,\beta)$. This yields *a posteriori* $\theta|\boldsymbol{x_n} \sim SqInvGa(\bar{\alpha}/2,\bar{\beta})$, where $\bar{\alpha} = \alpha + s^2$ and $\bar{\beta} = \beta + n$.

In this model HPD intervals do not have a closed-form expression. In the following examples we find the HPD credible bounds numerically and then we compute T_n and e^T_n.

Figure 1 shows the behaviour of e^T_n as a function of n for several values of the prior parameter α, which is the prior parameter that affects the skewness of $\pi(\theta|\boldsymbol{x_n})$. For comparison we also plot the expected value of the posterior skewness (denoted

by e_n^A). Table 1 reports the optimal sample sizes based on criterion (3) for different choices of γ and θ_d.
Here are the main comments.

- Overall, the values of e_n^T decrease as n increases. As a consequence a smaller value of the threshold λ in (3) yields larger values of the optimal sample size.
- The values of e_n^T are affected by the different choices of α at least for small values of the sample size n, i.e. when the prior is not overwhelmed by the data; whereas e_n^T results totally insensitive with respect to β.
- The choice of θ_d does not seem to affect the value of the optimal sample sizes.
- As the credibility level $1-\gamma$ decreases, the values of e_n^T are uniformly smaller for each given sample size n. In fact, when the value of $1-\gamma$ is smaller, the credible interval is defined by a narrower neighborhood of the posterior mode in which the posterior density is substantially symmetric with respect to the mode.

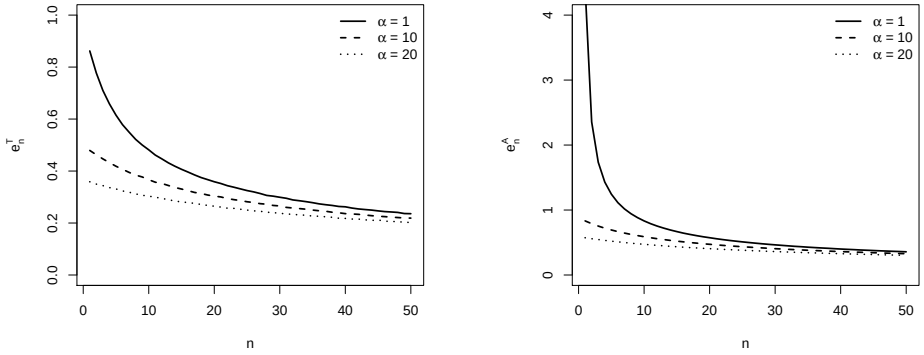

Fig. 1 Values of e_n^T and of e_n^A as functions of n, for different values of the prior parameter α.

$\lambda = 0.3$	θ_d		
γ	0.5	1	10
0.1	33	33	33

4 Concluding remarks

In this article we consider a measure of discrepancy between HPD and ET intervals based on their tail probabilities. We summarize this quantity, $T_n(\boldsymbol{X_n})$, by its predictive expected value, e_n^T. This quantity overlooks variability of $T_n(\boldsymbol{X_n})$. An alternative summary of the distribution of $T_n(\boldsymbol{X_n})$ is the predictive probability that $T_n(\boldsymbol{X_n})$ is less than λ, which takes into account not only its predictive expected value but also its variability.

As a second extension, we could consider alternative measures of discrepancy, such as the absolute differences between lower and upper limits of HPD and ET intervals. However, an advantage of our proposal is that it provides a relative measure of discrepancy whereas it is not in general straightforward to determine the range of the measure based on the difference between HPD/ET bounds.

In our contribution we limited the analysis to standard conjugate proper priors, which makes derivation of HPD and ET sets straightforward. This assumption can be easily dropped. A first alternative is to consider standard non-informative priors, as long as they lead to proper posteriors. For instance, it can be checked (see [4]) that the Jeffreys' prior is proportional to $1/\theta$ and yields a posterior still within the squared root inverse gamma model. The analysis of the progressive overlap between HPD and ET sets is typically interesting when non-informative priors are used, since these priors tend to induce higher posterior skewness compared to the proper priors in the conjugate family. This is what happens, for instance, in the Poisson-Gamma model (see [2]).

Of course one can easily consider non-conjugate priors. The additional difficulty in this case would be the necessity of implementation of numerical techniques in order to obtain HPD and ET intervals.

Finally, one further topic to explore more deeply is the relationship between the discrepancy T_n and indexes of posterior asymmetry of the posterior distribution as it is done, for instance, in the Poisson-Gamma model by [2].

Small-area statistical estimation of claim risk

Stima per piccole aree del rischio di sinistri: un approccio statistico

Francesca Fortunato, Fedele Greco and Pierpaolo Cristaudo

Abstract When dealing with *spatial* data, it is crucial to account for the spatial dependency amongst the areas in order to provide reliable estimates of the relative risks. In this work, we borrow techniques from epidemiology and disease mapping to assess the spatial pattern of motor claims and to identify high-risk areas. In particular, we perform a spatial Bayesian modelling approach, combined with the Integrated Nested Laplace Approximation for inference. A LASSO regression is primarily used for the choice of the geographic covariates to include in the model. The dataset at hand consists of 63132 geo-referenced motor claims occurred in the Municipality of Rome throughout 2018 and a set of spatially referenced variables provided by the ISTAT.

Abstract *Quando ci si occupa di dati geo-referenziati, è essenziale tener conto della dipendenza spaziale tra le aree così da fornire stime attendibili del rischio relativo. In questo lavoro, si prende spunto dai modelli epidemiologici per valutare il pattern spaziale dei sinistri auto e identificare le zone a più alto rischio. Nello specifico, si utilizza un approccio di tipo Bayesiano, combinato con l'approssimazione di Laplace per l'inferenza sui parametri. Come step iniziale, si implementa una regressione LASSO per selezionare le variabili da includere nel modello. Il dataset utilizzato contiene informazioni su 63132 sinistri auto accaduti nel Comune di Roma durante il 2018 e su alcune variabili spaziali fornite da ISTAT.*

1 Introduction

For a long time, insurance companies have computed the premium for a car insurance just based on some *apriori* factors such as the age and sex of the policyholder, the characteristics of the car he uses and the geographical zone where he lives or gravitates. Recently, companies have realized that also *micro-geography*, i.e. geographical information on a small and detailed scale, can be advantageously taken into account to price contracts at best. Models for premium rating on a small-area level (see [5] and [6]) are borrowed from spatial epidemiology, where the aim is to study the distribution of a disease given the number of occurrences at each location. The basic philosophy of this approach relies upon the belief that events happening in areas that are geographically close will likely display some spatial dependence after accounting for marginal/confounding effects. In practical terms, such dependence structure is enabled by allowing the risk of each location to depend on that of the neighbouring areas. In so doing, the underlying spatial pattern is expected to be correctly recovered and used to provide unbiased estimates of the risk rates.

In the statistical and actuarial literature, some recent works have focused on assessing the relative insurance risk while using the information on the *residence address* of the policyholders (see, for example, [7] and [11]). In this work, we propose to change the point of view and to involve in the analysis the *exact location at which each claim occurs*, rather than the policyholder's residence address. The model is specified in a Bayesian framework by simply extending the idea of hierarchy so as to account for similarities based on the neighbourhood or the distance. The computational burden is made feasible with the INLA approach, i.e. the use of Integrated Nested Laplace Approximation for inference.

We analyse a dataset consisting of 63132 geo-referenced motor claims occurred in the Municipality of Rome throughout 2018 and a set of spatially referenced variables provided by the ISTAT. The aim of the study is to provide insight knowledge about the risk associated to each small-area, while outlining a unified picture of the claim risk based on some relevant demographic and socio-economic variables.

2 Claim risk mapping: a hierarchical Bayesian approach

The most simple method to deal with discrete counts (e.g. number of diseases or claims that occur at a specific location) consists in assuming that these data follow a Poisson distribution. Specifically, given y_i the number of observed cases and θ_i the claim rate corresponding to area i ($i = 1, \ldots n$), then

$$y_i|\theta_i \sim \text{Poisson}(E_i\theta_i), \tag{1}$$

where E_i represents the 'expected' cases in the i-th area according to the reference population. This procedure is known as indirect standardization. The Standardized Incidence Ratio (SIR) is given by $SIR_i = y_i/E_i$, and is the maximum likelihood

estimator (MLE) of the area-specific relative risk θ_i. Although simple, this approach does not consider the spatial dependence among adjacent areas and, thus, it could provide biased estimates of the risk rates.

In order to cope with this issue, methods that *smooth* the SIRs across 'neighboring' areas have been introduced in this context. These methods include two random-effects: a spatial component that accounts for the nearby regions information and an unstructured component that favours shrinkage towards the global mean. If we assume that the Poisson model described in (1) still holds, then a log-linear relationship in the form of a *latent Gaussian*[1] *model* is specified on the linear predictor

$$\log(\theta_i) = \eta_i = \beta_0 + \mathbf{x}_i^T \beta + u_i + v_i, \tag{2}$$

where β_0 is the intercept, quantifying average risk rate in the entire study region, $\mathbf{x}_i$ and β are the area-specific covariates and the regression parameters, respectively, $v_i \sim N(0, \frac{1}{\tau_v})$ represents the spatial *unstructured* area-specific random effect and u_i is the spatial *structured* area-specific random effect.

Several structures can be used to model the spatial correlation $\mathbf{u} = (u_1, \ldots, u_n)$; one of the most popular approaches is the conditional autoregressive (CAR) model introduced by Besag in [1]. Following this approach, the conditional distribution for u_i is

$$P(u_i|\mathbf{u}_{-i}) = P(u_i|u_{j,j\in\mathcal{N}_i}) = N\left(\frac{1}{|\mathcal{N}_i|}\sum_{j\in\mathcal{N}_i} u_j, \frac{1}{|\mathcal{N}_i|\tau_u}\right), \tag{3}$$

where $\mathcal{N}_i$ denotes the set of neighbours to area i (i.e. the set of regions that share a common border with i), τ_u is a precision parameter (i.e. $\tau_u = 1/\sigma_u^2$, where σ_u^2 is the variance of the structured random effect) and the conditional variance is inversely proportional to the number of neighbours. A common choice for the priors of $\tau = (\tau_u, \tau_v)$ are the independent gamma distributions (see [4]), so as to enable the data to speak for themselves.

Due to the non-positive definiteness of the covariance matrix, there is no proper joint distribution for $\mathbf{u}$, as it is invariant to the addition of any constant. This issue can be fixed by imposing a sum-to-zero constraint such that $\sum_{i=1}^n u_i = 0$. The CAR specification, along with the exchangeable random effect described in (2), originate the so-called Besag-York-Mollié (BYM) model presented in [2]. The condition described in (3) ensures that the model described in (2) represents a Gaussian Markov Random Field (GMRF) [9], that is a GMRF characterized by a sparse precision matrix $\mathbf{Q}$.

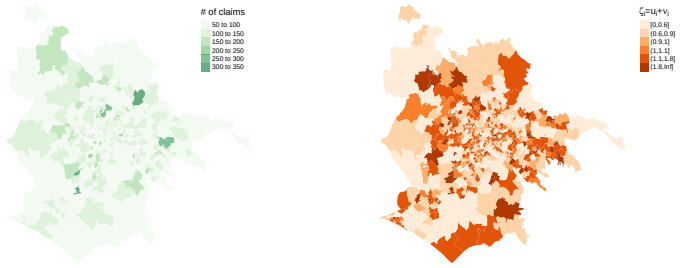
The most challenging aspect of Bayesian inference for spatial models rests in its high computational cost, given the added complexity due to the spatial structure. A number of strategies have been proposed in the literature (see [8] for a detailed review), but many of them (e.g. Monte Carlo Markov Chain, MCMC, algorithms and their variations) suffer from slow convergence and poor mixing for large and complex models. In order to solve these issues, Rue *et al.* [10] introduced an algorithm

[1] The Gaussian part refers to the fact that Gaussian priors are assigned to the vector of latent (nonobservable) components.

for full Bayesian inference of GMRF, based on INLA. Differently from MCMC methods that sample from the posterior distribution of parameters, INLA combines modern numerical techniques for sparse matrices with the Laplace method so as to provide accurate results in a shorter computing time. A very fast implementation of the INLA approach is available in the `R-INLA` package [3] that copes with a large variety of models.

3 Claim data

The dataset at hand consists of $N = 63132$ geo-referenced motor claims requiring the intervention of the traffic police and occurred in the Municipality of Rome throughout 2018[2]. In order to obtain insights about the association of claim frequency and some risk factors, $p = 92$ covariates are added to the dataset. These demographic and socio-economic variables are supplied by the Italian National Statistical Agency (ISTAT) and are available for each census area (i.e. the smallest territorial entity characterized by homogeneous both environmental and socio-economic characteristics). Since we believe that the census division provided by the ISTAT may be too crisp for our purposes (e.g. the variability present in some micro-samples might be not enough to identify meaningful patterns), we decide to consider (small) aggregations of these districts as the unit levels for our spatial regression. In the end, $n = 713$ sections of different shape are involved in the study. Covariates and claim counts are coherently added up, as depicted in Figure 1a, where the number of claims observed in each area is displayed.



(a) Map of the observed number of claims occurred in the Municipality of Rome (2018).

(b) Map of the posterior mean for the area-specific relative risks $\zeta_i = u_i + v_i$.

In order to explore the impact of the areal characteristics on the claim frequency, count data are initially modeled as pure *Generalized Linear Models* (GLMs). Namely, any spatial and unstructured effect is excluded from the model specification with the aim to identify a suitable subset of covariates that provides good

[2] These data are open and available at https://dati.comune.roma.it/catalog/dataset/d655

predictive performances. An effective algorithm for this purpose is the LASSO regression [12], implemented through the `glmnet` R-package with $\alpha = 1$. To avoid the randomness involved in training, a cross-validation procedure is run 100 times. Then, the cross-validated minimum error rates and the corresponding optimal λs (i.e. the regularization parameter) are averaged and the best λ is identified. The LASSO results in the choice of 28 different covariates; this number is further reduced by removing those variables showing a mean absolute correlation larger than 0.75. The spatial structured random-effect is finally included in the linear predictor (see Equation 2) and the model is iteratively fitted until all the β-coefficient show a significant effect. In the end, only just 12 geographic variables are involved in the analysis.

If exponentiated, the fixed effects can be directly interpreted as relative risks, i.e. as an increase or decrease in the probability of a claim according to a unit variation in the exposure factor, *ceteris paribus*. The risk rates provided by the BYM and GLM models are illustrated in Figure 2 and they seem to be in line with our expectations. Nevertheless, these estimates can be further improved if a more suitable strategy for the computation of the "expected" cases is employed. Namely, the use of information on the road or traffic density rather than a procedure that calculates the number of expected claims proportionally to the areal extension (i.e. our approach) would probably contribute to provide more accurate estimates. In this sense, the strong decrease in claim risk (about 60% for any unitary increase) associated to the "% of rural area within 500m" should be carefully interpreted as we improperly *expect* a "non-zero" number of claims in areas with few or no roads.

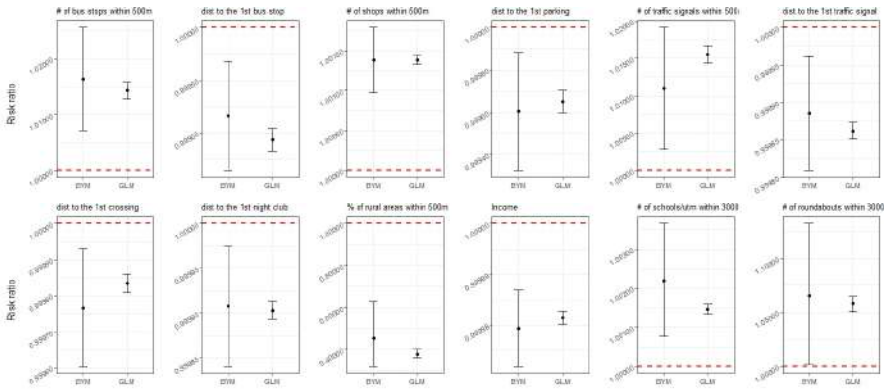


Fig. 2: Posterior mean and 95% credibility interval for the fixed effects on the original scale. The horizontal dashed line highlights a risk rate equal to 1, which corresponds to the absence of effect.

The area-specific relative risks are shown in the map of Figure 1b. They can be interpreted as the residual relative risks for each area (compared to the whole Municipality of Rome) after the fixed effects (i.e. the 12 covariates) are considered.

The analysis of the Deviance Information Criteria (DIC, i.e. the sum of the posterior mean of the deviance and the effective number of parameters) reported in Table 1 and associated to different model specifications suggests that the BYM model with covariates described in (2) is the most suitable for the data at hand[3]. This result implies that it is important to account for both the spatial dependence among the areas and some geographical variables to explain the claim risk in the Municipality of Rome.

Model	Linear predictor	DIC
IID	$\eta_i = \beta_0 + \mathbf{x}_i^T \beta + v_i$	5857
BYM (without covariates)	$\eta_i = \beta_0 + u_i + v_i$	5865
BYM (with covariates)	$\eta_i = \beta_0 + \mathbf{x}_i^T \beta + u_i + v_i$	**5854**

Table 1: DIC for different model specifications. The best model is in bold.

Subject-specific Bayesian Hierarchical model for compositional data analysis

Modello subject-specific gerarchico bayesiano per l'analisi di dati di composizione

Matteo Pedone and Francesco C. Stingo

Abstract We consider the problem of modeling association between continuous covariates and count tables. We propose a hierarchical model which takes into account the complex structure of interactions, imposes sparsity for covariate selection and allows for heterogeneity in the covariate effects through a subject specific regression and still it is computationally tractable. We illustrate the proposed approach through a simple example.

Abstract *Sviluppiamo un metodo generale per l'analisi delle associazioni tra covariate continue e conteggi. Proponiamo un modello gerarchico che tenga conto della complessa struttura delle interazioni, imponga sparsità per la selezione di variabili, che consideri l'eterogeneità nell'effetto delle covariate attraverso una regressione* subject-specific *e che sia computazionalmente efficiente. Infine esponiamo le performance del metodo proposto con un semplice esempio.*

need for adequate methods for the analysis of such peculiar data, that feature zero inflation and overdispersion, we developed a hierarchical method able to tackle these issues, yet preserving flexibility. Within the Dirichelet-multinomial regression framework, we propose a Bayesian hierarchical model that accounts for the complex structure of the association between continuous covariates and count tables. Moreover, as relationships between the predictor variables can be assumed to be non-zero, first order interactions are considered, leading to a high-dimensional scenario. In this framework effects can be hard to estimate, and this issue can be addressed via variable selection or regularization.

The regression formulation adopted conveniently allows us to construct regression that are subject-specific, which is often more appropriate than population-level models (Ni et al., 2019). To this end, the regression coefficients are allowed to change with the covariates; the model effectively allows the effects of the covariates on the counts to be heterogeneous even when the sample size is small. Inference is conducted through a Markov Chain Monte Carlo algorithm.

The remainder of the manuscript is organized as follows. Section 2 describes the proposed method. Section 3 reports a simulation study and we conclude with a brief discussion of the results and the forthcoming development in Section 4.

2 Model

We let $\mathbf{Y}_i = (Y_{i1}, \ldots, Y_{iJ})$, for $i = 1, \ldots, n$, represent a $J-$dimensional response vector of counts, where n is the number of available observations, J the number of categories and Y_{ij} denotes the count of category j in sample i. Let $\mathbf{X}_i = (X_{i1} \ldots, X_{iP})$, $p = 1, \ldots, P$, be the vector of independent covariates, where P is the number of continuous covariates.

For sample i we model the counts with a Multinomial distribution: $\mathbf{y}_i \mid \boldsymbol{\phi}_i \sim \mathit{Multinomial}(y_i^+, \boldsymbol{\phi}_i)$ with $y_i^+ = \sum_j y_{ij}$ being the sum of all counts in the $i-$th vector. The $\boldsymbol{\phi}_i$ parameter vector is defined on the $J-$dimensional simplex. Imposing a Dirichlet prior on $\boldsymbol{\phi}$, that is $\boldsymbol{\phi} \sim \mathit{Dirichlet}(\boldsymbol{\gamma})$, $\boldsymbol{\gamma} = (\gamma_1, \ldots, \gamma_J)$, $\gamma_j > 0 \; \forall \; j$, and being the Dirichlet distribution a conjugate distribution to the multinomial distribution, $\boldsymbol{\phi}$ can be integrated out and we obtain a compound distribution, the Dirichlet-Multinomial (DM) distribution. The probability mass of a $J-$category count vector $\mathbf{y}$ over $y_i^+ = \sum_j y_{ij}$ trials under Dirichlet-multinomial with parameter $\boldsymbol{\gamma} = (\gamma_1, \ldots, \gamma_J)$, $\gamma_j > 0$, is:

$$f(\mathbf{y} \mid \boldsymbol{\gamma}) = \frac{\Gamma(\sum_j \gamma_j)}{\Gamma(\mathbf{y}^+ + \sum_j \gamma_j)} \times \prod_{j=1}^{J} \frac{\Gamma(\mathbf{y}^+ + \gamma_j)}{\Gamma(\gamma_j)}. \tag{1}$$

Also known as the Dirichlet Compound Multinomial (DCM) or the Pólya distribution, it is a multivariate extension of the beta-binomial distribution. DM is a flexible model for count data, hence may be used when the Multinomial or Poisson model are not appropriate, due to observed overdispersion in the data.

Covariates are included through a log-linear regression model (Wadsworth et al., 2017), imposing dependence of the DM parameters on external covariates: $\zeta_j = \log(\gamma_j)$. Subject-specific regression is adopted, because is more appropriate than single (population-level) regression in some contexts (Ni et al., 2019).

$$\zeta_j = \mu_j \mathbb{1}_n + \sum_{p=1}^{P} \beta_{pj}(\mathbf{X}) \odot \mathbf{X}_p,\ \beta_{pj}(\mathbf{X}) = \theta_{pj}\mathbb{1}_n + h\left(\sum_{k>p}^{P} b_{pkj}\mathbf{X}_k, t\right) \tag{2}$$

where $\odot$ denotes the Hadamard product and $h(\cdot,\cdot)$ is a thresholding function such that $h(x,t) = xI_{[|x|>t]}$, with $I_{[\cdot]}$ denoting the characteristic function. Note that, being the coefficients $\{\beta_{pj}\}$ function of the covariates, we let effects vary similarly for similar covariate values, obtaining similar coefficients for close realizations of covariates.

The model depicted in Equations (2), even for modest dimension data leads rapidly to a high-dimensional framework. The population-level structure needs $J + (((P-1)\times P)/2)\times J$ parameter: for example, considering $J = 10$ and $P = 10$, we need to estimate 460 population-level parameters. Especially in the case of small sample size, inducing sparsity is vital for the correct estimation of the model. This is accomplished through *spike-and-slab* mixture prior for the main effects $\{\theta_{pj}\}$ (George and McCulloch, 1997) and *horseshoe prior* (Carvalho et al., 2010) for the interaction terms $\{b_{pkj}\}$. Since horseshoe prior encourages shrinkage of regression coefficients close to the null value, it is coupled with a soft-thresholding mechanism that allows to set exactly to zero effects shrunk toward small and negligible values.

Spike-and-slab mixture prior is a common approach for the selection of significant associations between the covariates and the response (George and McCulloch, 1997). It assumes a discrete mixing distribution with an atom at zero and one at a non-zero value. Spike-and-slab priors are placed on the main effects $\{\theta_{pj}\}$:

$$\theta_{pj} \sim \xi_{pj} Normal(0, \tau_j^2) + (1-\xi_{pj})\delta_0(\theta_{pj}), \tag{3}$$

where $\delta_0(\cdot)$ is a Dirac function and $\xi_{pj} \sim \text{Bin}(1, \omega_{pj})$. Moreover, we assume a beta hyper-prior for $\omega_{pj} \sim \text{Beta}(a,b)$, that automatically adjusts for multiplicity (Scott and Berger, 2010). This hierarchy is equivalent to placing a beta mixed binomial distribution on ξ_{pj}, which is a valuable property, as the prior expected mean of the beta distribution reflects the proportion of associations to be selected *a priori* (Wadsworth et al., 2017).

The horseshoe prior (Carvalho et al., 2010), as opposed to spike-and-slab, assumes an absolutely continuous mixing distribution and belongs to the class of global-local scale mixtures of normals. It is adopted for the coefficients that model the interactions among covariates, namely b_{pkj}:

$$b_{pkj} \sim Normal(0, \lambda_{pkj}^2\tau_{kj}^2),\ \lambda_{pkj} \sim C^+(0,1),\ \tau_{kj} \sim C^+(0,1), \tag{4}$$

where $C^+(\cdot)$ is a truncated Cauchy distribution and the matrix $\mathbf{b}_j$ is strictly triangular to ensure identifiability of the parameters. Parameters λ_{pkj}'s are called *local* shrink-

age parameters, while τ_{kj}'s are the *global* ones. They create an absolutely continuous mixture, though the discrete mixture approach is the underlying methodological foundation. The relationship between the two parameters of the scale mixture is such that the global parameter takes action on the noise, while the local one (which is an outlier to the global one) discloses the signals. This class of priors encourages shrinkage of regression coefficients, but it induces sparsity in a weaker sense. All coefficients will be nonzero, nonetheless only the significant associations will have large values -due to the heavy tails of the prior- compared to negligible values of the non significant ones, severely shrunk because the prior has an infitely tall spike in a neighborhood of zero. An advantage of horseshoe priors, with respect to spike-and-slab priors, is their computational efficiency.

To obtain truly sparse solutions, the horseshoe prior has been combined with the soft thresholding mechanism proposed and discussed in Ni et al. (2019), where the threshold is interpreted as minimum effect size. The threshold is not fixed *a priori*, and a prior distribution is imposed, in particular we assume $t \sim U(a,b)$. This modeling strategy implies that both the magnitude and the variability of the regression coefficients are taken into account in the selection mechanism.

2.1 Algorithm

We present the posterior inference procedure for the purpose of estimating the proposed model, via MCMC algorithm approach. The MCMC sampler goes as follows:

1) **Update** μ_j: by Metropolis-Hastings step with a symmetric random walk proposal;
2) **Update** θ, ξ: these parameters are jointly updated by Gibbs scan and a Metropolis acceptance step, with an adaptive proposal, as detailed in Wadsworth et al. (2017).
3) **Update b**: these parameters are updated with a Metropolis step, using an adaptive proposal;
4) **Update** λ, τ: these parameters are updated with Slice Sampler, following the procedure detailed in the Supplemental Material of Polson et al. (2014).;
6) **Update** t: by Metropolis-Hastings step with a symmetric random walk proposal.

3 Simulation Study

We perform a simulation study to evaluate the variable selection performance of our method. We simulate $n = 100$ samples, considering $P = 5$ covariates and $J = 5$ categories, being $P^\star$ the relevant covariates with each being associated with $J^\star$ relevant categories. The design matrix is obtained using a multivariate normal distribution $N(\mathbf{0}, \Sigma)$, $\Sigma_{i,j} = \rho^{|i-j|}$. For each covariate, the association coefficient θ_{pj} for the significant categories are sampled from the interval $[1.5, 3.5]$ with alternate sign.

Considering the exponential growth model defined in Chen and Li (2013) we obtained the proportion of the $j-$th category in the $i-$th sample. The overdispersion is regulated by the parameter $\psi \in [0,1]$, when $\psi \to 0$ the simulated values approximate Multinomial distribution, while the larger ψ, the more overdispersed are the values. To evaluate the performance of the method on different ground of sparsity, we generated the data with different number of non-zero principal effect, hence $p^\star = P^\star \times J^\star / P \times J$.

Table 1 Simulated data: performance assessment for 12 scenarios, characherized by different levels of sparsity in the main effects, different values of the dispersion parameter ψ and the assumption on the interaction generative mechanism.

	Strong Heredity			Weak Heredity		
	$p^\star = 0.08$	$p^\star = 0.12$	$p^\star = 0.16$	$p^\star = 0.08$	$p^\star = 0.12$	$p^\star = 0.16$
$\psi = 0.01$

Values are rounded averages over ten replicates. Results for Matthews' Correlation Coefficient, False Positive Rate and False Negative Rate are based on the median probability model.

Prior independence between the regression coefficients could often be a misleading assumption, so first order interactions are considered. Given the main effects, there are several assumptions that could be made on the interactions generative mechanism. We will consider two forms of heredity principle to this end: *strong heredity*, states that an interaction can only be included if both main effects are included, while *weak heredity* states that an interaction can be included if at least one main effect is included (Griffin et al., 2017). The values for these parameters are obtained sampling uniformly on the set $\{0, 1.0, 3.0\}$. Moreover, a priori, the sign of the interaction is not related to the signs of the main effects. We choose to take into account the kind of heredity of the interaction, but note that in principle any criterion could be used. In particular:

$$\text{sgn}(b_{pqj}) := \begin{cases} \text{sgn}(\theta_{pj} \cdot \theta_{qj}) \text{ if } \theta_{pj}, \theta_{qj} \neq 0; \\ \text{sgn}(u), u \sim U(-1,1) \text{ otherwise.} \end{cases}$$

In order to assess the performance of the proposed method and explore its capability to recover true associations and interaction, a simulation study is conducted. The selection is evaluated on the ground of the Matthews' Correlation Coefficient, False Positive Rate, False Negative Rate and the Area Under the Curve. The selection is compared under strong heredity e weak heredity assumption for a different level of sparsity in the main effects. The method is tested for low and moderate level of overdispersion in the data. The results are reported in Table (1).

4 Discussion

We presented a simple strategy for modeling associations between continuous covariates and counts, that can take into account *subject-specific* interactions. Our goal is to develop an approach for the selection of relevant associations between microbiome taxa and covariates. Several extensions are currently under investigation: for example, non-linear effects could be included to let covariates effects vary *smoothly* with the covariates.

Wasserstein consensus for Bayesian sample size determination

Consenso di Wasserstein per la determinazione Bayesiana della dimensione campionaria

Michele Cianfriglia, Tullia Padellini and Pierpaolo Brutti

Abstract The sample size determination problem deals with the selection of the optimal number of subjects to be enrolled in a study in order to achieve a pre–specified inferential goal. While this problem can of course be approached from a frequentist viewpoint, often the Bayesian paradigm is preferred as it allows to blend and balance the strength of the observed empirical evidence with the available prior knowledge. In this work, we focus on the case of a "community of priors" representing, for example, different expert opinions. Within this setup, we are interested in selecting the smallest sample size that guarantees "agreement" between these, possibly conflicting, opinions, having formalized the loose idea of "agreement" in terms of the Wasserstein distance between posteriors stemming from different priors.

Abstract *Il problema della determinazione della dimensione campionaria concerne la selezione del numero ottimo di soggetti da considerare in uno studio al fine di raggiungere un prestabilito livello di accuratezza inferenziale. In quest'ambito, l'approccio Bayesiano è in genere preferito perché permette di bilanciare i dati osservati con le informazioni a priori disponibili. Scopo di questo lavoro è partire da una"famiglia di a priori" che rappresentano, ad esempio, le opinioni di un pool di esperti, ed arrivare ad individuare il numero minimo di osservazioni necessario a garantire un accordo tra le diverse posizioni considerate. Il concetto di accordo è formalizzato attraverso la distanza di Wasserstein tra le distribuzioni a posteriori ottenute, ad esempio, a partire dalle diverse opinioni a priori degli esperti coinvolti.*

Key words: Bayesian consensus, sample size determination, Wasserstein distance, clinical trials.

1 Introduction

In the design of a statistical experiment a fundamental issue is the determination of the optimal sample size (SSD). Focusing, for example, on clinical trials, SSD is particularly critical as there is an immediate interpretation of the optimal sample size in terms of the minimum number of subjects to be enrolled in order to achieve a pre–specified inferential target. Historically, while both frequentist and Bayesian solutions have been provided for this problem, the Bayesian paradigm is often preferred as it allows to combine observed empirical evidence with all the prior knowledge already available, including historical data. Among others, examples of this approach can be found in [3, 7, 8, 10] and [4].

In their general formulation, common Bayesian criteria used to determine the optimal sample size need to control the inferential performance of specific functionals of interest of the posterior distribution, e.g. posterior mean or credible interval. For this reason the optimal sample size is usually defined as the minimum sample size for which the aforementioned functionals achieve some inferential goal on average or with large enough (predictive) probability.

Our goal in this work is to address the SSD problem in case where we are dealing with more than one prior distribution for the parameter of interest, a "community of priors". Indeed this is a not an uncommon setting as it can be used, for example, to model multiple scenarios we want to account for, or even different expert opinions. A possible approach to this problem detailed in [2], consists in aggregating different beliefs through the use of finite mixture models. Here however we adopt a different definition of consensus, which is not based on aggregation but rather on *distance minimization*. To this end, our work heavily relies on the *Wasserstein metric*, a well known distance between probability distributions that nowadays is gaining momentum in the statistics and machine learning communities.

Hence, once the loose idea of "agreement" has been formalized in terms of the Wasserstein distance between posteriors stemming from different prior distributions, we propose a Bayesian SSD procedure for the selection of the smallest sample size that guarantees "agreement" between possibly conflicting prior opinions. We detail our proposal in the case of the ubiquitous conjugate *Normal model* for which the Wasserstein distance admits an exact expression neatly depending on the posterior means and standard deviations of the distributions involved.

This paper is organized as follows. In the next section we introduce the new definition of consensus. In Section 3 two main Bayesian sample size criteria, that is the Predictive Expectation Criterion and the Predictive Probability Criterion, are redefined in terms of the Wasserstein distance, and an application to real data is reported. Finally Section 4 shows some motivating results based on the data analyzed.

2 A new perspective of consensus: Wasserstein consensus

In designing a new clinical trial it is quite common to take into account the results provided by previous, related, medical studies or to consult several experts. Since the information provided by these variety of sources can happen to be quite conflicting, once the uncertainty surrounding them is captured in terms of a suitable probability distribution, we are left with the statistical problem of working with a "community of priors" elicited over the same parameter of interest.

In the literature, conflicting prior opinions are typically handled by *robust methods* – such as finite mixture or ε–contaminated priors – as, for example, in [1, 2, 4]. There are two main issues with this approach: (i) we lose in "resolution" since we start the Bayesian machinery from a single, encompassing, prior built to cover the range, from optimistic to pessimistic, spanned by the pool of elicited distributions; and consequently (ii) we also lose the opportunity to address the SSD problem, or any other design problem for what matters, with the explicit goal of achieving any sort of "agreement" between conclusions stemming from different scenarios.

Broadly speaking, there are of course many ways to define "agreement". Within the Bayesian framework we are working with, this loose idea naturally translates into guaranteeing *posterior* "agreement" between possibly conflicting prior opinions. To date, the only work which addresses the issue of determining the optimal sample size in order to guarantee posterior consensus is [6].

In this work, we formalize Bayesian consensus via the Wasserstein distance between posterior distributions stemming from different priors. To this end, taking inspiration from the main Bayesian sample size criteria, we want to find the minimum number of subjects which ensures that a suitable posterior summary of the Wasserstein distance is lower than a pre–specified threshold.
The use of the Wasserstein distance has several advantages, for instance:

- we easily define "agreement" between experts: two experts "agree" if their inferential conclusions, namely their posterior distributions, are "close" enough;
- it "metricizes" convergence in distribution: if two distinct distributions are close with respect to the Wasserstein distance, then they are probabilistically similar;
- it tells us why distributions differ: the Wasserstein distance is a transportation distance and comes with a transportation plan that detail how to move the mass of a distribution to morph it into another.

3 Our proposal: Wasserstein based criteria

Before describing our proposal, let us recall the basic ideas and definitions behind the two main Bayesian sample size criteria. Generally speaking, these criteria are defined in terms of suitable summaries of the posterior distribution, that is

$$\rho_\pi(\theta|\mathbf{x}_n) = \int g(\theta)\pi(\theta|\mathbf{x}_n)\,\mathrm{d}\theta,$$

where different choices of $g(\theta)$ lead to different summaries of $\pi(\theta|\mathbf{x}_n)$. Denoting by $m(\cdot)$ the prior predictive distribution, we are now in position to define

- *Predictive Expectation Criterion (PEC)*: let e_n be the expected value of $\rho_\pi(\theta|\mathbf{x}_n)$ with respect to $m(\cdot)$. Given a suitable threshold η_e the optimal sample size is

$$n_e^\star = \min\{n \in \mathbb{N} : e_n > \eta_e\};$$

- *Predictive Probability Criterion (PPC)*: let p_n be the probability with respect to $m(\cdot)$ that $\rho_\pi(\theta|\mathbf{x}_n)$ is bigger than a constant γ. Given a suitable threshold $\eta_p \in (0,1)$ the optimal sample size is

$$n_p^\star = \min\{n \in \mathbb{N} : p_n > \eta_p\}.$$

A few comments: (i) these criteria are called *predictive* because they use the marginal predictive distribution $m(\cdot)$; (ii) in defining the Bayesian criteria we usually consider two distinct prior distributions, specifically π_A (*analysis prior*) – which is employed in determining the posterior distribution – and π_D (*design prior*) – which induces the marginal distribution of the data.

We can now define the Wasserstein based criteria. In the following, d_W denotes the 2–Wasserstein distance, based on the L_2 ground metric, between two posterior distributions derived by two different analysis priors.

- *Predictive Expectation Criterion (PEC)*: let e_n^W be the expected value of d_W with respect to $m(\cdot)$. Given a suitable threshold η_e the optimal sample size is

$$n_{e,W}^\star = \min\{n \in \mathbb{N} : e_n^W < \eta_e\}; \tag{1}$$

- *Predictive Probability Criterion (PPC)*: let p_n^W be the probability with respect to $m(\cdot)$ that d_W is bigger than a constant γ. Given a suitable threshold $\eta_p \in (0,1)$ the optimal sample size is

$$n_{p,W}^\star = \min\{n \in \mathbb{N} : p_n^W < \eta_p\}. \tag{2}$$

Please notice that the optimal sample sizes based on these criteria have a *particular* interpretation because we are searching for the smallest sample size that guarantees "agreement" between possibly conflicting opinions, therefore it is natural to reverse the inequality of the Bayesian criteria as done in (1) and (2). In addition, under a Normal conjugate model, the functions e_n^W and p_n^W admit a closed form expression making the computation of the Wasserstein based criteria extremely efficient. This is quite crucial since the computation of the Wasserstein distance becomes quite expensive and time consuming when multidimensional posterior distributions are involved.

4 A real data example

We conclude by showing how the Wasserstein based–criteria perform on a real data application. More in details, we revisit an example reported in [9], where results of a meta–analysis are reinterpreted from a Bayesian perspective. The setup is the following: a series of small randomized trials was conducted to assess a proactive effect of intravenous magnesium sulphate after acute myocardial infarction. Even if many studies were already conducted, further investigation was suggested and the massive ISIS-4 trial started. Unfortunately, this study did not provide evidence of any benefit contradicting previous conclusions (see [5] and Figure 1 for details).

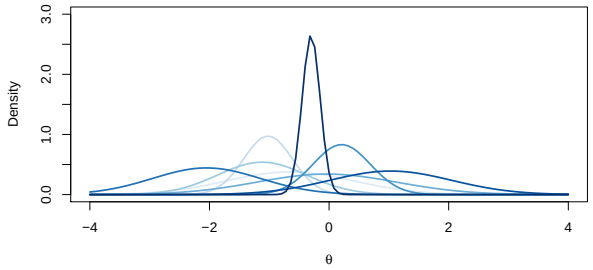

Fig. 1 Comparison between Normally distributed priors encoding evidence from previous studies. The parameter of interest θ is the log odds ratio of intravenous magnesium with respect to placebo. As suggested in [9], the variance of the analysis prior is σ^2/n_0, where $\sigma^2 = 4$ is fixed and n_0 represents the *effective number of events* in the study considered.

Table 1 shows the optimal sample size $n^{\star}_{e,W}$ obtained using our version of the PEC with $\eta_e = 0.05$. The marginal predictive distribution is based on a Normally distributed design prior with mean 0.058 and variance $\sigma^2 = 4/n_D$. Intuitively, different choices of the design prior sample size n_D reflect different strength of the skepticism toward the magnesium treatment: as n_D increases it becomes easier and easier to bring consensus between different parties since we have more and more information about the phenomenon. From a mathematical point of view, this aspect can be understood looking at the behavior of e^W_n as function of n_D.

n_D	$n^{\star}_{e,W}$	$n^{\star}_{e,M}$
4319	361	498
432	371	509
43	468	190

Table 1 Comparison between optimal sample sizes. The first column contains the prior sample size of the design prior, whereas the other two columns contain, respectively, optimal sample sizes associated with the Wasserstein and mixture versions of the PEC.

Finally, in order to highlight the need for "consensus–assessment", we compare our optimal sample sizes with those obtained by [2], where a finite mixture version of the standard PEC is used. Note that the two methods are *not* directly comparable as their inferential goals are different.

Nevertheless we stress the fact that consensus does not come automatically and "for free": the more the parties disagree, the higher is the number of subjects to be enrolled in the study in order to achieve inferential agreement.

Biostatistics

A comparison of the CAR and DAGAR spatial random effects models with an application to diabetics rate estimation in Belgium

Confronto tra i modelli CAR e DAGAR per effetti spaziali latenti con un'applicazione alla stima del tasso di diabetici in Belgio

Vittoria La Serra, Christel Faes, Niel Hens and Pierpaolo Brutti

Abstract When hierarchically modelling an epidemiological phenomenon on a finite collection of sites in space, one must always take a latent spatial effect into account in order to capture the correlation structure that links the phenomenon to the territory. In this work, we compare two autoregressive spatial models that can be used for this purpose: the classical CAR model and the more recent DAGAR model. Differently from the former, the latter has a desirable property: its ρ parameter can be naturally interpreted as the average neighbor pair correlation and, in addition, this parameter can be directly estimated when the effect is modelled using a DAGAR rather than a CAR structure. As an application, we model the diabetics rate in Belgium in 2014 and show the adequacy of these models in predicting the response variable when no covariates are available.

Abstract *Quando si vuole modellare un fenomeno epidemiologico su un insieme finito di siti, bisogna sempre tenere conto della presenza di un effetto spaziale latente, necessario per spiegare la struttura di correlazione che lega il fenomeno al territorio. In questo lavoro confrontiamo due modelli autoregressivi spaziali atti allo scopo: il CAR e il DAGAR. A differenza del primo, il secondo risulta naturalmente parametrizzabile in termini di correlazione media tra siti vicini, caratteristica questa correttamente stimabile allorché l'effetto venga modellato mediante un DAGAR anziché un CAR. Oltre che attraverso uno studio di simulazione, il comportamento dei due modelli viene testato su un'applicazione a dati reali relativi al tasso di diabetici in Belgio nel 2014.*

1 Introduction

Disease mapping is an area of spatial epidemiology whose purpose is to estimate the spatial pattern of disease rates over some geographical region of interest, often taken as a finite collection of sites, like cities or counties. Spatial units are usually organized in graph representations where each unit is a node and two nodes are connected by an edge if they can be considered "neighbors". In spatial epidemiology, for example, it is common to assume that two sites are neighbors if they share a boundary.

When observing an epidemiological phenomenon at a specific site, we can imagine it as being influenced by its behaviour in neighboring sites; this effect is usually modelled by adopting a hierarchical approach involving a suitable spatial autoregressive model for the so-called *latent spatial effect*, that is, a random process whose covariance structure captures information on the local spatial dependency that links the phenomenon to the territory.

2 CAR and DAGAR models

Among the available autoregressive models for a latent spatial effect – typically a zero-mean, structured–covariance multivariate process – one of the most used is the Conditional Autoregressive (CAR) model. This model adopts a *symmetrical* neighborhood structure, meaning that for a couple of nodes $\{i, j\}$ with neighborhood sets $\{N(i), N(j)\}$ we have:

$$j \in N(i) \Leftrightarrow i \in N(j). \tag{1}$$

The implied model on the latent spatial effect is then specified as

$$w_i | w_{-i} \sim \mathrm{N}\left(\sum_{j \in N(i)} \frac{\rho'}{n_i} \cdot w_j, \tau_w \cdot n_i \right), \forall i, \tag{2}$$

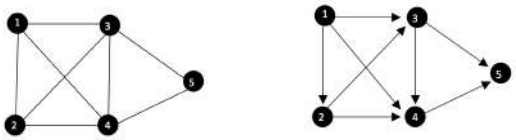
where n_i denotes the cardinality of $N(i)$, τ_w is a precision parameter and ρ' is the spatial correlation taken to be in $(0, 1)$ for easy of comparison.

A more recent addition to the disease mapping toolkit is the Directed Acyclic Graph Autoregressive (DAGAR) model introduced in [1]. Differently from the CAR, this model is based on an *asymmetric* neighborhood structure. More specifically, in order to get some desirable properties, to build a DAGAR neighborhood $N(i)^\star$, we do start from a symmetrical one $N(i)$, but we then impose a *fictional*[1] ordering on the nodes, which is used to "prune down" the original neighborhood $N(i)$ to get the new, simplified one, as follows:

[1] In practice, the sites of a specific territory rarely come with a natural order attached. Hence the ordering we need to introduce is typically fictional and subjective (for instance, based on longitude or latitude). In [1] the Authors proved the robustness of the results to changes in the ordering.

$$N(i)^\star = \{j \in N(i) \text{ such that } j < i\}, \forall i. \tag{3}$$

Using this constraint, we can turn an undirected graph into a directed one, as exemplified in Figure (1), together with the neighborhood reduction.



(a) An undirected graph.

(b) An associated directed graph.

Fig. 1: Focusing on node 3: (a) $N(3) = \{1,2,4,5\}$. (b) By Eq.(3), $N(3)^\star = \{1,2\}$.

For each node i, we want to specify a model for $w_i|w_{-i}$ and we do it by assuming an AR(1) model with parameter $\rho \in (0,1)$ on the local spanning tree made by the nodes $\{i, N(i)^\star\}$ and the edges connecting them. In this case, ρ^d is clearly the correlation between any two variables whose indices are d edges apart.[2] So we write:

$$\left(w_i, w_{N(i)^\star}\right) \sim \text{MVN}\left(0, \begin{bmatrix} 1 & v_i^\top \\ v_i & \Sigma_i \end{bmatrix}\right), \tag{4}$$

where v_i is a vector with all entries equal to ρ, whereas Σ_i is a square matrix with all ones on the diagonal and all ρ^2 outside. Assuming Eq.(4) and asking for $\mathbb{E}\left(w_i|w_{N(i)^*}\right)$ to be a linear combination of $\{w_j, j \in N(i)^\star\}$, we obtain the following conditional model:

$$w_i|w_{-i} \sim \text{N}\left(\sum_{j \in N(i)^\star} \frac{\rho}{1+(n_i^\star-1)\rho^2} \cdot w_j, \tau_w \cdot \frac{1+(n_i^\star-1)\rho^2}{1-\rho^2}\right), \forall i, \tag{5}$$

where $n_i^\star$ is the cardinality of $N(i)^\star$.

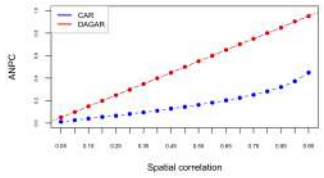
With this model specification, we see that the ρ parameter can be naturally interpreted as the correlation between two neighboring[3] nodes; the same cannot be said for ρ' in the CAR model. To check it empirically, we consider two types of territory characterized by a regular and an irregular grid of counties; on each of the two, we build a symmetrical neighborhood structure and we simulate 1000 times from a CAR model; we then impose a longitude-based ordering on the nodes, we reduce the neighborhood structure using Eq.(3) and we simulate 1000 times from a DAGAR model. Based on these simulations, we can approximate the Average Neighbor Pair Correlation (ANPC) under the two models as:

[2] We want $\rho \in (0,1)$ for the matrix ρ^D to be positive definite, if D is the distance matrix.

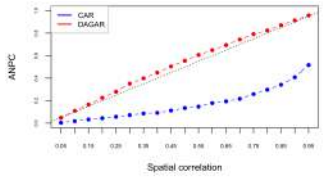
[3] It makes sense for such a correlation to be positive since we expect a "concordant" behaviour of the phenomenon in neighboring sites.

$$\text{ANPC} = \frac{\sum_{i\sim j} \mathbb{C}\text{or}\,(w_i, w_j)}{\sum_{i\sim j} n_i}, \text{ where } i \sim j \text{ means they are neighboring sites.} \quad (6)$$

This is repeated for different values of the spatial correlation parameter in $(0,1)$, respectively ρ' and ρ, holding τ_w fixed and equal under both models. The results are collected in Figure (2). As we can see, in both the regular and the irregular case, the ρ parameter in the DAGAR model almost equals the ANPC, whereas the CAR model is associated to an ANPC that systematically underestimates ρ'.



(a) 20×20 1^{st}-order regular grid. In the symmetrical structure, two nodes are neighbors if they are connected by an edge of the grid.



(b) Irregular grid made of the 44 municipalities of Limburg (BE). The symmetrical structure is built as an extension of a $k = 4$ NN one.

Fig. 2: Average correlation plots for neighbor pairs.

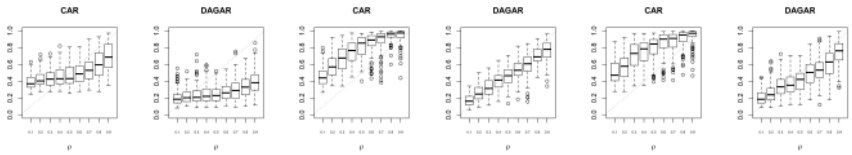
3 Simulation analysis

In this section we detail the results of the following simulation study: taking ρ as the spatial correlation parameter in each model, we fix it as a value in the set $\{0.1, \ldots, 0.9\}$, then we simulate the spatial effect w from one of these models: the CAR, the DAGAR and a Gaussian Process that ensures the true ρ to be equal to the ANPC.[4] We then simulate the response variable as $Y = X\beta + w + \varepsilon$ after having generated the covariates $X \sim \text{MVN}(0, \mathbb{I})$ and the error $\varepsilon \sim \text{MVN}(0, \tau_e \cdot \mathbb{I})$ for a fixed set of precision parameters $\{\tau_w, \tau_e\}$ and regression coefficients β. We fit a hierarchical model on the data: we give β an MVN prior, ρ a $\text{Unif}(0,1)$ prior, whereas the precision parameters τ_w and τ_e are given Gamma priors. We write the model in Nimble [2]. Posterior estimates of the parameters in the model are obtained as MCMC posterior means; the used algorithm is *Metropolis*.

Our results show that if the true ρ equals the ANPC, as in Figures 3(b) and 3(c), by fitting a DAGAR model on the latent spatial effect we are able to correctly recover both ρ and the correlation from posterior simulations. The same considerations can-

[4] Given ρ, simulate $w \sim \text{MVN}(\text{Mean} = 0, \text{Sigma} = \text{e}^{D \cdot \log(\rho)})$ where D is a scaled distance matrix; this process' average neighbor pair correlation is equal to ρ.

not be made for the CAR model. In fact, in the same settings, the CAR posterior estimates of ρ seem to systematically overestimate the true parameter value. Even when the effect is actually simulated from a CAR model, from Figure 3(a) we see that the posterior estimates for ρ do not seem to capture the true values of the parameter.



(a) Simulations from CAR (b) Simulations from DAGAR (c) Simulations from GP

Fig. 3: Posterior estimates for ρ. Each boxplot is made out of 100 posterior means.

On the other hand, other results (not shown here) suggest that both models can accurately estimate the regression parameters showing only small over/underestimation problems when dealing with the precision parameters.

4 Real data analysis

In this final section we consider an application to real data concerning the rates[5] of diabetics observed in 2014 in each of the 589 Belgian municipalities.[6]

The log-rates are shown in Figure 4(a). Here we can clearly see strong dissimilarities between two areas of Belgium that are notoriously very different: Flanders (North) and Wallonia (South). Qualitatively speaking, it seems that spatial correlation among neighbors would be very strong in both areas taken separately, but not over Belgium as a whole. Knowing the meaning of ρ in a DAGAR model (spatial correlation between two neighbors), fitting a single model on the whole area would lead to misleading estimates for this parameter. Therefore, in the following, we will work on the two areas separately.

In each area, we assume a fairly simple (no covariates) model for the log-rate $Y = \mu + w + \varepsilon$ and we fit two models, one with $w \sim$ CAR and one with $w \sim$ DAGAR, both having a Normal-distributed μ and a Unif$(0,1)$-distributed spatial correlation parameter, ρ' and ρ respectively; the symmetrical neighborhood structure is built from a sharing–a–boundary type of graph and the fictional ordering of the municipalities is based on their longitude.

[5] The rate in each municipality is computed as the ratio between the observed and the expected number of cases, marginalized over age and gender.

[6] Count data about the people who received diabetics-related medications in 2014 have been collected by the InterMutualische Agentschap (www.ima-aim.be).

In Table (1), we see some results of the model fitting procedure; estimates are obtained as MCMC posterior means.

Table 1

Area	Model	Spatial correlation	Error $= \frac{1}{n}\sum_{i=1}^{n}(y_i - \widehat{y}_i)^2$
North	CAR	0.666	0
	DAGAR	0.989	0.00119
South	CAR	0.751	0
	DAGAR	0.987	0.00084

As it is apparent, both models produce posterior estimates for the spatial correlation that are large in both areas, confirming our original guess – keep in mind that the estimates from the DAGAR can actually be interpreted as ANPC. In reconstructing the diabetics log-rate, we see from both Table (1) and Figure (4) that the two models worked very well, the CAR actually overfitting the data.

Overall, the two models appear to be very competitive, each with its pros and cons. Both worked reasonably well on the considered dataset, producing expected and hoped–for results even without additional information provided by covariates.

A functional approach to study the relationship between dynamic covariates and survival outcomes: an application to a randomized clinical trial on osteosarcoma

Un approccio funzionale per studiare la relazione tra covariate dinamiche e sopravvivenza: un'applicazione ad uno studio clinico randomizzato sull'osteosarcoma

Marta Spreafico, Francesca Ieva and Marta Fiocco

Abstract In clinical research, associating dynamic time-varying covariates (e.g. biomarkers or drug assumption) with an event-time outcome represents a challenging task that could be tackled exploiting Functional Data Analysis (FDA). In particular, FDA techniques can be used to represent dynamic time-varying covariates in terms of functions, which can be plugged into a Cox-type regression model to investigate the effect on survival outcomes. Data from MRC BO06/EORTC 80931 randomised controlled trial for treatment of osteosarcoma were analysed. Time-varying covariates related to alkaline phosphatase levels and chemotherapy dose during treatment were considered.

Abstract *Nella ricerca clinica, associare covariate tempo-dipendenti dinamiche (biomarcatori o assunzione di farmaci) ad un evento di interesse rappresenta un problema stimolante che può essere affrontato tramite l'analisi dei dati funzionali (FDA). In particolare, tecniche di FDA possono essere utilizzate per rappresentare le covariate tempo-varianti come funzioni del tempo. Tali funzioni possono poi essere inserite in un modello di regressione di Cox per studiare l'effetto che esse hanno sulla sopravvivenza. Abbiamo analizzato i dati relativi allo studio clinico randomizzato MRC BO06/EORTC 80931 per il trattamento dell'osteosarcoma, considerando come variabili tempo-dipendenti il livello di fosfatasi alcalina nel tempo e la dose di chemioterapia assunta durante il trattamento.*

1 Introduction

Osteosarcoma is a malignant bone tumour mainly affecting children and young adults. Multidisciplinary management including neoadjuvant and adjuvant chemotherapy with aggressive surgical resection [1] or intensified chemotherapy [2] has improved clinical outcomes but the overall 5-year survival remained unchanged in the last 40 years at 60–70%.

Depending on patient's health status or development of toxicity, biomarker values evolve and chemotherapy treatment is modified by delaying a course or reducing the dose intensity. Alkaline phosphatase (ALP) has been identified and reported as prognostic marker [3]: high ALP level is associated with poor overall or event-free survival and presence of metastasis [4, 5]. ALP levels have always been included in survival models as baseline time-fixed covariate. Similarly, chemotherapy is usually modelled by different allocated regimens (Intention To Treat - IIT analysis), without considering changes in drug assumptions over time. It has been shown that there is mismatch between target and achieved dose of chemotherapy [6] whose impact on patient's survival is still unclear. Therefore, the most appropriate and realistic way to look at both drug consumption and biomarkers is to model them as time-varying variables. In this way it is possible to investigate the dynamic effect of chemotherapy over time and to carry out information that may be related to the survival.

In clinical research, associating dynamic time-varying covariates with an event-time outcome related to a specific event of interest (e.g. death) represents a challenging task that could be tackled by exploiting Functional Data Analysis (FDA)[7]. In recent years FDA has been increasingly used in healthcare research, since it provides a novel modelling and prediction approach. There is a great potential for many applications in public health and biomedical fields [8]. In this work we focus on time-varying covariates related to ALP levels and chemotherapy dose during treatment in order to study how they influence patients' long-term survival.

2 Dataset

Data from MRC BO06/EORTC 80931 Randomised Controlled Trial (RCT) for treatment of osteosarcoma were analysed. Patients were randomized at baseline between Conventional (*Reg-C*) or Dose-Intense (*Reg-DI*) regimens, with identical anticipated cumulative dose but different duration. Chemotherapy was administered for six cycles C_j with $j \in \{1,...,6\}$ (a cycle is a period of either 2 or 3 weeks depending on the allocated regimen), before and after surgical removal of the primary osteosarcoma. In both the *Reg-C* and *Reg-DI* arms, doxorubicin (DOX: 75 mg/m^2) plus cisplatin (CDDP: 100 mg/m^2) were given over six cycles. Surgery to remove the primary tumour was scheduled at week 6 after starting treatment in both arms. Figure 1 shows the trial design. Laboratory tests, such as ALP test, were performed before each cycle to monitor patient's health status. Delays or chemotherapy dose

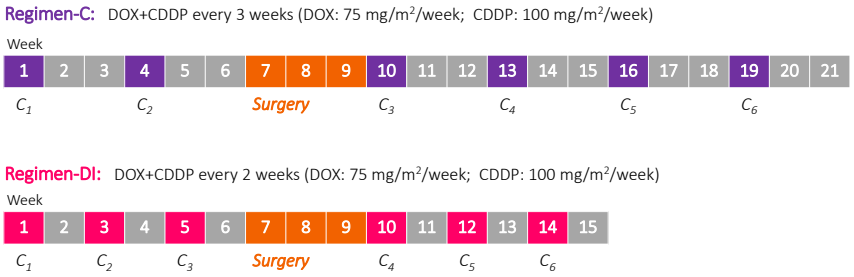

Fig. 1 Patients are randomized at baseline to one of the two regimens, with identical anticipated cumulative dose but different duration.

reductions during treatment were applied in the presence of toxicity. Details can be found in the primary analysis of the trial [2].

3 Methods

In this study, each patient is followed from date of randomization. As shown in Figure 2, the study period is divided in two intervals: a *pre-defined period*, used for the reconstruction of the time-varying covariates, and a *follow-up period*, used for the survival analysis. The *pre-defined period* starts from the date of randomization (T_R in Figure 2) and it is used to computed both longitudinal and functional representations of ALP biomarker and chemotherapy dose. The *follow-up period* is then used for the time-to-event analysis in which the event of interest is patient's death for any cause. Overall Survival (OS) is measured from the end of the *pre-defined period*, i.e. $T_0 = T_R + 180$ days, to the date of death or last visit.

The methodology applied for the analysis can be divided into the following steps:

1. select a proper cohort of patients, i.e. patients who completed the chemotherapy protocol within 180 days after randomization;
2. reconstruct the longitudinal trajectories of ALP biomarker and dose of chemotherapy;
3. use FDA techniques to reconstruct the functional data related to dynamic ALP biomarker and dose of chemotherapy in the interval $[T_R; T_0]$ starting from the longitudinal representations;
4. use Functional Principal Component Analysis (FPCA)[7] to summarise each function to a finite set of covariates, i.e. the FPC scores;
5. fit a Cox's regression model with FPC scores and baseline characteristics in order to quantify the association between time-varying processes and long-term survival [9].

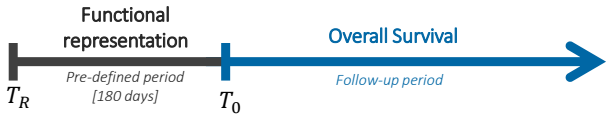

Fig. 2 Study design for a patient in the study cohort. The *pre-study period* is used to compute the functional representations of time-varying covariates. T_R is the randomization time and $T_0 = T_R + 180$ [days] is the time from which Overall Survival (OS) is computed. The *follow-up period* is used for survival analysis.

4 Application and Results

In the study cohort 376 patients that completed the chemotherapy within 180 days from randomization were included. Median age at randomization was 15 years (51.1% patients with age ≥ 15) with a percentage of male patients equal to 60.6% (228 patients). The median value of baseline White Blood Count (WBC) was $7.65 \times 10^9/L$ ($IQR = [6.30; 9.13]$) and regimen Dose-Intense was allocate in 52.3% of the patients (197). Median follow-up time, computed using the reverse Kaplan-Meier method [10], was 46.09 months ($IQR = [22.77; 76.91]$) and 296 patients (78.7%) were alive at the last follow-up visit.

The values of ALP biomarkers $y_i(t)$ were measured through laboratory tests, usually performed before each cycle of chemotherapy. For each patient i, a vector $\boldsymbol{y}_i = \{y_i(t_{il}), l = 1, ..., n_i\}$ of longitudinal values of ALP measurements was reconstructed, where t_{il} is the time of the l-th ALP test and n_i is the number of different laboratory tests for patient i. The time-varying standardized cumulative dose of drugs $\delta_i(t)$ was defined as the cumulative assumed dose of $DOX + CDDP$ up to time t divided by the total target dose over the six cycles. For each patient i and cycle j, a vector $\boldsymbol{\delta}_i = \{\delta_i(t_{ij}), j = 1, ..., 6\}$ of longitudinal values of standardized cumulative dose of chemotherapy over time was defined.

FDA techniques [7] were used to convert the longitudinal values into functional representations. In both cases B-spline basis functions were considered, and the functional data objects were expressed using a general functional form and a monotone functional form, for ALP biomarker and chemotherapy dose respectively. Data were then smoothed by (penalized) regression analysis, constraining functions to be positive and upper bounded for clinical indication. A graphical representation of functional ALP biomarker curves $\tilde{x}_i^{(ALP)}(t)$ (left panel) and of functional standardized cumulative dose curves $\tilde{x}_i^{(\delta)}(t)$ (right panel) are shown in Figure 3, in which each curve represents the functional predictor of a patient. Exploiting FDA to obtain a functional representation of the time-varying processes of interest is an effective exploratory technique to highlight trends and variations in the shape of processes over time.

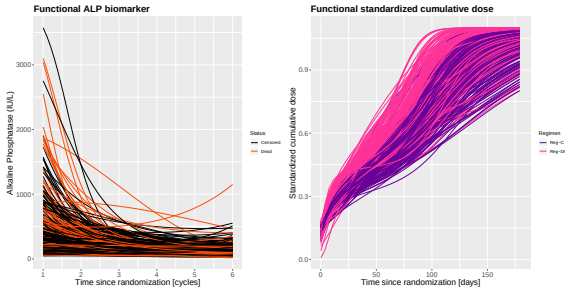

Fig. 3 Left panel: functional representations of ALP biomarker over cycles coloured by event status (black: *Censored*, red: *Dead*). Right panel: functional representations of standardized cumulative dose of chemotherapy over time coloured by allocated regimen (pink: *Reg-DI*, purple: *Reg-C*).

Once computed the functional predictors $\tilde{x}_i^{(ALP)}(t)$ and $\tilde{x}_i^{(\delta)}(t)$, to summarize each function into a finite set of covariates two Functional Principal Component Analyses (FPCAs) were performed. In both cases, we found that two principal components were enough to consider at least 95% of the explained variance, hence the finite set of covariates related to FPC scores was $\left\{f_{i1}^{(ALP)}, f_{i2}^{(ALP)}, f_{i1}^{(\delta)}, f_{i2}^{(\delta)}\right\}$.

To assess the role of available functional covariates with respect to the overall survival time of a patient, a multivariate functional Cox regression model adjusting for baseline characteristics $\boldsymbol{\omega}_i = (WBC_i, gender_i, age_i)$ was estimated:

$$h_i\left(t|\boldsymbol{\omega}_i, \tilde{x}_i^{(\delta)}(t), \tilde{x}_i^{(ALP)}(t)\right) = h_0(t)\exp\left\{\gamma_1 WBC_i + \gamma_2 gender_i + \gamma_3 age_i + \alpha_1^{(\delta)} f_{i1}^{(\delta)} + \alpha_2^{(\delta)} f_{i2}^{(\delta)} + \alpha_1^{(ALP)} f_{i1}^{(ALP)} + \alpha_2^{(ALP)} f_{i2}^{(ALP)}\right\}. \quad (1)$$

Gender, level of WBC at randomization and the score related to the first PC of alkaline phosphatase $f_{i1}^{(ALP)}$ were statistically significant at confidence level $\alpha = 5\%$. In particular, males experienced the event of interest 1.7-times faster than females. The higher the value of WBC at baseline, the lower the survival. The higher the value of the score related to the first PC of ALP biomarker $f_{i1}^{(ALP)}$, the lower the survival. This suggested that patients with higher trajectories ALP levels with respect to the mean curve had poor survival probability. FPC scores related to functional chemotherapy dose were not statistically significant. This suggest that even more informative representation of dose-intense profiles, do not show a beneficial effect on survival.

5 Conclusion

The novelty of this approach can take into account important information about the dynamic behaviours of the generating processes that underpin the data, represent-

ing interpretative and forecasting tools in osteosarcoma research. High ALP levels during time reflected poor overall survival and dose-intense profiles were not associated with good survival. However, functional representations were able to capture the individual realisations of the intended treatment, suggesting that other peculiar aspects of chemotherapy, such as latent accumulation of toxicity [11], should be taken into account.

The complexity of the phenomenon asks for the developments of new methodologies. This study showed that working in this direction is a difficult but profitable approach, which could lead to new improvements for subject-specific predictions and personalised treatment.

A Statistical Approach to the Alignment of fMRI Data

Un approccio statistico al problema dell'allineamento di dati fMRI

Angela Andreella, Ma Feilong, Yaroslav Halchenko, James Haxby, and Livio Finos

Abstract Multi-subject functional Magnetic Resonance Image studies are critical. The anatomical and functional structure varies across subjects, so the image alignment is necessary. We define a probabilistic model to describe functional alignment. Imposing a prior distribution, as the matrix Fisher Von Mises distribution, of the orthogonal transformation parameter, the anatomical information is embedded in the estimation of the parameters, i.e., penalizing the combination of spatially distant voxels. Real applications show an improvement in the classification and interpretability of the results comparing to various functional alignment methods.

Abstract *Gli studi di risonanza magnetica funzionale multi-soggetto sono critici. La struttura anatomica e funzionale del cervello varia tra i soggetti, l'allineamento delle immagini è indispensabile. In questo lavoro, si definisce un modello probabilistico per descrivere l'allineamento funzionale. Definendo una distribuzione a priori, come la Fisher Von Mises, per le matrici ortogonali, le informazioni anatomiche sono incorporate nel processo di stima, penalizzando la combinazione*

di voxel spazialmente distanti. Applicazioni reali mostrano un miglioramento nella classificazione e nell'interpretazione dei risultati rispetto ad altri metodi.

Key words: fMRI data; Hyperalignment; Fisher Von Mises; Generalized Procrustes Analysis

1 Introduction

Multi-subjects functional Magnetic Resonance Images (fMRI) studies permit to compare analysis across subjects. However, the anatomical and functional structure of brains varies across subjects, even in response to identical sensory inputs. The images must be aligned to a common spatial space. The alignment process could use anatomical or functional features of the brains or both. [10] proposed a spatial anatomical normalization, but it doesn't account for idiosyncratic functional topography. For that, [8] suggested a functional alignment, called hyperalignment, using sequential Procrustes transformations. The activations of different subjects are mapped into a common high dimensional model, representing a linear combination of voxel activations.

After [8], various modifications of hyperalignment appeared; however, these methods analyze only the huge computational effort without emphasizing the final interpretation of the transformed high dimensional space.

The method proposed shall implement an approach that permits to restrict the range of possible transformations used to map the neural response into a common high dimensional space. The restriction is based on the idea that the anatomical information could give a direction of the most plausible transformation, that match as best as possible the subject's data. We implement an alignment technique that exploits the anatomical features in addition to the correlation among voxels' time series. The objective of the Procrustes problem is to find an orthogonal transformation that minimizes the pairwise differences between two or more matrices, i.e., images. This minimization can be considered as a least-squares problem, allowing a definition of a statistical model describing the data generating process. Therefore, the set of transformation solutions can be shrinkage using a prior distribution for the orthogonal matrix transformation. The use of priors based on neurological information permits to improve the interpretability of the transformation matrix founded, rather than the hyperalignment method that doesn't impose any constraint to the orthogonal transformation solution. The prior distribution proposed is the Matrix Fisher Von Mises distribution. The specification of the location matrix parameter permits to penalizes spatially distant voxels in the Procrustes transformation. This penalization is expressed in terms of the idea that the rotation loadings of contiguous voxels are similar, and the rotation loadings of distant voxels are probably less similar. So, the location matrix parameter is defined as a similarity matrix derived from the Euclidean distance of the three-dimensional brain voxels coordinates. The

proposed method considers both anatomical and functional data features, in contrast to the hyperalignment that is anatomy free.

In the following, in Section 2 is introduced the Procrustes problem and the main technical contribution. Section 3 outlines the performance evaluation of the method proposed in the multi-subject classification framework.

2 Methodology

In this Section, we briefly revisit some results of [9] and [5] to set the stage and introduce notation.

2.1 Generalized Procrustes Analysis

The data are represented in a matrix $X_i \in \mathbb{R}^{t \times v}$, $i = 1, \ldots, m$, one for each subject. The t rows of X_i represent the response activation of v voxels during a stimulus, and the v columns represent the time series of activation for each v voxel. The matrices are ordered consistently across all subjects considering the rows because the stimuli are time-synchronized; this does not apply to the columns. For that, the alignment step is essential to perform inter-subject analysis.

Procrustes methods are useful for assessing the distance between matrices. When X_1 is transformed into the space of X_2 by an orthogonal transformation R, the Procrustes problem is called *Orthogonal Procrustes Problem* (OPP), i.e.:

$$\min_R ||X_1 - X_2 R||_F^2 \quad \text{subject to} \quad R^T R = R R^T = I_v \,. \tag{1}$$

A first solution of Eq. 1 was proposed by [9], the minimum is given by $\hat{R} = UV^T$, where U and V are derived from the singular value decomposition of the matrix $T = X_2^T X_1 = U \Sigma V$.

Analysing $m \geq 2$ subjects, the *Generalized Procrustes Analysis* (GPA), defined by [4], is considered, i.e.:

$$m \min_{R_i} \sum_{i=1}^{m} ||X_i R_i - M||_F^2 \quad \text{subject to} \quad R_i^T R_i = R_i R_i^T = I_v \qquad \forall i = 1, \ldots, m \,. \tag{2}$$

where $M = m^{-1} \sum_{i=1}^{m} X_i R_i$, called configuration average matrix. Eq. 2 hasn't a closed solution, [5] proposed an iterative procedure to estimate R_i .

The hyperalignment method proposed by [8] is a sequential approach of OPP (Eq. 1); therefore, the results depend on the order of the subjects. Also, It doesn't reach the global minimum imposed by the GPA (Eq. 2).

The next Section outlines the approach proposed, which is an extension of GPA (2), our estimation of R_i is guided by prior anatomical information.

2.2 Procrustes problem using prior information

The OPP is based on the least-squares criterion to find the optimal transformation. However, the solution founded by the GPA is not unique. Every random rotation of the founded solution is still a valid solution, i.e. the set of solutions equals $\left\{\hat{R}S : \forall S \in \mathcal{O}(m)\right\}$.

For that, we use prior information about the structure of R_i that leads the optimization step. The Procrustes problem is then analyzed from a likelihood perspective as proposed by [3], defining a statistical model called the perturbation model.

The minimization problem defined in Eq. 2 can be formulated as

$$X_i = MR_i^\top + E_i \qquad \text{subject to} \quad R_i^\top R_i = R_i R_i^\top = I_v \qquad \forall i = 1, \ldots, m \tag{3}$$

where E_i is the matrix with dimension $t \times v$ of the residual terms, and M is the configuration average matrix. E_i follows the multivariate normal matrix distribution [7], where each rows of $E_i \sim N(0, \sigma^2 I_v)$. The $M \in \mathbb{R}^{\mathrm{t}\times\mathrm{v}}$ matrix is the configuration average matrix. The X_i is then described as a randomly Gaussian perturbation of M. The R_i permits to represent each X_i in the shared space defined by M .

Therefore, we define a prior distribution for R_i, that takes values in the Stiefel Manifold $V_v(R^v)$. [1] proposed the matrix Fisher Von Mises distribution, lately used by [6]. It is described as:

$$f(R_i) \sim C(F,k)\exp(\mathrm{tr}(kF^T R_i)) \tag{4}$$

where $C(F,k)$ is a normalizing constant, $F \in \mathbb{R}^{\mathrm{v}\times\mathrm{v}}$ is the location matrix parameter and $k \in \mathbb{R}_{>0}$ the concentration parameter. The specification of the matrix F is the focal point. We think that closer voxels have similar rotation loadings while voxels very far each other should have less probably similar loadings. For that, the location matrix parameter F is constructed as a Euclidean similarity matrix using the three-dimensional coordinates of the voxels.

Without a prior assumption, [2] found that the least-squares solution to Eq. 3 is the Procrustes solution founded by [9]. Having the Fisher Von Mises prior distribution, we found that the solution proposed is a slight modification of the solution founded by [9] in the case of one subject, and a slight modification of the solution given by [4] in the case of multiple matrices. The modification is focused on considering the singular values decomposition of $X_i^\top M + kF$ instead of $X_i^\top M$.

Being a minor modification of the Generalized Procrustes [4], the method proposed can find the global minimum, unlike the hyperalignment method. Also, the hyperalignment and GPA methods are completely anatomy free. In contrast, the method proposed preserves the anatomical meaning of the space behaviour of the voxel in the brain or the region of interest. Also, if the hyperalignment method converges to the GPA, it is immediate to prove that the solution to the minimization is not unique. If not, the results still depend on the order of the subjects, leading to a replicability problem. So concluding, in the method proposed, the transformations are unique and also follow an anatomical structure.

3 Results

The protocol to evaluate the performance of the method follows the one used in [8]. Because the results of hyperalignment depend on the order of subjects, we permuted it 100 times and used the distribution of classification accuracy. Figure 1 shows that the accuracy computed by the method proposed is higher than the median result given by the hyperalignment in both analyses. Also, the new method generates unique transformations, simplifying the interpretation of the results.

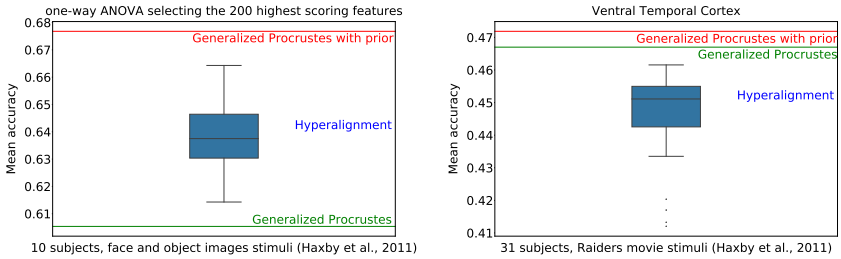

Fig. 1 Box-plots showing the classification mean accuracy permuting 100 times the order of the subjects, analyzing the Faces and Objects dataset by the Multi-class Linear Support Vector classifier (left) and the Raiders dataset by the one nearest neighbor classifier (right)

Figure 2 upper panel represents one of the classifier's coefficients used in the object recognition analysis with data aligned by the method proposed, while the lower panel by hyperalignment. The spatial regularization, imposed on the estimation of the orthogonal transformation, leads to a smoother map of classifier coefficients. It can capture the spatial information of the voxels and choose between the infinite possible solutions, the orthogonal transformation more reasonable. Also, the pairwise distance (measured as the norm of difference matrices) between subjects is lower, considering data aligned by the technique proposed (36.28) than data aligned by the hyperalignment method (444479.13). Thus, the brain images after hyperalignment result to be more different between each other.

4 Conclusions

Rephrasing the Procrustes problem as a statistical model, we can shrink the set of transformation solutions using a prior distribution, i.e., the Matrix Fisher Von Mises distribution, for the orthogonal matrix parameter. This assumption allows embedding anatomical information in the estimation of parameters, by penalizing the similarity of spatially distant voxels when we estimate the common reference space.

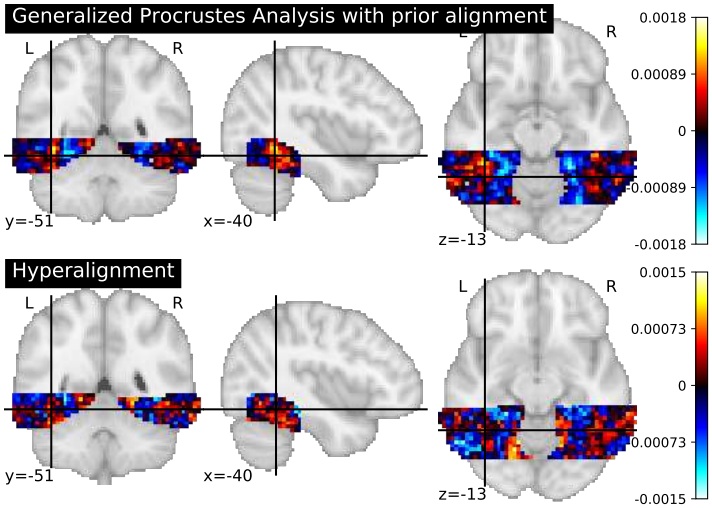

Fig. 2 Coefficients of the Multi-class Support Vector Machine considering the monkey face versus male face classifier analyzing the Faces and Objects data aligned by the Generalized Procrustes Analysis with prior information and by the hyperaligment method.

The method returns a unique solution of the rotation matrices, having anatomical meaning, so more interpretable. Using real data, we found that the alignment proposed improves the classification analysis between-subjects in comparison to hyperalignment. It also permits reaching the global minimum imposed by the GPA, and it doesn't depend on the order of the subjects, giving smaller between-subject distance.

Adaptive clinical trials: Bayesian decision-theoretic and frequentist approaches for cost-effectiveness analysis

Prove cliniche adattive: una comparazione tra approcci Bayesiani e frequentisti per l'analisi costi-efficacia

Martin Forster and Marco Novelli

Abstract We consider some recently published Bayesian and frequentist models of sequential experimentation and their use for conducting a cost-effectiveness analysis of health technologies alongside a clinical trial. Simulations compare a range of operating characteristics and are used to propose an agenda for future research.
Abstract In questo lavoro vengono comparati alcuni modelli bayesiani e frequentisti per la sperimentazione clinica sequenziale finalizzata all'analisi costi-efficacia delle tecnologie sanitarie. Attraverso simulazioni vengono approfondite le caratteristiche operative dei due approcci al fine di evidenziarne pregi e difetti e delineare alcune possibili sviluppi per la ricerca futura.

Key words: Clinical trials, Health economics, Bayesian inference, Response-Adaptive Randomization, Sequential sampling

1 Introduction

There is growing interest in the use of adaptive clinical trials to assess the effectiveness of health technologies [3]. For example, in the frequentist literature, [14] combine sequential monitoring with response-adaptive randomisation in a design which offers potential for increased power and earlier stopping, given a predefined type I error rate. [12] argue that the Bayesian approach provides a formal way to monitor accumulating data and decide whether to stop a trial. [10] and [5] present Bayesian decision-theoretic approaches to stopping a two-armed sequential trial.

e-mail: marco.novelli4@unibo.it

We consider some recent frequentist and Bayesian approaches using simulations based on the case study presented by [10], who considered a two-armed sequential clinical trial evaluating the cost-effectiveness of a new health technology relative to a known standard when there exists zero, or negligible, delay in observing the patient-level outcomes and treatment costs. Reflecting growing interest in the literature [6], our approach focuses on the cost-effectiveness of the technologies under consideration, rather than their effectiveness alone. The operating characteristics which we assess explicitly account for benefits which accrue to the population to benefit from the adoption decision, the proportion of patients allocated to each treatment during the trial, and the research costs of the trial itself.

2 Bayesian and frequentist designs

The designs address a common problem similar to those of [10] and [5]. A cost-effectiveness analysis of two health technologies, N ('new') and S ('standard', the incumbent technology), is carried out alongside a clinical trial in which patients are allocated sequentially and outcomes on effectiveness and treatment cost are observed without delay. The outcome of interest is the difference between the net monetary benefit (NMB) of technology N and technology S. NMB is defined as $Y_i = \lambda E_i - C_i$, $i \in \{N,S\}$, where E is a random variable denoting effectiveness and C denotes the known treatment cost. λ is the monetary valuation of one unit of effectiveness, a parameter required to convert health outcome data (such as a measure of quality of life) into monetary units.[1] Incremental net monetary benefit (INMB) is the difference between the NMB of N and S, that is, $X = Y_N - Y_S$. It is assumed that X has a normal distribution in the population, with unknown expected value μ_X, and variance σ_X^2, assumed known. The trial may recruit a maximum of M patients. Sequential monitoring of the estimate of INMB takes place. Interest lies in deciding when to stop the trial to choose the better of the two technologies on cost-effectiveness grounds. We consider two approaches.

1. Bayesian decision-theoretic designs of [10] (and of [5], when the delay in observing outcomes is set equal to zero): These methods build on the work of [4] and previous, related, works. Define W as a random variable representing beliefs about the unknown μ_X. We assume that it has a normal prior distribution, with expected value μ_0 and variance σ_0^2. Following, e.g., [4], we assume that pairs of patients are randomised sequentially to treatments N and S and that the resulting data are generated by a normal likelihood function. Each pairwise allocation costs $c > 0$ in research monies and the technology adoption decision benefits $P > 0$ patients. We consider the case of no discounting of benefits and costs. Given that the prior distribution is conjugate to the normal likelihood, Bayes' rule may be used to update the prior distribution sequentially and the posterior mean is used to estimate the unknown μ_X. The problem is to choose the sample size at which to stop recruitment to

[1] For example, in the United Kingdom's National Health Service, λ may be chosen to be equal to £20,000 for one Quality Adjusted Life Year [8].

the trial, $0 < T \leq M/2$, and pick the superior technology for treating the P patients. If the posterior mean is greater than zero, it is optimal to pick N, for incremental net benefit equal to $P\mu_X$; if it is less than or equal to zero, it is optimal to pick S, for incremental reward equal to 0. T maximises:

$$V(\mu_0, t_0) = \mathbb{E}\left[\sum_{i=1}^{T} -c + \max_{d_T \in \{S,N\}} \{0, PW\} \middle| \mu_0, t_0\right], \tag{1}$$

where d_T is the technology adoption decision at stopping and $t_0 = \sigma_X^2/\sigma_0^2$. The choice of a conjugate normal prior permits standard expressions to be obtained for the posterior mean and variance. The method of [10] may be applied to obtain an optimal policy for whether to continue the trial or to stop as a function of the posterior mean and the number of pairwise allocations. An approximation to the policy is obtained by recasting the model in continuous time and solving what is termed a 'free boundary problem', using the methods of [4].

2. Frequentist designs: In contrast to the Bayesian approach, which assumes pairwise randomisation to each arm of the trial, the frequentist models monitor the proportions randomised to N and S as the trial progresses, as well as the accumulating evidence on outcomes and costs. Adaptive randomization seeks to achieve a target allocation to N and S which is either a function of the unknown model parameters or the treatment costs. Choice of which technology to select is based on a test of the null hypothesis of equality of treatment cost-effectiveness, combined with the [11] and [9] boundaries to control the type-I error probability. We consider both response-adaptive (RA) and allocation-adaptive (AA) randomisation rules. As a RA design, we adopt the Doubly Adaptive Biased Coin Design (DBCD) [14] with randomization parameter 2, combined with the Normal target suggested in [1]. Here, the target is updated as the evidence from the trial accumulates, by combining the estimate of incremental net monetary benefit with a tuning parameter which manages the degree of imbalance between the two arms. For the AA rule, we take into account the completely randomized design (CRD) equipped with either a balanced allocation, or an optimal target allocation aimed to minimize the total study cost, subject to a minimal required level of statistical power [13].

3 Methods

We use as an application the case study presented by [10, section 4], who considered the use of azithromycin extended release (N) versus amoxicillin and clavulanate potassium (S) for treatment of acute bacterial sinusitis. This is suited to our models because follow-up of the cost-effectiveness data was almost immediate (average time to symptom resolution was about one week) and the treatment cost data were known. Parameter values are based on those reported in [10, Table 1], adapted slightly to illustrate ideas (see Table 1). The main change is to increase the research cost, c, ten-fold, building on the results from [7].

Parameter	Definition	Value
Common to both designs		
C_S	Cost of one course of treatment with AC	\$31.99
C_N	Cost of one course of treatment with AZ-ER	\$55.68
$\bar{E_S}$	Mean days to symptom resolution for AC	8.12
$\bar{E_N}$	Mean days to symptom resolution for AZ-ER	7.55
λ	Estimate of willingness to pay for a symptom free day	\$73.2
σ_X†	Standard deviation of individual NIMB	\$300.00
N	Maximum sample size (number of patients)	4000
Bayesian decision-theoretic design only		
c†	Marginal cost of sampling	\$1000
σ_0†	Standard deviation of prior distribution concerning μ_X	\$300.00
P	Number of patients to be treated	1,000,000

Table 1 Parameter values and sources used for the simulations (based on [10]; †adjusted).

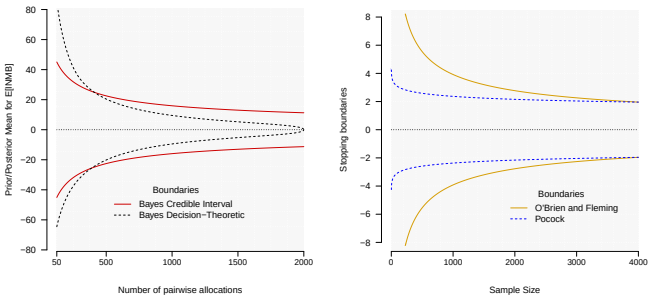

Fig. 1 Bayesian and frequentist stopping boundaries

To compare with existing Bayesian sequential models, we add a Bayesian design based on a 'credible interval' approach. This stops the trial when the probability that one of the two technologies is superior reaches 5% (see e.g. [12]). Matlab code [10] and R code is used. Monte Carlo simulation is used to obtain 10,000 paths for the posterior mean (Bayesian models) and the Wald test statistic, with $\alpha = 5\%$, (frequentist models), assuming that $\mu_X = \$18.2$ (obtainable from Table 1 data as follows: $\mu_X = -\$73.2 \times (7.55 - 8.12) - (55.68 - 31.99) \approx \$18.2$). For each design, the appropriate stopping boundary is used to stop each path and the new technology adopted, for reward equal to $P \times \$18.2$, or not adopted, for reward equal to zero.

4 Results and discussion

Results are dependent on the parameter values selected and should not be considered to hold in general. In particular, there is likely to be uncertainty around the willingness to pay parameter, λ, as well as σ_X^2. In addition, note that we focus on

	Frequentist		Bayesian

drawing from a population distribution with a fixed mean. An extension to a fully Bayesian analysis is left for future research.

The stopping boundaries are shown in Figure 1 and the operating characteristics in Table 2. A direct comparison of the Bayesian and frequentist stopping boundaries in Figure 1 is not possible because the scales are not common. Table 2 shows that the frequentist designs report higher expected sample sizes to stopping and lower proportions of correct decisions than do both Bayesian designs. This implies that Bayesian designs exhibit both lower trial costs and higher average IMB to patients, which in turn leads to a higher overall expected net benefit of the trial. Within the frequentist designs, the CRD outperform the DBCD with the CRD 1:1 being the best performing and the CRD close behind. This is mostly due to the fact that the balanced allocation maximises the power of the Wald test. As expected, the OBF rules are more conservative than the Pocock. Comparison of the standard deviations for sample sizes relative to their respective averages suggests that the Bayesian de-

signs are stopping some paths very early, a phenomenon that has also been observed in [7], who raised the concern that low sample sizes may hinder adoption of the preferred technology. What has not been accounted for in these rules, however, are the benefits accruing to trial participants, something that the DBCD and CRD designs seek to address through their choice of target allocation, but which the CRD 1:1 and both Bayesian designs do not.

Future research should explore more the commonalities and differences between the approaches, noting that, differently from the frequentist designs, the Bayesian ones currently do not implement allocation-adaptive and response-adaptive randomisation, although they do account for the size of the post-trial population to benefit. Further, although the frequentist designs' hypothesis tests include treatment costs, research costs are not currently considered. Research should also investigate further the variability of stopping times, a fully Bayesian approach to the simulation and, finally, credibility for deployment of the methods in health care systems.

Bootstrap corrected Propensity Score: Application for Anticoagulant Therapy in Haemodialysis Patients

Propensity Score aggiustato via Bootstrap: un'applicazione a dati di terapia anticoagulante su pazienti in emodialisi

Maeregu W. Arisido, Fulvia Mecatti and Paola Rebora

Abstract The inverse propensity score weighting (IPSW) has been often used to estimate causal effects of treatments for observational data. However, IPSW requires strong assumptions, in which their misspecifications may severely bias estimated treatment effect. We present a bootstrap based bias-correction to adjust the propensity score weights in case of misspecifications of one of the main assumption. We showed, using simulation, the approach performs well in correcting biases due to model misspecifications in various contexts.The method was also illustrated using a real data based on end-stage renal disease.

Abstract *Il metodo del Propensoty Score è ben noto e largamente impegato per la stima di effetti causali su dati osservazionali. Tuttavia, l'efficacia del metodo è condizionata da assunzioni stringenti che, qualora non verificate in pratica, possono condurre a severe distorsioni nella stima dell'effetto del trattamento. In questo lavoro presentiamo una soluzione bootstrap per "aggiustare" il metodo del propensity score nel caso di mancata specificazione di una delle principali assunzioni. L'efficacia di tale "aggiustamento" bootstrap è illustrata mediante un esercizio di simulazione che utilizza dati reali di pazienti all'ultimo stadio della malattia renale.*

Key words: bias-correction, bootstrap, Propensity score, simulation.

1 Introduction

When the goal is to establish the effectivness of a treatment, randomized controlled trials (RCTs) are the gold standard [2]. Due to various reasons, observational studies are used. The present work is inspired by an observational study where the aim was to explore the use of oral anticoagulant treatment (OAT) in reducing mortality due to atrial fibrillation in patients with end-stage renal disease (ESRD) [4]. A defect of such studies is that treatment allocation is influenced by baseline characteristics, which results in a bias affecting the estimated treatment effect. IPSW has been increasingly used to deal with such bias [8]. IPSW uses weights based on the propensity score to balance baseline covariates between the treated and control groups [6]. A key issue of IPSW is that strong assumptions are required to successfully balance the covariates and avoid the bias from the estimated treatment effect. The assumption of ignorability, which implies that there is no unmeasured covariates that affect both the outcome and treatment simultaneously, is a fundamental aspect of IPSW [8, 6]. Violation of this assumption deters the performance of IPSW.

We present a bootstrap-corrected IPSW (BC-IPSW) to address bias of estimated treatment effect when the propensity score weights are used for the estimation of treatment effect. The bootstrap has been commonly used for the estimation of standard errors of estimated treatment effect [e.g., 7]. However, the use of bootstrap together with the propensity score to avoid or minimize bias of the average treatment effect has been particularily rare. Recently, a simulation study by [5] showed that the bootstrap can be beneficial to reduce bias from the maximum likelihood estimator of the average treatment effect on a Gaussian outcome. The BC-IPSW firstly estimates a treatment effect using IPSW, based on multivariable logistic regression model. We then apply a bootstrap bias correction on the estimated treatment effect. The goal in this paper is twofold: (a) to evaluate whether OAT could lead to a reduction of mortality for the ESRD data, (b) to conduct simulations to examine the impact of IPSW misspecifications and assess to what extent the BC-IPSW reduces bias of the misspecification in various contexts. Section 2 below discusses the ESRD application data, section 3 presents the methodologies and simulation protocols. We present the results in section 5 and section 6 provides concluding discussion.

2 Motivating Real Data Application

The motivating application is based on determining the effectivness of Oral anticoagulant treatment (OAT) in reducing mortality due to atrial fibrillation in patients with end-stage renal disease (ESRD). OAT is the main treatment in ESRD, although presently evidences emerge that OAT leads to the risk of bleeding [4]. The data is coming from a prospective cohort study of 290 patients with AF and received OAT therapy in ten Italian haemodialysis centers. The patients were followed-up for 4 years from 31 October 2010 to 31 October 2014. At recruitment, 134 patients (46.2%) were taking OAT, in which $72(53\%)$ died. Among the 156 non treated patients, $98(63\%)$ died. There were 9 covariates measured at the begining of the four-

year study: age (≤ 65), gender, type of atrial fibrillation (AF), bleeding, antiplatelet therapy, hypertension, diabetes mellitus, ischaemic stroke, heart failure.

3 Methods

In this section, we outline the methods that permits to address the two aims introduced in the introduction. Let T_i^* be the failure time of subject i $(i = 1,\ldots,n)$ in a cohort of size $n = 290$. We are interested to estimate the true effect of OAT on mortality, denoted by β. Because of censoring, the observed survival time is defined as $T_i = \min(T_i^*, C_i)$, where C_i is the right censoring time and $\delta_i = I(T_i^* \leq C_i)$ is the event indicator, indicating whether the survival or the censoring time is observed.

3.1 The Naive Average Treatment Effect Estimate

To investigate how the problem of treatment bias impacts the estimate of the average OAT effect on mortality for the ESRD data, we first perform a *naive* analysis which ignores the risk of bias due to confounding between the treatment status and covariates using the Cox proportional hazards model [3] in the form

$$h_i(t) = h_0(t)\exp(\beta_o z_i + \alpha_1 x_1 + \alpha_2 x_2 + \cdots + \alpha_9 x_9) \tag{1}$$

where $h_0(t)$ denotes the unspecified baseline hazard, β_o is the log hazard measuring the association between the treatment z_i and the hazard $h_i(t)$, $(x_1, x_2 \ldots, x_9)$ denotes the vector of 9 baseline covariates and $(\alpha_1, \alpha_2, \ldots, \alpha_9)$ denotes their corresponding regression coefficients. The hazard ratio HR $= \exp(\beta_o)$ is interpreted as the relative change in the hazard at any time t for a subject who received OAT relative to a subject in the control group in the presence of confounding covariates.

3.2 Inverse Propensity Score Weighted Treatment Effect

IPSW allows to estimate weights based on propensity score to match the probability distributions of baseline covariates between the treated and control patients. Formally, let $p(x|z = 1)$ be the distribution of a covariate x for the treated patients and $p(x|z = 0)$ be the distribution of x for the control patients. Under RCT, we expect these two distributions be similar. When there is a lack of randomization, IPSW is used to estimate a weight $\omega(x)$ so that $p(x|z = 1) = \omega(x)p(x|z = 0)$. The weight $\omega(x)$ is unknown, and can be estimated by the logistic regression by postulating z_i as the probability of treatment assignment conditional on baseline covariates $x_1 - x_9$. We then obtain the maximum likelihood estimates of $\left(\alpha_1, \ldots, \alpha_9\right)$ and the weight ω is the predicted probability given as

$$\hat{\omega} = \frac{\exp(\hat{\alpha}_1 x_1 + \hat{\alpha}_2 x_2 + \cdots + \hat{\alpha}_9 x_9)}{1 + \exp(\hat{\alpha}_1 x_1 + \hat{\alpha}_2 x_2 + \cdots + \hat{\alpha}_9 x_9)} \tag{2}$$

Then, IPSW adjusted average treatment effect is estimated by $h(t) = h_0(t)\exp(\beta_p z_i)$, where the estimate of β_p represente IPSW adjusted average treatment effect on

mortality and obtained by maximizing the weighted partial likelihood. The estimate of β_p may still be biased due to the misspecification of the ignorability assumption.

3.3 Bias-Correction of the Inverse Propensity Score Weights

To reduce the bias of $\hat{\beta}_p$ due to the misspecification of the IPSW, we now focus on bootstrap bias correction of the IPSW (BC-IPSW). A classic nonparametric iid bootstrap is applied to the original ESRD data. The total number of bootstrap samples was set $B = 2000$ such that the size of each bootstrap sample is equal to that of the ESRD data ($n = 290$). In each bootstrap sample, the treatment effect $\hat{\beta}_p^*$ adjusted by IPSW is replicated.The bias of $\hat{\beta}_p$ as an estimator of the true β is $\text{bias}(\hat{\beta}_p) = E(\hat{\beta}_p) - \beta$. Then a bootstrap estimate for such bias is

$$\widehat{\text{bias}}_B(\hat{\beta}_p) = E(\hat{\beta}_p^*) - \hat{\beta}_p, \quad \text{where} \quad E(\hat{\beta}_p^*) = \frac{1}{B}\sum_{b=1}^{B} \beta_p^*(b) \tag{3}$$

Then, the bias-corrected estimate of β is given by

$$\bar{\beta}_c = \hat{\beta}_p - \widehat{\text{bias}}_B(\hat{\beta}_p) = 2\hat{\beta}_p - \hat{\beta}_p^* \tag{4}$$

4 Simulation Study

We conducted a simulation study to broadely compare the performances of each method. $M = 1000$, each with a sample size of $n = 290$ as in ESRD data, with follow-up time for 4 years ($t = 0, \ldots, 4$). A treatment status was generated from the Bernoulli distribution $z_i \sim \text{Bernoulli}(\hat{p}_i)$, where the probability $\hat{p}_i$ is the propensity score as estimated in (2). The survival time T_i^* was generated by evaluating the proportional hazard model of (1), where the Weibull hazard $h_0(t) = \lambda\rho t^{\rho-1}$ with the rate and shape parameters were $\lambda = 0.1$ and $\rho = 1.4$, respectively. The censoring time C_i was generated according to a uniform distribution in $(0,4)$. For each M simulatation, a BC-IPSW procedure based on $B = 2000$ bootstrap runs has been performed. To evaluate the impact of violating the ignorability assumption (i.e. unaccounted covariate) from the treatment response model, we consider two scenarios as in [1]: a *mild* misspecification, where covariate with weak impact assumed missing, and a *gross* misspecification, where a covariate with strong impact was missing. We summarize the simulation results using quantities such as bias, absolute percentage bias, mean-squared error and the 95% coverage probabilities.

5 Results

We first discuss the estimate of OAT effect on mortality for the ESRD dataset. The estimated hazard ratio (HR) from each method indicated that OAT treatmen has the benefit of reducing mortality as the HRs$<$1, although the impact is different for each method. The HR of 0.90(95% CI:0.60-1.35) from the naive analysis is less than the HR of 0.79(95% CI:0.46-1.16) obtained from IPSW model. This shows that the difference between the hazard of the treated and the control groups is quite small

for the naive case. Further, these two method estimated a statistically non-significant OAT effect, but IPSW produced a narrow 95% confidence interval. The BC-IPSW estimated a HR=0.65(95% CI: 0.42-0.99) which implies a statistically significant effect of OAT on mortality. This HR indicates that the rate of mortality for the OAT treated group decreases by 35% compared with the rate in the control group. Table 1 shows the results of the simulation study with the true $\beta \in (-0.3, 0.4)$, corresponding to the scenarios of a negative and a positive association between treatment and mortality. In both scenarios, the naive method estimated higher bias compared with the biases in the other two approaches. For $\beta = -0.3$, the naive method estimated a percentage bias of 5% and this bias was lowerd to 3.33% when IPSW was used. The BC-IPSW resulted in a further lowered percentage bias of 0.67%. In terms of accuracy, the three approaches were comparable as the MSEs are relatively similar, indicating that the treatment selection bias affects the estimated treatment effect with the impact less pronounced in precision and coverage properties.

Table 1 Results of the simulation study based on naive, IPSW and BC-IPSW, with the true $\beta \in (-0.3, 0.4)$. The shown are estimate, bias, absolute percentage bias (%Bias), Emperical Monte Carlo standard error (ESE), mean squared error (MSE) and 95% coverage probabilities (CP)

True β	Method	Estimate	Bias	%Bias	MSE	ESE	CP
	Naive	-0.315	-0.015	5.000	0.041	0.202	95
-0.3	IPSW	-0.290	0.010	3.333	0.039	0.196	95
	BC-IPSW	-0.298	0.002	0.667	0.041	0.203	95
	Naive	0.417	0.017	4.250	0.035	0.185	96
0.4	IPSW	0.385	-0.015	3.750	0.035	0.185	95
	BC-IPSW	0.403	0.003	0.750	0.033	0.181	96

Table 2 reports misspecification of the ignorability assumption. The impact of the misspecification is clearly observed in the estimates of the IPSW and BC-IPSW. For $\beta = -0.3$, we observe a percentage bias of 11.33% for the IPSW under slight misspecification. This corresponds to an extra 8% bias as compared with the same scenario without misspecification (see, Table 1). The extra bias could be as large as 13% under gross misspecification. When the BC-IPSW is applied, the percentage bias was reduced to 5% and 7.33% for the mild and gross misspecifications, respectively. A similar bias reducing performance was observed for $\beta = 0.4$.

6 Discussion

We presented a bootstrap based bias correction mechanism when treatment effect is estimated via inverse propensity score weights (BC-IPSW) for observational studies. Application of the method on a real ESRD data indicated an improved estimate of the OAT effect, in which the benefit of OAT implied by a statistically significant reduction of mortality for patients receiving the treatment. We showed, by the simulation study, the BC-IPSW performs well in correcting biases due to model misspecifications. When the misspecification is due to failure of the ignorability

Table 2 Simulation results under the gnorability assumption misspecification. The shown are bias, absolute percentage bias (%Bias), mean squared error (MSE) and 95% coverage probabilities (CP).

		slight misspecification				gross misspecification			
β	Method	Bias	%Bias	MSE	CP	Bias	%Bias	MSE	CP
	Naive	-0.015	5.000	0.041	95	-0.015	5.000	0.041	95
-0.3	IPSW	0.034	11.333	0.038	95	0.049	16.333	0.040	93
	BC-IPSW	0.015	5.000	0.040	95	0.022	7.333	0.040	94
	Naive	0.012	3.000	0.038	93	0.012	3.000	0.038	93
0.4	IPSW	0.035	8.750	0.036	94	0.059	14.750	0.036	93
	BC-IPSW	0.019	4.750	0.036	96	0.055	13.750	0.036	94

assumption, the BC-IPSW method substantially reduces the bias. This is apparent when the misspecification is due to missing a weak covariate from the treatment response model. In the event of a gross misspecification, the BC-IPSW never provided estimates that are less biased than the estimate obtained by the naive analysis.

Combining multiple sources to overcome misclassification bias in epidemiological database studies

Integrazione di fonti diverse per correggere la distorsione da errata classificazione negli studi epidemiologici su basi di dati

Francesca Beraldi, Rosa Gini, Emanuela Dreassi, Leonardo Grilli and Carla Rampichini

Abstract In epidemiological database studies, the true value of the outcome of interest is unknown, and it is measured with error through indicators implemented by appropriate algorithms. Differential misclassification of the study outcome over the exposure groups may severely bias the results of database studies. In this work, we address misclassification bias by proposing an estimator of the risk ratio that exploits two indicators from different sources: a main indicator with high Positive Predictive Value (PPV) and an auxiliary indicator with high sensitivity. We also develop a bootstrap test for differential sensitivity. We conduct a simulation study to explore the properties of the proposed methods under multiple scenarios.

Abstract *Negli studi epidemiologici su basi di dati il vero valore della variabile di risultato non è noto, ma è misurato con errore attraverso indicatori implementati da opportuni algoritmi. In questo contesto, se l'errore di misura è differenziale per strati di esposizione si possono produrre distorsioni rilevanti. Proponiamo di risolvere il problema dell'errore di classificazione differenziale tramite uno stimatore del rapporto tra rischi basato su due indicatori derivati da fonti diverse: un indicatore principale con un alto valore predittivo positivo (PPV) e un indicatore ausiliario con alta sensibilità. Sviluppiamo, inoltre, un test bootstrap per la sensibilità differenziale. Le proprietà dei metodi proposti sono valutate in vari scenari tramite uno studio di simulazione.*

Key words: bootstrap test, risk ratio, measurement error, validity indices

1 Background

One of the major aims of epidemiology is to assess the relationship between an exposure E and an outcome Y. Here we assume that both the exposure and the outcome are binary and we focus on estimating the *risk ratio* $RR_Y = \pi^E/\pi^{\overline{E}}$, where $\pi^E = Pr(Y = 1|E = 1)$ and $\pi^{\overline{E}} = Pr(Y = 1|E = 0)$. In database studies, E and Y are measured with error by means of indicators derived through specific algorithms from archives that are typically designed for other purposes. Here we assume that E is known without error, whereas Y is measured with error by an indicator M_Y. Therefore, the observed risk ratio based on M_Y, denoted with RR_{M_Y}, is different from the true risk ratio RR_Y. The bias of the observed risk ratio depends on the validity indices: sensitivity $SE = Pr(M_Y = 1|Y = 1)$; specificity $SP = Pr(M_Y = 0|Y = 0)$; positive predictive value $PPV = Pr(Y = 1|M_Y = 1)$; negative predictive value $NPV = Pr(Y = 0|M_Y = 0)$. Each validity index can be defined with respect to an exposure group: for example, $SE^{\overline{E}} = Pr(M_Y = 1|Y = 1, E = 0)$ is the sensitivity for non-exposed individuals. The misclassification error is said to be *non-differential* if it does not depend on the exposure group, namely if $SE^E = SE^{\overline{E}}$ and $SP^E = SP^{\overline{E}}$.

The relationship between the true risk ratio and the observed risk ratio [1] is

$$RR_Y = RR_{M_Y} \frac{PPV^E}{PPV^{\overline{E}}} \frac{SE^{\overline{E}}}{SE^E} \tag{1}$$

The common approach to overcome the measurement error problem is to assume that the sensitivity is non-differential across exposure groups ($SE^E = SE^{\overline{E}}$), so that the last factor in equation (1) disappears. This assumption is motivated by the large sample sizes usually needed to estimate the sensitivities. Then the naif approach is to assume that the PPV is the same in the two exposure groups, so that $RR_Y = RR_{M_Y}$. Typically, to justify this assumption, the current practice is to search for an indicator with PPV=1, which is hard to achieve; moreover, an indicator with high PPV is more likely to have differential sensitivity, thus increasing the bias of the risk ratio. Therefore, a better approach is to devise a validation study to estimate the PPV in the two exposure groups in order to adjust the observed risk ratio [2]. We refer to this procedure as the *single-indicator strategy*. Note that this strategy rests on the assumption of non-differential sensitivity, which is not tested in current epidemiological practice. Unfortunately, differential sensitivity is plausible in many settings. For example, in safety studies persons exposed to a drug with a suspect adverse outcome may be more easily diagnosed and recorded, and thus correctly classified by a specific indicator.

2 Proposed strategy

In database studies, there usually are several possible indicators. Let us consider a situation where the set of available indicators includes a *main indicator A* with high PPV and an auxiliary indicator B with high sensitivity. The role of the auxiliary indicator is to define a *composite indicator* $A \cup B$ to be exploited for estimating the risk ratio. To this end, the auxiliary indicator B should have high sensitivity so that the composite indicator $A \cup B$ has sensitivity equal to 1. In fact, the prevalence in a given exposure group $g \in \{E, \overline{E}\}$ can be written as

$$\pi^g = \frac{P_A^g PPV_A^g + P_B^g PPV_B^g - P_{A\cap B}^g PPV_{A\cap B}^g}{SE_{A\cup B}^g} \tag{2}$$

where $P_{M_Y}^g$ is the proportion of cases with $M_Y = 1$ in group g (observed prevalence), which is always available. We assume that the composite indicator has unit sensitivity ($SE_{A\cup B} = 1$), which can be attained by appropriately choosing the auxiliary indicator B. Under this assumption, the only unknown quantities in equation (2) are the PPVs, which can be estimated from validation studies on A and B. Then we make the simplifying assumption that A and B have no intersection ($A \cap B = \emptyset$), so equation (2) reduces to $\pi^g = P_A^g PPV_A^g + P_B^g PPV_B^g$. The ratio of the estimates of π^E and $\pi^{\overline{E}}$ is the proposed estimate of the risk ratio. We refer to this procedure as the *multiple-indicator strategy* or *component strategy*. This strategy directly estimates the risk ratio instead of trying to remove the bias using equation (1). The advantage is to avoid the assumption of non-differential sensitivity; the drawback is the need to estimate the PPV of the auxiliary indicator B in addition to the PPV of the main indicator A, implying a loss of accuracy in the estimation of the risk ratio.

The choice between the single-indicator strategy and the multiple-indicator strategy should be based on whether the sensitivities of A are equal across the exposure groups, namely whether the hypothesis $H_0 : SE_A^E = SE_A^{\overline{E}}$ is true. Therefore, we build a test for this hypothesis, which we show to be equivalent to

$$H_0 : \frac{P_B^E PPV_B^E}{P_A^E PPV_A^E} - \frac{P_B^{\overline{E}} PPV_B^{\overline{E}}}{P_A^{\overline{E}} PPV_A^{\overline{E}}} = 0 \tag{3}$$

In this setting, the multiple-indicator strategy with indicators A and B is not used for direct estimation of the risk ratio, but it is exploited to test the assumption of non-differential sensitivity, which is crucial for an effective adjustment of the bias in the single-indicator approach. The test statistic is obtained by replacing the values of PPV in equation (3) with the estimates from validation studies. The sampling distribution is intractable, thus we build a bootstrap test. Specifically, we take 1000 bootstrap samples from the validation sample of A and similarly for B, then we compute the 95% percentile confidence interval for the test statistic and reject the null hypothesis when the interval does not contain zero.

3 Simulation study

We devise a simulation study to evaluate the performance of two competing strategies: use the main indicator A to compute the observed risk ratio, then adjust it with the PPV of A in the exposure groups, under the assumption of non-differential sensitivity (RR1, *single-indicator strategy*); exploit the auxiliary indicator B to construct the composite indicator $A \cup B$, which allows to estimate the risk ratio without assuming non-differential sensitivity (RR2, *multiple-indicator strategy*).

In the simulation study we generate a population of $N = 10000$ individuals, with a proportion of exposed equal to 0.2, and prevalences set to $\pi^E = 0.10$ and $\pi^{\overline{E}} = 0.05$. We consider two indicators such that $SE_{A\cup B} = 1$ and $A \cap B = \emptyset$, with the following specificities: $SP_A^E = 0.95$, $SP_A^{\overline{E}} = 0.90$, $SP_B^E = 0.20$, $SP_B^{\overline{E}} = 0.15$. For the main indicator A we devise two scenarios: *a*) non-differential sensitivity with $SE_A^E = SE_A^{\overline{E}} = 0.40$; *b*) differential sensitivity with $SE_A^E = 0.80$ and $SE_A^{\overline{E}} = 0.45$. The sensitivities of B derive from the previous values. Finally, the PPVs are estimated with validation samples of size n_A and n_B, which are initially set to 100 and then increased.

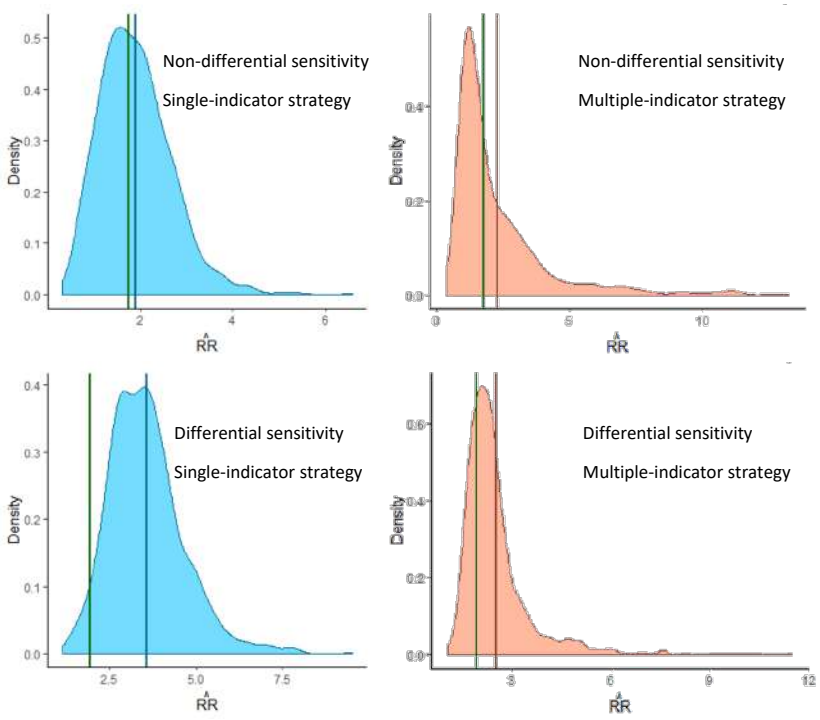

Fig. 1 Kernel density plots of the Monte Carlo distributions of the competing estimators of the RR under the two scenarios. Green vertical line: true value; other vertical line: Monte Carlo mean. PPVs estimated with validation samples of size $n_A = n_B = 100$.

We evaluate the performance of the competing approaches RR1 and RR2 through the Monte Carlo sampling distributions obtained by repeating 1000 times the extraction of the validation samples. Figure 1 reports kernel density plots of the Monte Carlo distributions of the competing estimators of the RR under the two scenarios.

The simulation results are in line with our expectation: in scenarios where the assumption of non-differential sensitivity is violated, the multiple-indicator strategy works well and it is clearly superior to the single-indicator strategy. On the other hand, under non-differential sensitivity the single-indicator strategy is preferable due to a lower variability, even if this is relevant only for small validation studies: in fact, the variances of the two estimators RR1 and RR2 become similar with larger validation studies (e.g. $n_A = 200$ and $n_B = 500$). In the simulation study we also evaluate the proposed bootstrap test for non-differential sensitivity ($H_0 : SE_A^E = SE_A^{\overline{E}}$). It turns out that the test works properly, but the power is low (about 0.5) with validation studies of size $n_A = 100$ and $n_B = 100$. In order to achieve a power of 0.8 the required sizes are $n_A = 200$ and $n_B = 500$, which are higher than the sizes usually adopted in validation studies.

Deep Sparse Autoencoder-based Feature Selection for SNPs Validation in Prostate Cancer Radiogenomics

Selezione Variabili tramite Deep Sparse Autoencoders per validazione di SNPs in Radiogenomica del Cancro alla Prostata

Michela Carlotta Massi[1,2], Francesca Ieva[1,2,3], Anna Maria Paganoni[1,2,3], Andrea Manzoni[1], Paolo Zunino[1], Nicola Rares Franco[1], Tiziana Rancati[4], and Catharine West[5,6]

Abstract Prostate cancer is the most diffused cancer affecting the male population. As therapies improve their effectiveness, surviving patients might be affected by complications induced by radiotherapy in the long run. To predict the onset of such rare late toxicities, because of the failure of phenotypic characteristics, the attention is shifting towards identifying specific genetic locations (Single Nucleotide Polimorphisms, or SNPs) associated with them. Because of the complexity of the problem, SNPs identified in a study are rarely validated on a different cohort of patients. In this case study we apply a novel approach for feature selection (namely a Deep Sparse Autoencoder-based Feature Selection method), to validate SNPs associated with radiotherapy-induced late toxicity causing urinary frequency variation (UFV).

Abstract *Il cancro alla prostata è il più diffuso tra la popolazione maschile. Nonostante il miglioramento nei trattamenti, i pazienti comunque essere affetti da complicazioni indotte dalla radioterapia nel lungo periodo. Per predire l'emergere di queste rare tossicità tardive, visto il fallimento nell'utilizzare caratteristiche fenotipiche dei pazienti, l'attenzione si sta spostando sull'identificare loci genetici (SNPs) a loro associate. Per la complessità del problema, le SNP individuate in uno studio sono raramente validate su una coorte differente di pazienti. In questo caso studio applichiamo un nuovo metodo di selezione delle variabili (un metodo basato su Deep Sparse Autoencoders), per validare le SNPs associate con la variazione tardiva della frequenza urinaria.*

1 Introduction

Prostate cancer is the most diffused cancer affecting the male population in Europe. According to the American Cancer Society, about 1 american man in 9 will be diagnosed with prostate cancer during his lifetime. Because of the recent advancements in treatments, survival rates are high, but patients might suffer from debilitating complications resulting from therapies in the long run (radio-therapy induced late toxicity) [1, 2].

Traditional methods based on patients' phenotypic characteristics and treatment details fail in stratifying the treated population and in predicting the onset of such negative, but still very rare, side-effects. For this reason, the attention is shifting towards investigating possible relations between the genotype and the adverse outcomes in the so called 'precision medicine' approach, driving the need for novel statistical methods to address this question.

This case study was conducted with the support of Fondazione IRCSS Istituto Nazionale dei Tumori, the Italian National Cancer Research Institute, that provided us with data regarding the REQUITE [3] cohort of prostate cancer patients, with the aim of validating some specific genetic markers (in the form of Single Nucleotide Polymorphisms, SNPs) that could be predictive for late toxicity. The identification and validation of predictive biomarkers is an objective of paramount importance in a setting such as Genome-Wide Association Studies (GWAS), as the complexity of the problem, the rarity of the *traits* (or negative outcome) and the numerosity of the genetic traits to evaluate makes it extremely complex and rare for different studies to recognize similar patterns in data.

In this short paper we present a novel approach to SNPs validation, exploiting a Deep Sparse Autoencoder-based (DSAE) feature selection method to identify relevant SNPs associated with radiotherapy-induced late Urinary Frequency Variation (UFV). The task at hand requires us to identify predictive features for an extremely small minority class in a setting characterized by complex non-linear interactions among genetic loci, small sample size, several confounding factors, noisy data and the need for results interpretability to drive real clinical research.

For this reason, the work presented in this study exploits a feature selection method tailored to identify relevant features to discriminate the minority class from the majority class, and improve minority class classification accuracy. The adopted methodology for this case study was developed in a previous work in [4], where a detailed description of the algorithm can be found. For this reason, in Section 2 we will provide only a brief description of the main concepts, while the rest of the paper will be devoted to the case study.

The benefits of this Deep Learning (DL) model for our objective are several: it is a non-linear and stratified model, allowing to learn complex and hyerarchical relationships in data; additionally, the model deals well with large numbers of features, and has the capability of autonomously ignore noise.

2 Methods

Deep Sparse AutoEncoders (DSAE). An AutoEncoder (AE) is a neural network whose output provides a reconstruction of the input (Hinton and Salakhutdinov, 2006). The network can be seen as constituted by two parts: an encoder and a decoder.

The encoder function $\mathbf{h}_i = f(\mathbf{W}\mathbf{x}_i + b)$, encodes each input vector $\mathbf{x}_i$ into an encoded version of itself of size H. Here $f : \mathrm{R}^{\mathrm{J}} \rightarrow \mathbb{R}^{\mathrm{H}}$ is usually non-linear, $\mathbf{W}_{H\times J}$ is called *weight matrix* and $\mathbf{b}$ is an H-dimensional *bias* vector.

The decoder maps back the encoded vector to the J-dimensional space in most cases using a squashing non-linear function $\hat{\mathbf{x}}_i = g(\mathbf{W}'\mathbf{h}_\mathbf{i} + \mathbf{b}')$, $g : \mathbb{R}^{\mathrm{H}} \rightarrow \mathbb{R}^{\mathrm{J}}$ with parameters $\mathbf{W}'$ and $\mathbf{b}'$. The model is trained through gradient descent of the loss function $L(\mathbf{x}, \hat{\mathbf{x}})$; where L is typically the Mean Squared Reconstruction Error (RE), i.e. the mean squared Euclidean distance between the input values and the reconstructed values for each observation.

To force the model to learn more useful representaitons of the input data, one approach is to force sparsity in the central hidden layer. A sparse representation can be obtained adding a penalty term that penalizes the L_1 norm of the vector $\mathbf{h}_i^{(l)}$ of activation of the hidden nodes (where (l) indicates the layer the hidden nodes belong to, and it should be considered the most internal layer in case of a Deep AE), for each observation i, controlled by the parameter λ, i.e.:

$$L_i = L(\mathbf{x}_i, \hat{\mathbf{x}}_i) + \lambda |\mathbf{h}_i^{(l)}|. \tag{1}$$

The parameter λ can be optimized through grid search or can be arbitrarily chosen in the design phase of the model.

DSAE for Minority Class Feature Selection. The main idea behind the choice of a DSAE as a mean to perform feature selection is that the model trained to reconstruct *normal* observations only (majority class, or *healthy* patients) would make higher errors by trying to reconstruct anomalous patterns in *outliers* (minority class, or *unhealthy* patients showing late toxicity). Indeed, it is on the analysis of the average RE performed by the model on each feature for each class that we identify those that could discriminate better between the two classes. A detailed description of the proposed methodology can be found in our previous work [4]. In Figure 1 we propose a schema of the algorithm after the trained DSAE is tested on both healthy and unhealthy patients. Note that as a result the algorithm provides a subset of features which dimension depends on a parameter ($\delta \in [0,1]$) set by the user: the closer the δ value is to 1, the smaller the subset.

3 Urinary Frequency: Case Study Setting

From the original dataset, we selected a cohort of 1,296 patient, among which 55 (4.2%) belonged to the class of *cases* (y=1, i.e. the patients reported radiotherapy-induced late UVF), while 1241 (95.8%) belonged to the *controls*'s class. Each pa-

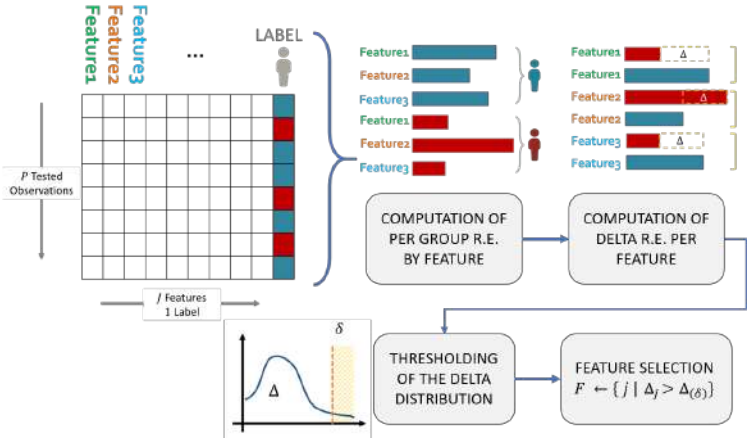

Fig. 1 Schema of the proposed algorithm: after training the DSAE on healthy patients only, the model is supplied with a test set composed of healthy and unhealthy patients. The passages in this schema depict all the steps from the collection of the RE to the feature selection based on δ. More details can be found in [4].

tient was characterized by 43 genetic traits (SNPs), among which 9 were identified in previous studies as predictive biomarkers for this endpoint. In Table 1 we list the biomarkers to validate. The unbalancing of the classes and the complexity of the problem (there potentially exist complex non-linear relations among biomarkers affecting the outcome [6]) makes this field of application an interesting fit for the peculiarities and potentials of our proposed model [4]. We performed the training and testing of the DSAE 50 times, extracting from the 1,296 the training set (1,186 observations, i.e. all *controls* except the 55 included in the test set) and test set (110 observations, half *cases* and half *controls*). The algorithm was implemented in Python. The DSAE had one input layer with 43 nodes, and three encoding hidden layers (with 40, 30 and 20 nodes respectively), followed by three decoding layers (30, 40, 43 nodes respectively). The training of each DSAE was performed for 400 hundred epochs, with a batch size of 10 observations, and the whole procedure of sampling, training and testing took on average (over the 50 repetitions) 3.22 minutes to complete. Note that the training time of the whole algorithm highly depends on the number of repetitions of sampling and training, and could be highly reduced in case less repetitions are needed to capture the most relevant variations between the two classes, or the number of minority class observations is sufficiently large to require a smaller number of sampling procedures on the healthy

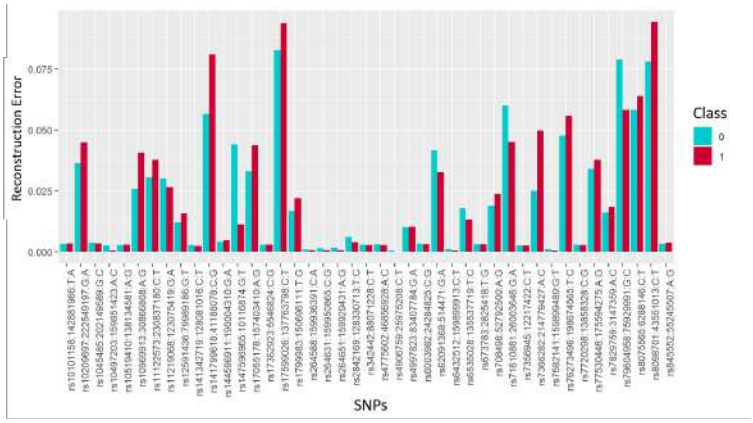

Fig. 2 Reconstruction Error by SNP and by Group (cases in red and controls in blue)

population to guarantee a robust comparison.
Once the AE was trained to reconstruct the training set of the healthy population, the test set (composed of healthy and unhealthy observations) was supplied to the model, collecting the Reconstruction Error (RE).
As in the process depicted in Figure 1, we obtained a matrix where each patient (row) that belonged to the test set at least once was associated with an outcome and a set of REs for each feature (SNP). This allowed us to group patients w.r.t. the enpoint, and estimate the average RE for each SNP for *cases* and *controls*.

4 Results

In Figure 2 we report the results of the procedure just described. The bars in the barplot represent the reconstruction error for each group (cases in red, controls in blue). On the x-axis one can read all the 43 SNPS, each one with two associated bars. To validate the SNPs in a robust way, we selected different values for the δ threshold (δ equal to 0.75, 0.8, 0.85 and 0.9). In Table 2 are reported the 9 SNPs previously identified in literature (already mentioned in Table 1) as predictive for the onset of late UFV after radiotherapy. As shown in Table 2, for δ=0.75 the model identifies as relevant (thus validating) 4 out of 9 SNPs coming from literature. Interestingly, the four identified SNPs present the highest odds ratio w.r.t. the outcome, according to the study that first mentioned them. Note that the study in [5] was performed on a different cohort of patients. The fact that the identified SNPs are those most evidently related to the outcome on different data is both a proof of our methodology to identify the most discriminative features, and of the generalizability of its results. Unfortunately, we do not have access to the data from the mentioned study to cross-validate our method on that cohort. Another notable aspect of our results, is that the four identified SNPs remain relevant almost for all δ values, except for one that is excluded after the last threshold (0.9).

5 Conclusion

In this paper we presented a novel approach to SNPs validation through the use of a DSAE-based feature selection method to select relevant minority class features. We applied the methodology to a case study that required us to validate SNPs previously identified in literature as predictive for the onset of radiotherapy-induced late UFV. Despite the complex unsupervised setting does not allow us to compare our results with a *ground truth*, the robustness of the identified SNPs and the height of the Odds Ratio associated to them on another cohort of patients support our results.
Using a DL approach in a GWAS seems therefore to be a viable strategy to tackle the peculiar complexities of this setting, and opens the venue for relevant future research.

Graphical models for count data: an application to single-cell RNA sequencing

Modelli grafici per dati di conteggio: un'applicazione a dati di RNA a singola cellula

Nguyen Thi Kim Hue, Monica Chiogna, and Davide Risso

Abstract Biological processes involve complex interactions between genes. Such interactions may be represented employing a conditional independence graph. Here, we propose the use of a PC-stable algorithm to estimate the neighbourhood of each node in the graph, thus learning its structure. We apply our algorithm to two single-cell RNA sequencing datasets, demonstrating that we can identify important genes as hub nodes in the networks.

Abstract *Molti processi biologici sono caratterizzati da complesse interazioni tra geni. Queste interazioni possono essere rappresentate da un grafo di indipendenza condizionale. In questo lavoro proponiamo un algoritmo PC-stable per la stima della struttura del grafo. Applichiamo l'algoritmo proposto a due dataset di sequenziamento di RNA a singola cellula, dimostrando la sua abilità nel trovare geni importanti come nodi hub della rete.*

timation of the structure of such graphs from observed data is, generally speaking, a challenging task. State-of-the-art inference procedures assume that the data arise from a multivariate Gaussian distribution. However, high-throughput omics data, such as that from next generation sequencing, often violate this assumption. Such violations are particularly evident in single-cell RNA sequencing (RNA-seq), a technology that has enabled researchers to sequence the RNA of individual cells. In contrast to established sequencing techniques, which require the aggregation of thousands of cells, single-cell RNA-seq permits the study of gene expression at single cell resolution, allowing researchers to answer previously inaccessible questions (e.g., how stem cells develop into mature cells [1]). The resulting data are discrete, usually highly skewed, possibly zero inflated. In these contexts, the assumption of normality is far from being met.

In order to accommodate the distributional features observed in single cell gene expression, McDavid et al (2019) [2] proposed a Hurdle model, equivalent to a finite mixture of singular Gaussian distributions. The interesting aspect of the Authors' proposal is the possibility of accounting for zero-inflation. Nevertheless, a continuity of the data is still implicitly assumed.

In this work, we propose an algorithm for learning the structure of graphs for count data. The algorithm exploits an iterative testing procedure, which can easily account for sparsity of the data. A biological validation of the algorithm, performed by applying it to two case studies, shows its abilities to retrieve biologically relevant information.

2 Our proposal

A probabilistic graphical model requires the definition of a pair, $(G, \mathscr{F})$ say. Here, $G = (V, E)$ represents an undirected graph, where V is the set of nodes, and $E = \{(v,t) : v \neq t\}$ represents the set of undirected edges. Moreover, $\mathscr{F}$ represents a family of probability measures for the random vector X_V, indexed by the set V, on the sample space $\mathscr{X}_V$. Each node in the graph corresponds to a random variable $X_v, v \in V$; the existence of an edge (v,t), $v,t \in V$, indicates the dependency of the random variables X_v and X_t.

In conditional independence graphs, a connection is established between the graph G and a set of independence assumptions for the variables in X_V. The local Markov property assures that a variable X_v depends on the other variables only through its neighbors. This connection opens to the possibility of factorizing members of $\mathscr{F}$ over the graph G.

Here, we assume that the distribution of each variable X_v, conditional to all possible subsets of variables in $V \setminus v$, is a Poisson distribution:

$$X_v | x_{K\setminus\{v\}} \sim P\big(\exp\big\{\sum_{t\in K\setminus\{v\}} \theta_{vt|K} x_t\big\}\big), \quad \forall v \in K \subset \{1,\ldots,p\}, \tag{1}$$

A missing edge between node v and node t corresponds to the condition $\theta_{vt} = \theta_{tv} = 0$. On the other hand, one edge between node v and node t implies $\theta_{vt} \neq 0$ and $\theta_{tv} \neq 0$.

A conditional independence graph $G = (V, E)$ on X_V can be estimated by estimating, for each node $v \in V$, its neighborhood. Hence, one can proceed by estimating the conditional distribution of $X_v | X_{V \setminus v}$ and fixing the neighbourhood of v to be the index set of variables X_w on which the conditional distribution depends.

To estimate the neighbourhood of each node, we employ the PC-stable algorithm, a variant of the PC algorithm first proposed by [3]. The PC algorithm starts with a complete graph on V. Marginal independences for all pairs of nodes are tested, and edges removed when marginal independences are found. Then, for every pair of linked nodes, independence is tested conditional to all subsets of cardinality one of the adjacency sets of the two nodes. This testing procedure is iterated, increasing in turn the size of the conditioning sets, until this reaches its maximum limit, or a limit imposed by the user. Reasons for choosing the PC algorithm are many, spanning from its consistency (assuming no latent confounders) under i.i.d. sampling [3], to its ability to deal with a large number of variables and only moderately large sample sizes. The variant that we employ, PC-stable [4], allows to control instabilities due to the order in which the conditional independence tests are performed. To perform the tests, Wald-type test statistics are employed, for which a normal asymptotic distribution can be obtained by standard asymptotic theory (for details, we refer readers to [5]).

The chosen learning strategy has some advantages over alternative approaches based on sparse regressions (see [5]). Sparsity can be easily implemented by a control on the conditional set size, instead of a control on parameter magnitudes, which can lead to over-shrinkage. Moreover, it offers computational advantages, especially when sparse networks are the target of inference. Finally, hypothesis testing is scale-invariant, i.e., is not affected by scale transformations of regressors. For a discussion of convergence of the algorithm in the Poisson setting, see [5].

3 Single-cell RNA sequencing: two case studies

We consider two sets of single cell RNA-seq data, from the same biological system, but with two different technologies, with a particular focus on the transcription factor (TF) genes of the neuronal and sustentacular cell lineages. The first dataset, called `data1`, obtained using the Fluidigm C1 system, consists of 634 cells and 850 TF genes. The second, called `data2`, obtained using the 10X Genomics platform, consists of 634 cells and 877 TF genes. As measurements of both data were zero-inflated and highly skewed, standard preprocessing was applied to the data (see [5, 6]). In particular, we selected the top 20% variables with the highest mean; normalized the data by 75% quantile matching; selected the top 50% most variable genes across the data; and used a power transform X^{α} (with $\alpha = 0.219$ for the first data;

and $\alpha = 0.5$ for the second data). The distributions of the normalized data in the two datasets for four representative genes are shown in Figure 1.

4 Results

The biological system under study is the mouse olfactory epithelium (OE), which is often employed to study tissue regeneration by adult stem cells. Following an injury, OE stem cells generate, through a series of intermediate states, olfactory neurons and sustentacular cells, following two distinct developmental lineages, called the neuronal lineage and the sustentacular lineage, respectively [1]. We applied our algorithm to both groups individually (i.e., considering the neuronal lineage and sustantacular cell lineage separately), and to all data at once.

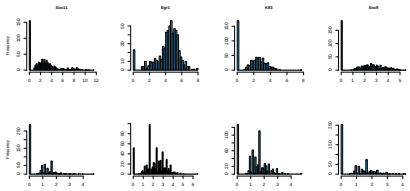

Fig. 1: Distribution of RNA-Seq read counts for four genes: `data1` (top), `data2` (bottom).

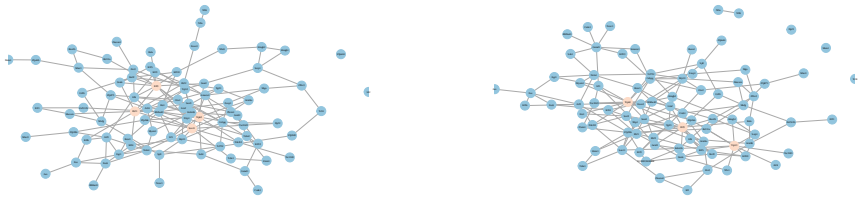
Figure 2 shows the networks estimated using our algorithm at a significance level of 5% on `data1` for each lineage. In the neuronal lineage, the TF genes Sox11, Ebf1, Elf3, and Trp63 are hub nodes (i.e., nodes with at least 9 edges). All these genes are known to be important in neurogenesis or stem cell differentiation. For instance, Tpr63 is a gene essential to maintain the quiescent state of stem cells. In fact, by knocking out this gene stem cells will differentiate into mature cell types [1].



(a) Neuronal lineage

(b) Sustentacular cell lineage

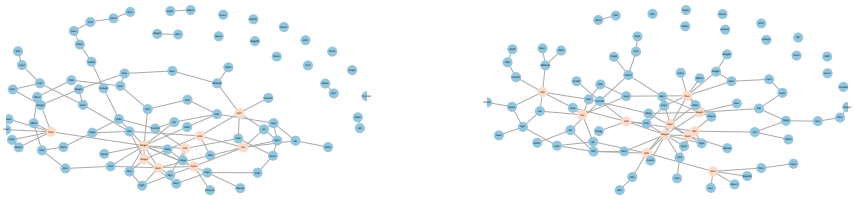
Fig. 2: Olfactory gene networks estimated by our algorithm on `data1` (hub nodes coloured orange).

For the sustantacular cell lineage, three hub nodes are identified: Trp53, Elf3, Trp63 (see Figure 2b). In addition to Trp63 (discussed above), the identification of Elf3 is of note: while there is no specific indication in the literature that it plays

an important role in the olfactory epithelium, this gene is known to be important in other epithelial systems [7] and is a good candidate for follow up studies.

The networks estimated from `data2` are showed in Figure 3. Here, we identified nine hub nodes (i.e., nodes with at least 5 edges) in the neuronal lineage: Ybx1, Hmga1, Hmga2, Fos11, Atf5, Klf4, Trp53, Fos, Atf3 (see Figure 3a); and eleven hub nodes in the sustantacular cell lineage: Ybx1, Hmga1, Hmga2, Fos, Atf3, Xbp1, Myc, Elf5, Sox2 (see Figure 3b).

Again, many of these genes are known in the field to be important (some of which in common with `data1`). For instance, Klf4 is expressed in neural stem cells and controls axonal regeneration [8]. Moreover, Sox2 is essential for maintaining the self-renewal property of stem cells [9]. It is interesting to note that, for each dataset, gene networks obtained from different lineage trajectories are consistent, i.e., many common interactions between two TF genes are found by applying the algorithm to each group individually.



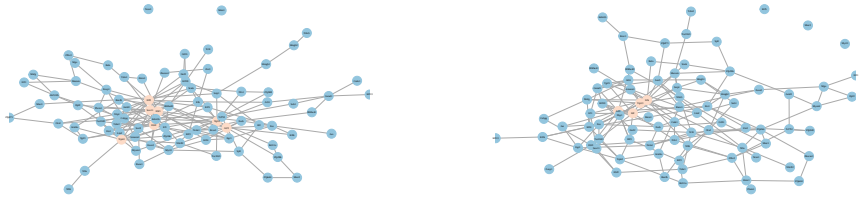
(a) Neuronal lineage (b) Sustentacular cell lineage

Fig. 3: Olfactory gene networks estimated by our algorithm on `data2` (hub nodes coloured orange).

We then applied our approach to each full dataset (the two lineages together). Figure 4a shows that, for `data1`, the network obtained in this way is consistent with the networks obtained from each lineage separately. However, this is not the case for `data2`. An explanation for this could be the `data2` contains more zeros, due to the nature of the platform (see Figure 1). Hence, our algorithm based on a Poisson model is less accurate in this case.

5 Discussion

In our work, we have inferred gene networks from two OE datasets using a PC-like algorithm. However, structure learning of graphical models for single cell gene expression is difficult due to the lack of detectable expression of many genes, giving rise to zero-inflated expression patterns. In the joint analysis of `data2`, our algorithm was unable to reconstruct the full network possibly because of zero inflation, which the Poisson is not able to model. The Poisson assumption limits the poten-



(a) `data1` (b) `data2`

Fig. 4: Olfactory gene networks estimated by our algorithm on `data1` and `data2` (hub nodes coloured orange).

tial of principled graphical modelling in various applications. Future work can thus focus on developing new algorithms using different distributions that are more sensitive to zero-inflation and overdispersion, such as the zero-inflated Poisson or the (zero-inflated) negative binomial.

Interregional mobility, socio-economic inequality and mortality among cancer patients

Mobilità inter-regionale, disuguaglianze socio-economiche e mortalità in pazienti oncologici

Claudio Rubino, Mauro Ferrante, Antonino Abbruzzo, Giovanna Fantaci, Salvatore Scondotto

Abstract This paper investigates 3-years mortality after discharge in patients residing in Sicily (Italy) diagnosed with cancer among: colon, stomach, liver, and lungs, between 1/1/2010 - 31/12/2011. The effect of mobility and socio-economic status on mortality is evaluated through survival analysis approach. Results shows that out-of-region hospitalization is associated with higher survival time; no association of mortality with socio-economic status appears. The extent of patients' mobility, and its relation with mortality raises regional policy considerations.

1 Introduction

Interregional mobility is a relevant phenomenon, due to its implications under the financial and the equity perspective. In publicly funded healthcare systems covering the whole population, patients are able to choose any hospital that best meets their needs. In these systems, since tariffs are generally fixed at the national level, patient mobility can act as a stimulus for hospital competition [1]. However, it can be also an issue for the patient that has to look out of her region to receive better quality of care [8]. Especially in case of severe health needs, patients' mobility might indicates a threat to equity in the healthcare system at the country level [2].

In Italy the phenomenon is remarkable: out-region hospitalizations are almost 1 over 10, involving about 730 thousands patients in 2018 [9]. The greatest pattern of patient mobility involves southern regions, thereby generating additional amounts of financial flows in favor of central–northern regions [3]. Previous studies [7] have shown an impact of socioeconomic inequality on interregional mobility, with a a highest propensity for being hospitalized outside the region among people residing in less deprived areas compared to those living in areas with highest deprivation. In the current analysis, patient-level data regarding in- and out-region hospitalizations in cancer patients residing in Sicily (Italy) are used to evaluate 3-year mortality. The analysis is performed by considering four different cancer sites, namely: stomach, colon, liver, and lungs.

2 Data and Methods

In this study, patient-level data on hospital discharge records (SDO) of patients residing in Sicily were made available from the Epidemiology Department of Sicily Region. The analysis included all people residing in Sicily who had been diagnosed with one of four selected cancer site, among: stomach (ICD-9-CM: 151), colon (ICD-9-CM: 153, 154, or 1590), liver and intrahepatic bile ducts (ICD-9-CM: 155, 156), trachea bronchus and lung (ICD-9-CM: 162), hospitalized in and beyond Sicily between 1 January 2010 - 31 December 2012. Further selection criteria were that patients had not been hospitalized for cancer in the previous seven years, and that each patient had only one type of cancer. SDO dataset was used also to determine whether the hospitalization occurred in- or out-region, as well as other patient-level characteristics, including gender, age, and Charlson comorbidity index [5]. Information on mortality was derived from the Regional register of causes of death (ReNCaM). Finally, the availability of information on the census tract of residence for those patients residing in municipalities with more than 10,000 inhabitants, allowed for the inclusion of the deprivation index [4] of the census tract of residence. The cohort under analysis comprises 8937 incident episodes of hospitalization of patients with a diagnosis of colon ($n = 3912$), liver and intrahepatic bile ducts ($n = 1483$), stomach ($n = 787$), and trachea, bronchus and lung ($n = 2755$). The phenomenon of interregional mobility concerned approximately 5.5% of the

patients under investigation, and it ranges from a minimum of 5.1% for colon, to a maximum of 6% for trachea, bronchus and lung. 3-years mortality is approximately 55.7%, and it ranges from 34.4% for colon to 76.3% for trachea, bronchus and lung.

Four separate Cox models [6] (one for each cancer site) have been estimated to evaluate the effect of several risk factors (reported in Table 1) on the survival time. It is worth noting that, given the multilevel structure of the socioeconomic status, the inclusion of random effects were initially considered. However, the census tract of residence did not proved to be a relevant source of heterogeneity with respect to survival time; therefore, the simpler non RE model was finally considered. The Cox model allows us to examine how specified factors influence the rate of a particular event happening (e.g., survival time for patients with stomach cancer) at a particular point in time. This rate is commonly referred as the hazard rate. The Cox model is expressed by the hazard function denoted by $h(t)$:

$$h(t) = h_0(t) \times \exp(\beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_p x_p) \tag{1}$$

where t represents the survival time, $h(t)$ is the hazard function determined by a set of p covariates $(x_1, x_2, \ldots, x_p)$, the coefficients $(\beta_1, \beta_2, \ldots, \beta_p)$ measure the impact (i.e., the effect size) of covariates. The hazard function can be interpreted as the risk of dying at time t. The term h_0 is called the baseline hazard. It corresponds to the value of the hazard if all the x_i are equal to zero (the quantity $\exp(0)$ equals 1). The t in $h(t)$ reminds us that the hazard may vary over time. It is assumed that the linear predictor does not depend on time, hence the hazard ratio (HR) for any pair of individuals with different values of the covariates vector (e.g. $\mathbf{x}_1$ and $\mathbf{x}_2$) is time constant (proportional hazard assumption) and it is given by $\exp((\mathbf{x}_1 - \mathbf{x}_2)^T \boldsymbol{\beta})$. Proportional hazard assumption was checked by looking at the correlation between survival time and the scaled Schoenfeld residuals. When proportional hazard assumption was not met, the relevant categories were included in the model as time-dependent coefficients [10]. The estimated time-varying coefficients are decreasing (logarithmic) functions of time.

3 Results

The distribution of factors potentially associated with patient mortality, along with corresponding mortality rate for the cancer sites considered are reported in Table 1. For all the cancer sites considered, three-years mortality increases with age and Charlson Index category. It is lower for patients who have been hospitalized outregion compared to those who do not. Mortality doesn't seem to be influenced by gender, with the exception of trachea, bronchus and lung (0.70 for females vs 0.78 for males). In general, an increase in the level of deprivation appears to be slightly associated with mortality rates. Fig. 1 shows Kaplan-Meier estimates of the survival functions both for patients who experienced mobility and for patients who do not, for each cancer site; dashed lines indicate the median survival times. P-values refer

to the Log-Rank tests of difference between the two groups, which resulted significant for all the sites considered. Table 2 shows the results of the Cox models for all the four cancer sites considered. The results of the models show that the relative risk of 3-years mortality for all the cancer sites considered is significantly lower for patients who experienced interregional mobility compared with to those who do not. The effect of gender was significant only for trachea, bronchus and lung site, with males being the highest risk group. For all the sites considered, the risk of death significantly increases with age and according to the Charlson index category, whereas the effect of deprivation on survival time turned out to be not statistically significant.

4 Conclusion

Our analysis shows that interregional mobility is associated with a lower risk of mortality for all the cancer sites considered. These results raise concerns on the equity in the provisioning of healthcare services at the national level. Despite its potential action as stimulus for competition, patient mobility is generally seen as a phenomenon that should be reduced [9]. In line with the National Outcomes Programme (PNE), the provision of indicator of treatment quality represents a fundamental tool to guide patient choice, and for the monitoring of quality of care.
