PET radiomics-based lesions representation in Hodgkin lymphoma patients

Rappresentazione delle lesioni di pazienti affetti da linfoma di Hodgkin basata su radiomica PET

Lara Cavinato, Martina Sollini, Margarita Kirienko, Matteo Biroli, Francesca Ricci, Letizia Calderoni, Elena Tabacchi, Cristina Nanni, Pier Luigi Zinzani, Stefano Fanti, Anna Guidetti, Alessandra Alessi, Paolo Corradini, Ettore Seregni, Carmelo Carlo-Stella, Arturo Chiti, Francesca Ieva

Abstract As medical image analysis has been proven to entail tumor-specific information, the so-called radiomics paradigm holds the promise to characterize the disease and infer long term outcomes of chemotherapy. In this work, we propose an insightful framework for disease characterization in Hodgkin lymphoma which could inform future research. Particularly, an intra-patient similarity index (ISI) was built to represent the homogeneity of the patients' disease, while a radiomics-based fingerprint was create for local lesion description. Through descriptive statistics and classification algorithms, ISI-weighted fingerprint has been showed to be discriminatory between responders and relapsing patients.

Abstract *Recentemente, l'informazione derivante da immagini mediche è stata introdotta in maniera massiva nell'analisi quantitativa delle lesioni, volta alla creazione di modelli diagnostici e prognostici. Questo paradigma, in particolare ma non limitatamente al contesto oncologico, prende il nome di radiomica. Nel presente lavoro, proponiamo un metodo di profilazione dei pazienti affetti da linfoma di Hodgkin in termini di omogeneità paziente-specifica della malattia (ISI) e descrizione locale dellle lesioni, basata su caratteristiche radiomiche. Attraverso statistiche descrittive e algoritmi di classificazione, tale metodo si è rivelato essere discriminante dei pazienti che hanno risposto e quelli refrattari alla prima linea di chemioterapia.*

1 Introduction

Hodgkin's lymphoma (HL) is one out of a group of blood cancers that develop from lymphocytes. Although most of the cases end up with long term outcome [3], up to 30% of patients with early or advanced stage HL can become refractory or relapsing [1], bringing the first-line therapy into failure. For this reason, detecting cases at high risk of event recurrence at baseline would inform and significantly impact on HL patients therapy trial. However, at this stage, according to the gold standard of the International Prognostic Score, stratification and therapeutic strategies are based on clinical risk factors [1]. The staging system for patients with HL relies on the number of involved lesion sites, the severeness of lesions (i.e. bulky), the nodal or extra nodal nature of the disease, the presence of typical systemic symptoms (B symptoms) and lymph nodes stage (on one or both sides of the diaphragm). Early prognostic factors are often investigate the presence of a large mediastinal mass, an elevated sedimentation rate, the involvement of multiple nodal sites, including extra-nodal, age $\geq$ 50 years, or massive splenic disease [6].

Over the last years, research has moved forward to a more quantitative approach. Indeed, the value of image analysis applied to Positron Emission Tomography (PET)/Computer Tomography (CT) for response evaluation and treatment monitoring has been suggested and showed as a promising strategy [2]. Specifically, standardized texture feature extraction in PET/CT images, i.e. radiomics, quantifies the heterogeneity of tracer uptake within a metabolically active region of interest, i.e. tumor lesions. In combination with patients' information, such data are fed into statistical models developed for both research and clinical purposes, such as diagnosis or prognosis. Accordingly, radiomics-derived lesion description of refractory/relapsing HL has been supposed to differ from the one of long term responders [2]. Although straightforward, this workflow might suffer from several limitation and critical issues, such as the enormous amount of parameters that may be computed within image regions, the high co-linearity between features and the lack of biological interpretation which can be inferred from the analyses. The present study aimed at developing a methodological framework in HL for radiomics feature reduction and selection in order to locally describe lesions, different in size and nature, while combining their characterization at patient's level though an intra-patient similarity index. The ultimate perspective of such patient representation lies on further modeling responding/refractory phenotypes in first-line chemotherapy response assessment.

2 Materials and Methods

In accordance with the Declaration of Helsinki, this observational retrospective study was approved by the local ethics committee of all the three centers involved and the signature of a specific informed consent was waived.

Data have been collected from 85 patients with pathological diagnosis of HL undergoing a pre-treatment PET/CT scan. In particular, two categories of patients have been analyzed: non-relapsing/refractory (non-R/R), i.e. long term responders, and relapsing/refractory (R/R) subjected to more than one chemotherapy line and candidate to immunotherapy. Patients with extravasation at injection site, no clinical data availability or having only one tumor lesion have been excluded.

In order to assess imaging data, pre-treatment (baseline) [18F]FDG-PET/CT and the study before immunotherapy have been analyzed for non-R/R HL and R/R HL patients, respectively. PET/CT images have been acquired according to standard institution-specific procedure protocols and images have been retrieved and qualitatively evaluated with LIFEx package (LIFEx website) [4]. Specifically, HL [18F]FDG-avid lesions have been identified, semi-automatically segmented by clinical experts and labeled as lymph nodal or extra-nodal. Fifty-two radiomic features have been computed with respect to every region of interest from histograms of grey levels, geometric factors, co-occurrence and higher order zone-length and run-length matrices. After z-score normalization, a feature reduction has been performed as described by the framework below where the pairwise distances were calculated according to the Euclidean distance definition. An intra-patient similarity index (ISI) defined by the silhouette has been built and treated as a proxy of lesions' homogeneity within patients. Specifically, high values of silhouette implies high similarity within patient's lesions and, viceversa, low values were interpreted as high heterogeneity among patient's tumor sites.

Feature reduction and similarity computation framework:

- Step 1 Selection of all the lesions meeting the inclusion criteria of the current analysis, grouped by patients;
- Step 2 Volume-based grouping of radiomics variables: whether covariates show significant correlation (p-value of the chi-squared test > 0.8) or uncorrelation (p-value of the chi-squared test < 0.0001) with respect to lesion volume, they are grouped into two set of features, representing volume-related (*VOL_set*) and heterogeneity-related (*NOVOL_set*) information respectively;
- Step 3 Application of principal component analysis on both *VOL_set* and *NOVOL_set* of covariates, resulting in two new set of features describing 95% of the total variability;
- Step 4 Juxtaposition of *VOL_set* and *NOVOL_set* of covariates to form a representative fingerprint of each lesion in the cohort;

Step 5 Computation of the silhouette (equation 1) within each patient as the comparison between cohesion (equation 2) and separation (equation 3) of his/her lesions:

$$s(P_i) = \frac{b(P_i) - a(P_i)}{maxa(P_i), b(P_i)} \tag{1}$$

where

$$a(P_i) = \frac{1}{|P_i| - 1} \sum_{i,j \in P_i, i \neq j} d(i,j) \tag{2}$$

$$b(P_i) = \min_{k \neq i} \frac{1}{|P_k|} \sum_{i \in P_i, k \in P_k} d(i,k) \tag{3}$$

Step 6 Evaluation of similarity indexes in different groups.

3 Results

First, ISI values have been computed and analyzed within each group, non-R/R and R/R, independently. Specifically, homogeneity across subjects has been assessed including only nodal and both nodal and extra nodal lesions. While accounting for nodal lesions of the two groups, probability density functions were compared; on contrary, when extra nodal lesions were added upon the nodal ones, overall-ISI results have been evaluated in terms of variation with respect to nodal-ISI: increments of values suggest an increasing in the homogeneity of lesions coming from different sites, while decrements are a proxy of heterogeneity in lesions of diverse nature. The analysis shows the different profiles of distributions of non-R/R (0.11 ± 0.42 - 18/26 positive) and R/R (0.24 ± 0.45 - 38/49 positive). Overall, the comparison between distributions suggest a higher intra-patients lesions similarity in the R/R dataset than in the non-R/R one. In the non-R/R dataset, distribution of ISI built upon nodal lesions is centered in -0.01 ± 0.46, increasing up to 0.12 ± 0.61 after adding extra-nodal lesions: positive ISI increases from 4/8 to 6/8. Similarly, the distribution of ISI in R/R dataset evolves from from 0.13 ± 0.46 to 0.42 ± 0.43 as extra-nodal lesions are included beside the nodal ones: positive ISI rise from 12/19 to 17/19. Overall, these results support a higher intra-patients lesions similarity in the R/R dataset than in the non-R/R.

In order to test ISI discrimination power between the two groups, a Logistic Regression (LR) model has been built upon the only ISI value per patient, resulting in a significant odds ratio of 1.85. Basing on this evidence, a classification model has been performed on the ISI-weighted fingerprint covariates: indeed, each lesion's vector of covariates enclosed both radiomic fingerprint - as described above - and its patient's ISI value. ISI thus represents a grouping/weighting factor, suitable for

mantaining the hierarchical inherent nature of data. Specifically, from the original dataset comprising 85 patients and 543 observations, 115 non-R/R and 255 R/R lesions have been randomly sampled to form the training set, while the test set included 57 non-R/R and 116 R/R lesions. Since class imbalance represents a diriment issue to be addressed in medical applications, a Random Undersamplig Boosting of Tree Ensemble (RUBTE) was used for classification purposes [5]. The RUBTE performance has been evaluated in terms of accuracy (82%), sensitivity (70%) and specificity (88%). Furthermore, results at lesion level were aggregated at patient's level through majority voting. Accordingly, true positive rate rose to 89%, although accuracy slightly fell to 73% and recall dropped to 38%.

4 Discussion and conclusion

The present work underlines the different radiomics information entailed on non-R/R and R/R lesions. R/R patients showed higher intra-patients lesion similarity with respect to non-R/R ones, behavior further confirmed while introducing extra-nodal lesions to nodal ones. Indeed, in the non-R/R group, the addition of extra-nodal lesions ones had a minor effect on similarity. Physicians speculated that non-R/R group, naïve from any treatment, including either long term responders, and primary refractory patients is keen on being the most heterogeneous one. Conversely, R/R patients would be biologically more homogeneous, since repeated treatments might result in resistant clones selection.

Despite the current approach suffer from several limitations due to the retrospective design of the study and the reduced sample size, the goal of defining a methodological feature reduction framework to demonstrate the potential predictive value of radiomics in HL has been achieved. Further efforts will be focused on testing our ISI-weighted fingerprint as representative for any kind of lesion at baseline.

Prediction of late radiotherapy toxicity in prostate cancer patients via joint analysis of SNPs sequences

Predizione della radiotossicità tardiva per pazienti con tumore alla prostata basata sull'analisi congiunta di sequenze di SNPs

Nicola Rares Franco[1], Michela Carlotta Massi[1,2], Francesca Ieva[1,2,3], Anna Maria Paganoni[1,2,3], Andrea Manzoni[1], Paolo Zunino[1], Tiziana Rancati[4], and Catharine West[5,6]

Abstract Over the past few decades, oncological research and radiotherapy techniques have experienced massive improvements. However, many treatments that are currently used suffer from mild to severe side-effects. Focusing on the case of radiotherapy for prostate cancer patients, we assess the already suggested possibility of predicting long-term radiotoxicity through genomic factors. We construct and validate a radiosensitivity indicator that is based on the analysis of SNPs (Single Nucleotide Polimorphism) sequences. Differently from previous works, we directly account for interactions among SNPs and provide a final score that can be easily incorporated into larger models that allow for additional predictors.

Abstract *Negli ultimi decenni, la ricerca oncologica e le tecniche di radioterapia hanno visto miglioramenti sostanziali. Tuttavia, molti dei trattamenti utilizzati soffrono al momento di effetti collaterali blandi e severi. Concentrandoci sul caso della radioterapia per pazienti con cancro alla prostata, indaghiamo la possibilità, già suggerita da ricerche precedenti, di predirre la radiotossicità tardiva attraverso fattori genetici. Quindi, costruiamo e validiamo un indicatore di radiosensibilità basato sull'analisi di sequenze di SNPs (Single Nucleotide Polimorphism). Diversamente da altri lavori in letteratura, teniamo esplicitamente conto di possibili interazioni tra SNPs e forniamo uno score finale facilmente incorporabile in modelli con predittori aggiuntivi.*

1 Introduction

Radiotherapy (RT) is a widely used treatment for prostate cancer [6] which has the benefit of performing well in terms of patient's survival [9]. On the other hand, it is acknowledged that a significant percentage of men who undergo RT report late toxicity side-effects [1].

Currently the risk of severe toxicity is kept under control as modern treatments have become more and more accurate [4], but mild to moderate effects are still very common (up to 50% of the treated patients) [6]. These issues can significantly impact patients' lives and play an important role when men consider treatment options [2], which is why new suitable prevention tools are needed.

During the last decade, many authors have investigated the factors that determine radiosensitivity (such as age, abdominal surgeries etc. [8]), as well as the possibility of making accurate predictions before the treatment. An emerging approach is that of including genetic risk factors, which is mainly motivated by the evidence that radiosensitivity is a heritable human trait [12]. Several works have been conducted in this direction (e.g. [5, 3, 7, 9]), highlighting deep connections between the RT-caused late toxicity and certain genetic mutations. In particular, each mutation was associated with a different SNP, which means that it involved variations of a single nucleotide at a specific position in the genome.

Our work, which is conducted in collaboration with Fondazione IRCCS Istituto Nazionale dei Tumori (Milan, Italy), falls in this branch of research and can be seen as a natural continuation of [9]. There, by combining machine learning and statistical techniques, the authors were able to identify the SNPs associated with long-term toxicity through the use of a deep sparse autoencoder [10]. Nevertheless, the deep learning approach adopted in [9] had the benefit of accounting for possible interactions among SNPs.

Starting from here, we move towards the problem of making reliable predictions. At this purpose, we propose a radiosensitivity indicator that is based on genomic information encoded in sequences (or patterns) rather than standalone SNPs. We validate our model on real data and discuss possible variants as well as future applications.

2 Models and methods

We assess the problem of predicting the expected presence (or absence) of a certain long-term RT side-effect O, in terms of a -fixed- group of p SNPs $\left\{S^1,..,S^p\right\}$. In full generality, this corresponds to studying a model of the type

$$\mathbf{E}\left[O|S^1,..,S^p\right] = f\left(S^1,..,S^p\right)$$

and the goal is to properly estimate f. In practice though, determining f through real data is an ill-posed problem up until one reduces the search to a suitable family

of functions [11]. For instance, if one requires f to be of the form $f(x_1,..,x_p) = \sigma(\beta_0 + \sum \beta_i x_i)$, where $\sigma(x) := \frac{1}{2} + \frac{1}{2}\tanh\left(\frac{x}{2}\right)$ is the sigmoid while the β's are the parameters to be estimated, then everything reduces to the well known case of classical logistic regression; however, since we want to account for interactions among SNPs, we avoid this approach.

Our idea is to consider models of the form:

$$f\left(S^1,..,S^p\right) = \sigma\left(\mu_0 + \alpha|\mathscr{R}|^{-1}\sum_{R\in\mathscr{R}}\mathbf{1}_R\left(S^1,..,S^p\right) + \beta|\mathscr{P}|^{-1}\sum_{P\in\mathscr{P}}\mathbf{1}_P\left(S^1,..,S^p\right)\right) \tag{1}$$

where $\sigma : \mathbf{R} \to [0,1]$ is a fixed link function (e.g. the sigmoid), while $\mathscr{R}$ and $\mathscr{P}$ are suitable collections of SNPs sequences, whereas μ_0, α and β are scalar coefficients to be estimated during the training phase.

2.1 SNPs patterns

Following the classical SNPs encoding, each SNP S^j is a tricotomic variable taking values in $\{0,1,2\}$. Consequently, we may define the collection of all possible SNPs patterns (or sequences) to be

$$\mathscr{S} = \left\{A_1 \times ... \times A_p \quad | \quad A_i = \{0\},\ \{1\},\ \{2\},\ \{0,1,2\}\right\}$$

For a pattern $\mathbf{S} = A_1 \times ... \times A_p \in \mathscr{S}$, we define its length as

$$L(\mathbf{S}) := |\{A_i \neq \{0,1,2\}\}|$$

For instance, if $p = 3$ then $\mathbf{S} := \{0\} \times \{0,1,2\} \times \{2\}$ is a pattern of length 2, where the first SNP equals 0 while the third one equals 2 (in fact, by definition one has $\{(S^1,\, S^2,\, S^3) \in \mathbf{S}\} \iff \{S^1 = 0,\, S^3 = 2\}$). As the cardinality of $\mathscr{S}$ grows exponentially with p, it is clear that a model based on such sequences will -somewhere- need a feature selection procedure.

2.2 Radiosensitivity score

We are given a dataset $\left\{(s_i^1,..,s_i^p,o_i)\right\}_{i=1}^N$ consisting of N i.i.d. observations, each reporting the values of the p SNPs and the presence/absence (respectively 1 or 0) of the late RT side-effect in a different individual.

The first step is to extract the inferable SNPs patterns. This can be done by defining a subset $\mathscr{S}_0 \subseteq \mathscr{S}$ consisting of patterns that show up with a sufficient frequency in both the group of healthy $\{o_i = 0\}$ and diseased $\{o_i = 1\}$ patients. If p is large,

the search of patterns can become computationally heavy: at this purpose it can be convenient to consider only patterns having length less or equal than a fixed $L_0 < p$.

Next we study the effect of each single pattern $\mathbf{S} \in \mathscr{S}_0$ over the outcome O. One way of doing this is determining the odds-ratio $OR(\mathbf{S})$, which in practice corresponds to studying the joint behavior of $\mathbf{1}_{\mathbf{S}}\left(S^1,...,S^p\right)$ and O over the sample. This allows us to split the patterns into two groups

$$\mathscr{R}_0 = \{\mathbf{S} \mid OR(\mathbf{S}) > 1\}, \qquad \mathscr{P}_0 = \{\mathbf{S} \mid OR(\mathbf{S}) < 1\}$$

respectively the risk and the protective patterns. In general, due their combinatorial nature, the cardinality of both $\mathscr{R}_0$ and $\mathscr{P}_0$ will be huge. As a remedy, we propose a feature selection algorithm based on an elbow analysis and a suitable metric over the space of patterns: at the end of this procedure, we obtain the two subsets $\mathscr{R} \subset \mathscr{R}_0$ and $\mathscr{P} \subset \mathscr{P}_0$.

Finally, according to equation (1), we estimate the coefficients μ_0, α and β through logistic regression. We define the radiosensitivity score of the ith individual as

$$RS_i = \alpha|\mathscr{R}|^{-1} \sum_{R\in\mathscr{R}} \mathbf{1}_R\left(s_i^1,..,s_i^p\right) + \beta|\mathscr{P}|^{-1} \sum_{P\in\mathscr{P}} \mathbf{1}_P\left(s_i^1,..,s_i^p\right)$$

Experiments over real data show that the *RS* score can perform very well in terms of predicting long-term radiotoxicity (for some side effects we obtain classifiers having AUCs greater than 0.75). Furthermore, the coefficients α and β seemingly always happen to be statistically significant and have the expected signs, i.e. $\alpha > 0$ and $\beta < 0$: this is of particular interest as it allows us to interpret the *RS* score as a weighted sum of a risk and a protection score.

3 Future steps

We propose a novel approach for predicting radiosensitivity that, unlike other works in the literature, accounts for joint effects of multiple SNPs. We believe that our promising results can have a significant impact in our understanding of how genetic factors are encoded through SNPs and how they affect late RT toxicity.

As future steps we wish to investigate possible variants of our algorithm, as well as the possibility of incorporating the *RS* score into larger models where the late toxicity is infered through a mix of genetic and classical factors.

Predictive versus posterior probabilities for phase II trial monitoring

Confronto tra l'uso di probabilità predittive e a posteriori per il monitoraggio di prove cliniche di fase II

Valeria Sambucini

Abstract Bayesian monitoring of clinical trials is typically based on posterior or predictive probabilities. In the first case, the decision rules are based on the posterior probability that the experimental treatment shows the required performance, given the interim data. In the second case, the idea is to evaluate the predictive probability of observing a positive result if the trial were to continue to its pre-specified maximum sample size. In this paper, we compare the two strategies when applied to a single-arm phase II trial based on binary efficacy and toxicity endpoints.

Abstract *Le procedure Bayesiane per monitorare gli studi clinici si basano tipicamente sul computo di probabilità a posteriori o predittive. Nel primo caso, le regole decisionali si basano sulla probabilità a posteriori che il trattamento sperimentale mostri le prestazioni richieste, date le informazioni ad interim. Nel secondo caso, si valuta la probabilità predittiva di osservare un risultato positivo al termine della prova clinica, quando la dimensione campionaria massima prestabilita è stata raggiunta. Oggetto di querto lavoro è il confronto tra le due strategie quando applicate a uno studio di fase II a braccio singolo basato su due endpoint binari di efficacia e tossicità.*

Key words: Bayesian monitoring, binary bivariate endpoint, phase II clinical trials, posterior probabilities, predictive probabilities.

1 Introduction

The Bayesian approach is particularly suitable to interim monitoring of clinical trials, since it inherently allows to incorporate the evidence from current data in

Valeria Sambucini
Dipartimento di Scienze Statistiche, Sapienza Università di Roma
e-mail: valeria.sambucini@uniroma1.it

the interim rules. The methodologies typically exploit either posterior probabilities or predictive probabilities.

In general terms, let us assume that a phase II single-arm trial with a maximum of N patients is conducted to test the null hypothesis of no treatment effect $H_0 : \theta \in \Theta_0$ versus the alternative $H_1 : \theta \in \Theta_1$. Here, θ denotes the parameter of interest that measures the "goodness" of the experimental treatment. When the interim data d_n have been observed among the first n patients, the futility stopping rule based on posterior probabilities consists in terminating the trial, declaring the new treatment not enough promising, if the posterior probability assigned to the alternative hypothesis is not sufficiently high, that is if

$$Pr(\theta \in \Theta_1 | d_n) < \lambda,$$

where λ is a pre-specified threshold.

As an alternative to this procedure, there are decision rules which exploit accumulated data to evaluate the posterior predictive probability of claiming that the experimental treatment is promising at the scheduled end of the trial. More specifically, let us denote by D_{N-n} the random future data, whose posterior predictive distribution conditional on the current information is $m(\cdot|d_n)$. We also assume that at the end of the study the treatment will be declared promising if the posterior quantity $Pr(\theta \in \Theta_1 | d_n, D_{N-n})$ will exceed a desired threshold λ. Then, the futility decision rule at the interim look is to stop the trial early if we obtain low values for the predictive probability

$$\mathbb{P}_{m(\cdot|d_n)}\Big(Pr(\theta \in \Theta_1 | d_n, D_{N-n}) > \lambda\Big),$$

where $\mathbb{P}_{m(\cdot|d_n)}$ denotes the probability measure associated with $m(\cdot|d_n)$.

Monitoring procedures based on both the approaches for phase II trials that consider a single binary response variable have been widely discussed in the literature. In this context, Yin [5] (section 5.6.5) provides a comparison between using posterior and predictive probabilities for trial monitoring: the main difference that comes to light is that the predictive rules, differently from the posterior ones, are able to compromise the current information and the amount of future data.

In this paper, we focus on two binary endpoints of interest. As a typical application, we can consider a single-arm phase II trial based on efficacy and toxicity binary outcomes. Several reasons why phase II trials should formally incorporate also toxicity outcomes are provided in [1]. Different decision rules to monitor both the endpoints by exploiting posterior probabilities have been presented since the 90s (see [4] and [6], among others), whereas the use of the predictive approach has been proposed more recently (see [2] and [3]). In line with Yin [5], we aim at comparing the two approaches by highlighting the main differences of the decision rules based on the same scenarios assumed to be observed at the interim look.

The outline of the article is as follows. In Section 2 we formalize the problem and describe the Bayesian monitoring procedures based on posterior and predictive

probabilities. In Section 3 a numerical comparison is provided. Finally, Section 4 contains some concluding remarks.

2 Bayesian monitoring rules based on two binary endpoints

When efficacy and toxicity binary outcomes are of interest, there are 4 exclusive events that each patient may experience: $1 = (E,T)$, $2 = (E,T^C)$, $3 = (E^C,T)$ and $4 = (E^C T^C)$, where E and T denote *efficacy* and *toxicity*, whereas E^C and T^C indicate *no efficacy* and *no toxicity*, respectively.

Let N be the maximum achievable sample size. For $k = 1,2,3,4$ and given n current patients, let us denote by x_k the number of subjects who experienced event k and by θ_k the probability that event k occurs, with $\sum_{i=1}^{4} x_i = n$ and $\sum_{i=1}^{4} \theta_i = 1$. The vector of interim data, $\mathbf{x} = (x_1,x_2,x_3,x_4)$, comes from a multinomial distribution with parameter $\theta = (\theta_1,\theta_2,\theta_3,\theta_4)$. From standard conjugate analysis, if we introduce a Dirichlet prior distribution for θ, $\theta \sim \text{Dir}(\alpha_1,\alpha_2,\alpha_3,\alpha_4)$, the corresponding posterior distribution is

$$\theta|\mathbf{x} \sim \text{Dir}(s_1,s_2,s_3,s_4),$$

where $s_k = \alpha_k + x_k$ for $k = 1,2,3,4$.

The most used approach to monitor both the bivariate endpoints consists in exploiting marginal models. In practice, the stopping rules are based on two separated conditions that involve $\theta_E = \theta_1 + \theta_2$ and $\theta_T = \theta_1 + \theta_3$, i.e. the marginal probabilities of efficacy and toxicity, whose posterior densities are

$$\theta_E|\mathbf{x} \sim \text{Beta}(s_1 + s_2,\ s_3 + s_4)$$
$$\theta_T|\mathbf{x} \sim \text{Beta}(s_1 + s_3,\ s_2 + s_4).$$

One possible way of proceeding is to specify two target values of interest, θ_E^* and θ_T^*, and focus on the posterior probabilities that $\theta_E > \theta_E^*$ and $\theta_T < \theta_T^*$, in order to define the treatment success both at the interim look or at the end of the study.

2.1 Predictive probabilities vs posterior probabilities

At the interim stage where n patients have been observed, the rules based on posterior probabilities establish that the trial continues and additional patients need to be enrolled if

$$Pr(\theta_E > \theta_E^*|\mathbf{x}) > \gamma_E \qquad \text{and} \qquad Pr(\theta_T < \theta_T^*|\mathbf{x}) > \gamma_T, \tag{1}$$

where γ_E and γ_T denote two pre-specified thresholds. In practice, it is required to obtain from the current data sufficiently high posterior probabilities that the new treatment is enough effective and that it is not highly toxic.

To implement the procedures based on predictive probabilities, we need to consider the future efficacy and toxicity data that will be obtained among the remaining $N-n$ patients, $\mathbf{Y} = (Y_1, Y_2, Y_3, Y_4)$. We have that the posterior predictive distribution of $\mathbf{Y}$, conditional on $\mathbf{x}$, is the Dirichlet-Multinomial distribution,

$$m_{N-n}(\mathbf{y}|\mathbf{x}) = \text{DirMultinom}(N-n, \mathbf{s}), \tag{2}$$

where $\mathbf{s} = (s_1, s_2, s_3, s_4)$. If we observe the future data $\mathbf{Y} = \mathbf{y}$ at the end of the trial, the posterior distributions of θ_E and θ_T will be

$$\begin{aligned} \theta_E|\mathbf{x}, \mathbf{y} &\sim \text{Beta}(h_1 + h_2,\ h_3 + h_4) \\ \theta_T|\mathbf{x}, \mathbf{y} &\sim \text{Beta}(h_1 + h_3,\ h_2 + h_4), \end{aligned}$$

where $h_k = \alpha_k + x_k + y_k$ for $k = 1, 2, 3, 4$. Moreover, the treatment will be declared promising if

$$Pr(\theta_E > \theta_E^*|\mathbf{x}, \mathbf{y}) > \lambda_E \qquad \text{and} \qquad Pr(\theta_T < \theta_T^*|\mathbf{x}, \mathbf{y}) > \lambda_T, \tag{3}$$

where λ_E and λ_T denote two probability cutoffs, reasonably chosen as high values. Therefore, we can compute the predictive probability of a successful conclusion should the trial be conducted to the maximum planned sample size by summing the predictive probabilities of all the possible future outcomes that simoultaneuously satisfy the conditions in (3). Thus, the predictive probability of interest is

$$PP = \sum_{\mathbf{y}} m_{N-n}(\mathbf{y}|\mathbf{x}) I\Big\{ Pr(\theta_E > \theta_E^*|\mathbf{x}, \mathbf{y}) > \lambda_E \Big\} I\Big\{ Pr(\theta_T < \theta_T^*|\mathbf{x}, \mathbf{y}) > \lambda_T \Big\}, \tag{4}$$

where $I\{\cdot\}$ is the indicator function. Then, the futility rule establishes that the trial continues if PP exceeds a desired threshold θ_L, generally chosen as a value less than 0.2. Otherwise the trial terminates. In other words, additional patients are enrolled if it is not unlikely that the experimental treatment will show the desired performance in terms of efficacy and safety at the conclusion of the study.

3 Numerical comparison

To make a comparison between using posterior and predictive probabilities for trial monitoring in the presence of two binary efficacy and toxicity outcomes, we consider a hypothetical scenario observed *ad interim*. More specifically, we assume that 9 responses $(x_1 + x_2)$ and 5 toxicities $(x_1 + x_3)$ have been observed among $n = 20$ current patients. By setting $\theta_E^* = 0.45$, $\theta_T^* = 0.25$ and $\alpha = (0.25, 0.25, 0.25, 0.25)$, we have that the posterior probabilities of interest are $Pr(\theta_E > \theta_E^*|\mathbf{x}) = 0.503$

and $Pr(\theta_T < \theta_T^*|\mathbf{x}) = 0.482$, whatever are the maximum planned sample size and the joint counts of the current data. On the contrary, the predictive probability in (4) strongly depends on N and on the joint structure of the interim data. This is because it involves the posterior predictive distribution in (2), that provides different probability values for different combinations of the element of $\mathbf{x} = (x_1, x_2, x_3, x_4)$ compatible with the same marginal number of total responses and total toxicities.

In the specific case we are considering, we can express all the possible current data consistent with 9 responses and 5 toxicities in terms of the number of observed responses without toxicities (i.e. x_2). In Figure 1 we show the behaviour of PP as a function of x_2 for different values of N, when $\theta_E^* = 0.45$, $\theta_T^* = 0.25$, $\lambda_E = \lambda_T = 0.9$ and $\alpha = (0.25, 0.25, 0.25, 0.25)$. As x_2 increases, the current data provide more support to the experimental treatment and, as a consequence, the predictive probability of declaring the treatment success at the planned end of the study increases. Moreover, the higher N, the larger PP. This is because, given the current information, for low values of the number of remaining patients it is unlikely that the posterior probabilities of a high efficacy and a low toxicity will reach the thresholds 0.9 at the end of the study. On the contrary, if $N - n$ is large, the strength of the interim data is less relevant and the predictive probability of interest grows. In Table 1 the variations of PP as a function of x_2 and N are provided for different couples of values of θ_E^* and θ_T^*. The computations of the posterior probabilities of interest are also shown at the bottom of the table. As expected, both the predictive and the posterior probabilities decreases as the target values become harder to reach (i.e. θ_E^* increases and/or θ_T^* decreases).

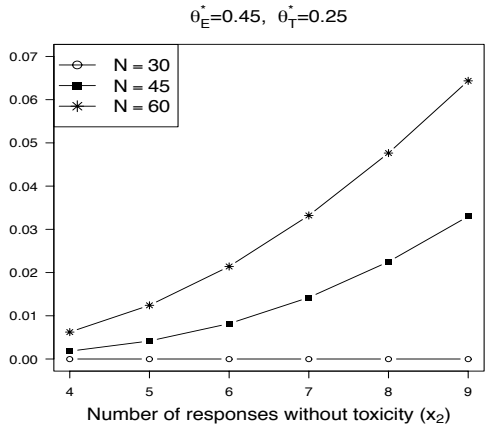

Fig. 1 Behaviour of PP as a function of all possible values of x_2 consistent with the fixed number of total responses ($x_1 + x_2 = 9$) and total toxicities ($x_1 + x_3 = 5$) for different values of N, when $n = 20$, $\lambda_E = \lambda_T = 0.9$ and $\alpha = (0.25, 0.25, 0.25, 0.25)$.

Table 1 Variations of PP for different values of x_2, θ_E^*, θ_T^* and N, when $\lambda_E = \lambda_T = 0.9$ and $\alpha = (0.25, 0.25, 0.25, 0.25)$. The values of the posterior probabilities in (1) are also provided.

	$\theta_E^* = 0.5,\ \theta_T^* = 0.2$			$\theta_E^* = 0.45,\ \theta_T^* = 0.25$			$\theta_E^* = 0.4,\ \theta_T^* = 0.3$		
x_2	$N = 30$	$N = 45$	$N = 60$	$N = 30$	$N = 45$	$N = 60$	$N = 30$	$N = 45$	$N = 60$

	$Pr(\theta_T < 0.2\|\mathbf{x}) = 0.275$			$Pr(\theta_T < 0.25\|\mathbf{x}) = 0.482$			$Pr(\theta_T < 0.3\|\mathbf{x}) = 0.677$		

4 Conclusion

Similarly to the case of a single binary endpoint, also when dealing with two binary outcomes, monitoring rules based on predictive probabilities represent a compromise between interim data and future sample size. By contrast, the rules based on posterior probabilities are not affected by the remaining number of subjects in the study.

More interestingly, if the definition of a successful treatment is based on conditions imposed on the marginal probabilities of efficacy and toxicity, monitoring strategies based on predictive probabilities enables to account for the joint structure of the interim data. Thus, the current information is fully exploited, taking in account also the association between the two endpoints.

Profile networks for precision medicine

Reti profilo per la medicina di precisione

Andrea Lazzerini · Monia Lupparelli · Francesco C. Stingo

Abstract We propose a class of profile graphical models to model the effect of an external factor on the dependence structure of a multivariate set of variables. The main aim is to provide a joint representation based on a single graph of the probability distribution of a multivariate random vector given different levels of an external factor. In particular, we explore the marginal dependence structure by using the subclass of bi-directed profile graphical models and we show that the selected graphical model is compatible with a two block regression graph. An application is discussed based on protein networks in various subtypes of acute myeloid leukemia.
Abstract *Proponiamo una classe di modelli grafici profilo per studiare l'effetto di un fattore esterno sulla struttura di dipendenza di un insieme di variabili. Lo scopo è rappresentare congiuntamente in un unico grafo la distribuzione di probabilità congiunta di un vettore casuale di variabili, dati diversi livelli di un fattore esterno. In particolare, si esplora la struttura di dipendenza marginale utilizzando la sotto classe di modelli grafici profilo bi-direzionali e si mostra la compatibilità del modello grafico selezionato con un grafo di regressione a due blocchi. Si discute un'applicazione su reti di proteine per diversi sottotipi di leucemia mieloide acuta.*

Key words: multiple graphs, regression graphs.

1 Introduction

We propose a novel class of graphical models to study the effect of an external factor on the marginal dependence structure of a multivariate random vector of outcomes. Exploring marginal independencies in a multivariate setting may provide relevant insights when the association structure is induced by ignoring the effect of latent/unobservable variables.

Let $Y_V = (Y_i)_{i \in V}$ be a random vector of outcomes indexed by the finite set V with $p = |V|$. Also, let us consider the categorical variable X representing an external factor for the random vector Y_V. The variable X takes level $x \in \mathscr{X}$ with $q = |\mathscr{X}|$. For any $x \in \mathscr{X}$, let $Y_V(x)$ be a *profile outcome vector*, that is the random vector $Y_V|\{X = x\}$ conditioned on a specific profile x of the factor X, and let $P[Y_V(x)]$ be the corresponding *profile outcome distribution*, that is the conditional probability distribution $P(Y_V|\{X = x\})$. Then, for a given multivariate random vector Y_V and an external factor X, let $Y_{V|\mathscr{X}} = [Y_V(x)]_{x \in \mathscr{X}}$ be the finite set of all profile outcome vectors and let $P(Y_{V|\mathscr{X}}) = [P(Y_V(x))]_{x \in \mathscr{X}}$ be the corresponding set of all profile outcome distributions. Given a partition $A, B, C \subseteq V$, the *profile marginal independence* $Y_A(x) \perp\!\!\!\perp Y_B(x)$ corresponds to the factorization

$$P[Y_A(x), Y_B(x)] = P[Y_A(x)] \times P[Y_B(x)], \quad x \in \mathscr{X}. \tag{1}$$

of the joint profile distribution $Y_V(x)$.

Let $B = (V, E_B)$ be a *bi-directed graph* defined by a set of vertices $i \in V$ and a set of edges $(i, j) \in E_B$, drawn as bi-directed edges, joining pairs of vertices $i, j \in V$. Vertices $i \in V$ are associated to variables Y_i of a random vector Y_V and, under suitable Markov properties, missing edges in the graph corresponds to marginal independencies for the joint probability distribution $P(Y_V)$. For the pairwise Markov property, a missing edge $(i, j) \notin E_B$ corresponds to the marginal independence $Y_i \perp\!\!\!\perp Y_j$, for any $i, j \in V$. For technical aspects see [4]. A *regression graph* $R = [\{R_T\}_{T \in \mathscr{T}}, E_R]$ is defined by a set of vertices partitioned in components R_T, for any T in a finite set $\mathscr{T}$ and a set of edges E_R. Vertices i, j within any component R_T can be joined by bi-directed edges and vertices between components, $i \in R_T$ and $j \in R_{T'}$ are joined by directed edges preserving the same direction such that cycles are not allowed, for any $T, T' \in \mathscr{T}$, with $T \neq T'$. Regression graph models allow to explore the dependence structure of Y_V given X and the effect of X on each $Y_i \in Y_V$. The corresponding Markov properties and more details are given in [1]. An example of bi-directed and regression graph can be found in Fig. 1 and Fig. 2 respectevely (ignore for the moment the first graph on the left inside of both figures). Consider the bi-directed graph $B(0) = (V, E_{B_0})$ where $V = \{a, b, c, d\}$ and $E_{B_0} = \{(a, b), (b, c), (b, d)\}$. For the pairwise Markov property it holds for instance that $Y_a \perp\!\!\!\perp Y_d$. Consider now the regression graph $R = [\{R_T\}_{T \in \mathscr{T}}, E_R]$ where $\mathscr{T} = \{\{X\}, \{a, b, c, d\}\}$ and $E_R = \{(X, a), (X, b), (a, b), (a, c), (b, c), (b, d)\}$. For the pairwise Markov property it hold for example that $X \perp\!\!\!\perp Y_d$ and $Y_c \perp\!\!\!\perp Y_d | X$.

The drawback of regression graph models is that they do not provide information on how the joint dependence structure of Y_V may considerably vary for any

level $x \in \mathscr{X}$. From this perspective, useful insights are given by the use of multiple graphical models. A collection of *multiple bi-directed graphs* $B_{V|\mathscr{X}} = \{B(x) = (V, E_B(x))\}_{x \in \mathscr{X}}$ associated to the profile outcome distributions $P(Y_{V|\mathscr{X}})$ represents a class of independence models for any profile outcome vector $Y_V(x)$, with $x \in \mathscr{X}$. Basically, any graph $B(x) \in B_{V|\mathscr{X}}$ represents the marginal independence structure of the outcomes Y_V given a profile $x \in \mathscr{X}$ of the factor X. These graphs may reasonably have different skeletons for any $x \in \mathscr{X}$, so that the outcome independence structure is not invariant with respect to different factor levels. On the other side, the drawback of multiple graphs is that they do no provide information about the effect of the external factor X on single outcomes $Y_i \in Y_V$; for further details see [2, 6].

In essence, our idea is to provide a single graph able to embed, at the same time, information about the effect of an external factor on the values of a set of outcomes, as a regression graph does, and on the dependence structure of each profile outcome, as a collection of multiple graphs does. Regression graphs and multiple graphs are special cases of the proposed profile graphical models.

2 Profile bi-directed graphical models

A *profile bi-directed graph* $\mathscr{G}_B = (V, \mathscr{E}_B)$ is defined by the full set V of vertices and a $(p \times p)$ matrix $\mathscr{E}_B$ of $\mathscr{Z}$-labelled edges, drawn as bi-directed line, which are labelled according to any subset $\mathscr{Z} \subseteq \mathscr{X}$. Let $(i, j)^{\mathscr{Z}}$ be the generic element of $\mathscr{E}_B$ associated to any couple $i, j \in V$, where the presence or non-presence of the edge between i and j is univocally determined by the subset $\mathscr{Z}$ of the state space $\mathscr{X}$. Given $(i, j)^{\mathscr{Z}} \in \mathscr{E}_B$ for any pair $i, j \in V$, if $\mathscr{Z} = \mathscr{X}$, vertices i and j are not coupled by any edge, if $\mathscr{Z} \subset \mathscr{X}$, we have that vertices i and j are coupled by a $\mathscr{Z}$-labelled edge. In particular, if $\mathscr{Z}$ is a nonempty proper subset of $\mathscr{X}$, $\mathscr{Z} \subset \mathscr{X}$ and $\mathscr{Z} \neq \emptyset$, vertices i and j are joined by a dotted $\mathscr{Z}$-labelled edge, if $\mathscr{Z} = \emptyset$, vertices are joined by a full edge and, for sake of simplicity, the $\emptyset$-label is removed by the edge.

Under suitable Markov properties the profile graph $\mathscr{G}_B$ provides an independence model for the joint distributions of a random vector $Y_{V|\mathscr{X}}$ of profile outcomes. In particular, a missing edge in $\mathscr{G}_B$ corresponds to a profile marginal independence for every level $x \in \mathscr{X}$, and, therefore, to a marginal independence for the entire vector $Y_{V|\mathscr{X}}$. A $\mathscr{Z}$-labelled dotted edge in $\mathscr{G}_B$ corresponds to profile marginal independencies holding only for the levels $x \in \mathscr{Z}$, with $\mathscr{Z} \subset \mathscr{X}$. For instance, under the *profile bi-directed pairwise Markov property* we have that (i) a missing edge for a pair $i, j \in V$ of vertex implies $Y_i(x) \perp\!\!\!\perp Y_j(x)$, for any $x \in \mathscr{X}$; (ii) a $\mathscr{Z}$-labelled dotted edge for a pair $i, j \in V$ of vertex implies $Y_i(x) \perp\!\!\!\perp Y_j(x)$, for any $x \in \mathscr{Z}$.

Finally, we assume a partition of the vertex set $V = V_\square \cup V_\bigcirc$ in order to specify the set of vertices which are independent or dependent, respectively, of the external factor X. Then, any vertex $i \in V_\square$ is drawn as a square vertex, while any $i \in V_\bigcirc$ is drawn as a circled vertex. In the class of profile graphs we consider, any pair $i, j \in V_\square$ are not allowed to be joined by a $\mathscr{Z}$-labelled dotted edge, for any nonempty $\mathscr{Z} \subset \mathscr{X}$. Also, given the partition $V = V_\square \cup V_\bigcirc$, for any $i \in V_\square$, we have that $Y_i \perp\!\!\!\perp X$.

We give an illustrative example. Figure 1 shows a profile bi-directed graph associated with the profile outcome vector $Y_{V|\mathscr{X}}$, with $V = \{a,b,c,d\}$, and the corresponding induced class of multiple bi-directed graphs $B(x)$, $\forall x \in \mathscr{X} = \{0,1,2\}$. Figure 2 shows the same profile graph of 1 with square vertices according to the compatible regression graph R. Under the pairwise Markov property, for example, we have that $Y_a(x) \perp\!\!\!\perp Y_c(x)$ for $x = 0$ because the two nodes are joined by a dotted $\{0\}$-labelled edge, while $Y_c(x) \perp\!\!\!\perp Y_d(x)$ for any $x \in \mathscr{X}$ because there is no edge between the two nodes. There is no independence between b and d since they are joined by a full edge. Furthermore, the partition $V = V_\square \cup V_\bigcirc$ of the vertex set provides information about the dependence of each vertex $Y_i \in Y_V$ with respect to X. For instance, we have that $Y_c \perp\!\!\!\perp X$. Notice that multiple graphs imply all the profile marginal independencies, however they do not provide information about the dependence of any $Y_i \in Y_V$ with respect to X while regression graphs imply the latter but not the profile marginal independencies when $\mathscr{Z} \subset \mathscr{X}$, $\mathscr{X} \neq \emptyset$. Conversely, profile graphs involve them all.

3 Protein networks

The proposed method is used to analyze protein expression data from patients affected by acute myeloid leukemia (AML). The goal of this analysis is to reconstruct a protein network for each subtype of the disease; comparing the networks for these groups provides insight into the differences in protein signaling that may affect whether treatments for one subtype will be effective in another.

A set of protein levels is observed in a sample of 213 newly diagnosed AML patients. Data are available upon request at the MD Anderson Department of Bioinformatics and Computational Biology. Protein expression were collected using the reverse phase protein array (RPPA) technology. For previous work on inference of protein networks from RPPA data see [7] . Patients are classified by subtype according to the French-American-British (FAB) classification system. The subtypes, based on criteria including cytogenetics and cellular morphology, show varying prognosis. Then, it is reasonable to expect a different protein interactions in the subtypes. A set of 18 proteins is considered and they are known to be involved in apoptosis and cell cycle regulation according to the KEGG database [3]. We consider 4 AML subtypes, for which a reasonable sample size is available: M0 (17 subjects), M1 (34 subjects), M2 (68 subjects), and M4 (59 subjects).

Our interest is modelling the effect of the AML subtype on the joint dependence structure of the protein levels and, in particular the interest is exploring via a graphical modelling approach how this structure may change under different AML subtype. We are also interested in changes of expression across subtypes. Profile graphical models are an encompassing tool that coherently and jointly performs all inferential tasks of interest. Therefore, considering the $p = 18$ protein levels following a multivariate Gaussian distribution and $q = 4$ different subtypes of AML, where the levels $x \in \mathscr{X} = \{0,1,2,3\}$ denote the subtypes M0, M1, M2, M4 respectively, we estimate and select the profile bi-directed graphical model represented in Figure 3, with a suitable profile Lasso approach in a neighborhood selection scheme [5].

Let us give a short comment on the results obtained. The selected graph shows, for instance, that $Y_{\text{BAD.p155}}(x) \perp\!\!\!\perp Y_{\text{GSK3}}(x)$, for any $x \in \mathscr{X}$. Also, it shows, for instance, that $Y_{\text{AKTp.308}}(x) \perp\!\!\!\perp Y_{\text{AKTp.473}}(x)$, for any $x \in \{0,3\}$. The single levels of the proteins AKT1, BAD.p112, BAD.p112, BAD.p155, BAX, GSK3, GSK3.p and XIAP are independent of the subtypes of AML. Pairwise associations between the proteins AKT1, BAD.p112, BAX, GSK3.p, PTEN and XIAP are independent of the AML subtypes. The remaining proteins have at least one pairwise association that varies with the AML subtype.

Proton-Pump Inhibitor Provider Profiling via Funnel Plots and Poisson Regression

Profilazione dei Distributori di Inibitori della Pompa Protonica con Funnel Plot e Regressione di Poisson

Dario Delle Vedove, Francesca Ieva, and Anna Maria Paganoni

Abstract Proton-pump inhibitors (PPI) are one of the most prescribed medication worldwide. Even if they are largely recognized as a safe drug, long-term use can lead to an increased risk of collateral disease. Funnel plots have been proposed as a useful tool for assessing and visualizing surveillance data about PPI prescriptions. We studied a way to operate funnel plot analyses on both raw PPI patient rates and adjusted rates considering the effects of risk factors. Taking as a case study the German region of Saarland during 2010, 2013 and 2016, we showed that funnel plots of raw rates and of risk adjusted rates lead to partially different conclusions that can be proficiently compared and discussed.

Abstract *Gli inibitori della pompa protonica (PPI) sono una delle categorie di farmaci più prescritte al mondo. Nonostante siano largamente riconosciuti come farmaci sicuri, un uso prolungato potrebbe condurre ad un aumentato rischio di effetti collaterali. Abbiamo proposto i funnel plot come utile strumento di valutazione e visualizzazione per le prescrizioni di PPI. Abbiamo progettato un modo per applicare i funnel plot sia ai tassi di pazienti a cui sono stati prescritti PPI, sia a tali tassi corretti tenendo in considerazione fattori di rischio. Prendendo come caso studio la regione tedesca del Saarland durante gli anni 2010, 2013 e 2016, abbiamo mostrato che i funnel plot sui tassi semplici e sui tassi corretti conducono a*

1 Introduction

Proton-Pump Inhibitors (PPI) are among the most prescribed class of medicines in wide areas of the world [4], due to their effectiveness for long-lasting reduction of stomach acid production [12]. However, in the last few years, some issues related to the PPI use for chronic or inappropriate conditions raised: even if it is a class of drugs which is considered to be well tolerated, increasing concerns are emerging about their abuse. Some studies recognize a significant association between PPI long-term use and an increased risk of gastric cancer and harmful interaction with other drugs [1, 10]. For these reasons, it is worth monitoring the prescribing phenomenon to avoid not only the spread of diseases related to the overprescription of PPIs, but also to save large amount of money for one of the most consumed class of medications that may be reallocated somewhere else.

In order to understand the goodness of resource distribution, valuable insights can be gathered by comparing performances of medical care providers, or, in other words, "profiling" them. It is a worthwhile process for targeting improvement strategies [11]. A challenge of the quality of healthcare research is to account varying population and hospital characteristics while developing statistical procedures to distinguish under and over performing medical providers. In particular, we aim to detect practices with a proportion of patients who received PPI prescriptions significantly larger than the average and detect them. In other words, we want to understand if there are prescribers providing PPI with laxed standards which are possibly misusing healthcare resources.

2 Materials and Methods

2.1 Data

Data were provided by Central Research Institute of Ambulatory Health Care, called Zi, from Germany. It is a non-profit foundation under private law, financed by the 17 Associations of Statutory Health Insurance Physicians (called KVs).

Data are aggregated to practice-level and concern number of patients, costs, daily defined doses, age, gender, and an analogous of all these information about PPI prescription and patients. For each observation, we have also if the practice has one

or more specialization (among general medicine, cardiology and neurology or psychiatry), the KV of the practice, the year (2010, 2013, 2016) and the quarter. Comprehensively, the dataset counts 702,353 rows, and between 50 and 65 thousands observations each quarter.

2.2 Statistical methods

Funnel plot is a valuable statistical method introduced in meta-analyses studies that allows to visually detect outliers [3]. The funnel plots use normal Gaussian control limits approximating binomial distribution, due to the fact that our objective variable is the rate given by the proportion between patients who received PPI prescriptions and the total amount of patients who received a prescription. These limits are given by

$$\hat{\theta}_0 \pm \Phi(1-\frac{\alpha}{2})\sqrt{\frac{\hat{\theta}_0(1-\hat{\theta}_0)}{\rho}} \tag{1}$$

where $\hat{\theta}_0$ is fixed at the overall provincial rate as estimated from the data, $\Phi()$ is the cumulative inverse normal distribution evaluated for $1-\alpha\%$ control limits (we set $\alpha = 0.05$) and ρ is the number of observations to compute a rate. It is a precision parameter, determining the accuracy with which the indicator is being measured [13].

Funnel plots are based on the assumption that the null distribution fully expresses the variability of the in-control units. If we are not in this case, observations in funnel plot may result 'over-dispersed' around the target. In general, this issue raises when unmeasured covariates that are not taken into account in any risk-adjustment method. To deal with this behaviour, we can inflate a factor $\sqrt{\hat{\phi}}$, where $\hat{\phi} = \frac{1}{I}\sum_i z_i^2$, I is the institution number and z_i is the standardized Pearson residual of the i-th practice, so the control limits become $\hat{\theta}_0 \pm \Phi(1-\frac{\alpha}{2})\sqrt{\frac{\hat{\phi}\hat{\theta}_0(1-\hat{\theta}_0)}{\rho}}$. In order to minimize the influence of outlying case, it may be useful to compute the inflation factor with Winsorised z-score [9].

Risk adjustment was operated choosing a priori covariates that may explain practice rate variability. We fitted a Poisson regression against PPI patient number with a $\log(total\ patients)$ offset. Demographic factors (age, gender) and economic factors (cost) were successively included in the model.

The adjusted rate is computed as the product of the average PPI patients rate and the ratio of observed to expected values from the Poisson regression model. These models are compared with Pearson goodness-of-fit statistics [2].

3 Results

In order not to introduce effect modifications due to geographical location and to the nature of prescribers, we decided to limit the analyses to practices located in Saarland and specialized only in general medicine (more than 80% of the practices in the KV). Saarland was chosen as the smallest German territorial KV for practical reasons, but also because of its representativeness in terms of rural and urban areas for the whole country [8]. On the other hand, depending on the quarter, 82-89% of patients receiving a PPI prescription in Saarland is treated by a general medicine practice.

It is interesting to notice how the proportion of PPI prescriptions had a constant growth in this subset of practices: from 4.9% of the total amount of prescriptions at the beginning of 2010 to 6.1% in the end of 2016, reflecting a similar national trend, but sharper.

We are interested in explaining how the amount of patients who received at least a PPI prescription varies. We considered the average age of patients, since the proportion of the population prescribed PPI therapy may increase with age [6]; the gender proportion in each practice, since gender differences may exist in response to PPI [7, 14]; average cost of PPI definded daily doses; and the total amount of patients receiving a prescription.

Modeling the probability of a patient who received a PPI prescription as binomial, we produced a funnel plot of PPI patient rate vs patient number, but significant overdispersion was observed. Inflating into the variance a multiplicative factor computed with Winsorised z-scores (in this case, we used 5% most extreme top and bottom z-scores), it was possible to solve this issue. We found 4 to 8 % of outliers per quarter, but only 2-3% of the practices have a suspiciously high number of PPI patients. Figure 1(a) shows a funnel plot referring to the 4-th quarter of 2016. It is interesting to notice that 7 out of 803 of the practices are always high outliers over quarters, when we have information about them.

On the other hand, we considered the PPI patient count coming from a Poisson distribution. In searching for a model with a better fit to the data, we adjusted for age mean, sex percentage and average cost of a PPI daily defined dose. With the Pearson chi-square goodness of fit it was shown that risk adjusted Poisson regression improves the model fit significantly with respect to the unadjusted one, i.e., computed with the only total patient count as covariate. Also in this case we checked that there is overdispersion, so it is worth to introduce a multiplicative factor into the control limits, which was computed again with 10% Winsorized z-scores. Again 4-7% of practices outside the 95% limits are detected, 2-3% of which are high outliers. It can be observed in figure 1(b). In this setting, 6 out of 803 of the practices are always high outliers over quarters.

Comparing the two methodologies, we noticed that that there are at least two providers that result to be high outliers in both the settings in any quarter. The funnel plot for raw rate is more conservative with high outliers, but less with low outliers compared with the funnel plot for adjusted rates. Moreover, comparing out-of-bound practices found with the different funnel plots allows us to understand if high rates

can be justified with explanatory variables or not. For example, in the 4-th quarter of 2016, a practice with 336 has a PPI patient rate of 0.39, resulting to be a high outlier. Correcting for risks, it comes out that the adjusted rate is not so surprising after having accounted for our covariates.

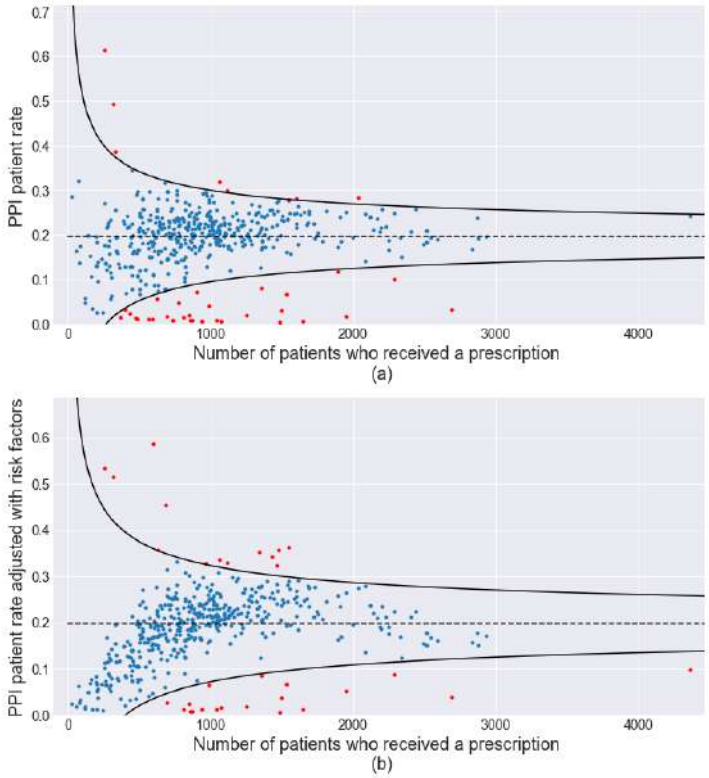

Fig. 1 Funnel plots for Saarland during the 4-th quarter of 2016: (a) funnel plot of raw PPI patient rate; (b) funnel plot of PPI patient rate adjusted with age, gender and cost factors.

4 Conclusions

Funnel plots provide a clear and operative tool for health surveillance and anomaly detection, also in presence of overdispersion. Overdispersion is not an unusual phenomenon in health data, and funnel plot has the ability to easily visualize it. In order to avoid misprescriptions due to laxed standards of providers, the purpose is to provide an easy-to-consult tool which can report in a comprehensible way the possibility that a practice is significantly out of standards. We proposed a joint use

of this graphical instrument and a statistical model as Poisson regression to detect out-performing institutions in terms of rate of patients who receive PPI prescriptions. Comparing suspicious practices in both the outcomes, it is possible to make more robust considerations about the behaviour of physicians.

Acknowledgements We would like to express our gratitude to Central Research Institute of Ambulatory Health Care in Germany (Zi) for data provision.

Selecting optimal thresholds in ROC analysis with clustered data

Scelta di soglie ottimali nell'analisi ROC con dati raggruppati

Duc Khanh To, Gianfranco Adimari and Monica Chiogna

Abstract We tackle estimation of receiver operating characteristic (ROC) surfaces and selection of the optimal pair of thresholds for continuous diagnostic tests given covariates in clustered data when the disease status is described by three ordinal classes. The approach is based on a linear mixed-effect model which accounts for both the clusters and the covariates effects. The asymptotic properties of estimators are studied. Simulation studies are performed to assess the performance of estimators.

Sommario *Per test diagnostici continui, si studia il problema della stima della superficie ROC e della individuazione di valori di soglia ottimali nel caso di dati raggruppati e in presenza di variabili esplicative. Si propone un approccio basato su un modello lineare a effetti misti e si studiano le proprietà degli stimatori individuati, il cui comportamento nel finito è valutato attraverso esperimenti di simulazione.*

Key words: clustered data, ROC surface, linear mixed-effect model

1 Introduction

The receiver operating characteristic (ROC) surface has been popularly used in biomedical studies to evaluate the ability of a diagnostic test (or biomarker) to distinguish among one of three classes of a disease status. Let Y be a diagnostic test result measured on a continuous scale, and let Y_1, Y_2, Y_3 be the test result for subjects in class 1, 2 and 3, respectively. Without loss of generality, we assume that higher

Monica Chiogna
Department of Statistical Sciences "Paolo Fortunati", University of Bologna, Via Belle Arti, 41; 40126 Bologna, Italy. e-mail: monica.chiogna2@unibo.it

values of test result are associated to higher severity of the disease. Given a pair of thresholds (t_1, t_2), with $t_1 < t_2$ in the range of diagnostic test results, three true class fractions can be defined as $\text{TCF}_1(t_1) = \Pr(Y_1 \leq t_1)$, $\text{TCF}_2(t_1, t_2) = \Pr(t_1 < Y_2 \leq t_2)$ and $\text{TCF}_3(t_2) = \Pr(Y_3 > t_2)$. The ROC surface for the diagnostic test Y is obtained by plotting ($\text{TCF}_1(t_1)$, $\text{TCF}_2(t_1, t_2)$ and $\text{TCF}_3(t_2)$) in a unit cube over all possible values of t_1 and t_2 (Nakas and Yiannoutsos, 2004). For practical uses, choosing optimal thresholds is a relevant issue.

Recently, several methods have been developed to estimate the ROC surface (Nakas and Yiannoutsos, 2004; Xiong et al, 2006) and to select an optimal pair of thresholds (Nakas et al, 2010; Attwood et al, 2014). Most of them consider a setting in which measurements on statistical units can be considered realizations of statistically independent random variables, and the diagnostic test is not influenced by any covariate. In some medical studies, however, statistical units are enrolled in clusters (e.g., families), and the diagnostic test can be affected by some covariates. In this setting, Xiong et al (2018) used a linear mixed-effect model to account for the cluster and the covariates effects, and proposed an approach to estimate the volume under the ROC surface (which is summary measure of the diagnostic test accuracy).

In this paper, we employ the same model as in Xiong et al (2018) to estimate the ROC surface. Then, in order to properly address the problem of selecting an optimal pair of thresholds, we adapt to the clustered-data case three criteria based on the generalized Youden index, the so-called perfection point and the maximum volume of the cuboid under ROC surface.

2 The linear mixed-effect model

Suppose to have p covariates, $X_1, \ldots, X_p$ say, possibly associated with the diagnostic test Y. Let c be the total number of clusters (for instance families), randomly selected from the population. For the cluster k-th, $k = 1, \ldots, c$, let n_{ki} be the total number of subjects belonging to class i-th of disease, $i = 1, 2, 3$. Note that n_{ki} could be equal to 0 for some clusters. In order to account for the clustering effect on Y, as well as for covariates' effects, we consider the following linear mixed-effect model (see also Xiong et al, 2018):

$$\begin{aligned} Y_1 &= \alpha_{k_1} + z_1^\top \beta_1 + \varepsilon_1, \\ Y_2 &= \alpha_{k_2} + z_2^\top \beta_2 + \varepsilon_2, \\ Y_3 &= \alpha_{k_3} + z_3^\top \beta_3 + \varepsilon_3, \end{aligned} \tag{1}$$

where (Y_1, Y_2, Y_3) is a triplet of test scores from three randomly sampled subjects from the three disease classes, (k_1, k_2, k_3), $k_i \in \{1, \ldots, c\}$, are cluster memberships indicating the clusters from which Y_1, Y_2, Y_3 are observed, $z_i = (1, x_{1i}, \ldots, x_{pi})^\top$ are fixed (i.e., not random) covariates values, and $\beta_i = (\beta_{0i}, \beta_{1i}, \ldots, \beta_{pi})^\top$, $i = 1, 2, 3$, are vectors of parameters representing covariates effects. In model (1), α_k are random effects accounting for the presence of clusters, and ε_i are subject-level random er-

rors. We assume that: (i) the random effects α_k and the subject-level random errors ε_i follow a normal distribution, i.e., $\alpha_k \sim \mathcal{N}(0,\sigma_c^2)$ and $\varepsilon_i \sim \mathcal{N}(0,\sigma_i^2)$ with $i=1,2,3$; (ii) $\alpha_1,\alpha_2,\ldots,\alpha_c$ and $\varepsilon_1,\varepsilon_2,\varepsilon_3$ are all independent. These assumptions are standard in the linear mixed-effect modelling framework (McCulloch and Searle, 2001).

Let $\beta=(\beta_1^\top,\beta_2^\top,\beta_3^\top)^\top$ and $\theta=(\sigma_c^2,\sigma_1^2,\sigma_2^2,\sigma_3^2)^\top$ be the unknown parameters in model (1). An unbiased estimator $\widehat{\gamma}=(\widehat{\beta}^\top,\widehat{\theta}^\top)^\top$ of $\gamma=(\beta^\top,\theta^\top)^\top$, can be obtained resorting on restricted (or residual) maximum likelihood (REML) estimation (McCulloch and Searle, 2001). Under some regularity conditions, the REML estimator $\widehat{\gamma}$ is consistent and asymptotically normal, with mean γ and covariance matrix Λ, i.e., $\widehat{\gamma}\dot{\sim}\mathcal{N}(\gamma,\Lambda)$. The asymptotic covariance matrix Λ can be consistently estimated by using the sandwich formula (Liang and Zeger, 1986).

3 The proposal

3.1 Covariate-specific ROC surface

According to model (1), the marginal distribution of Y_i, $i=1,2,3$, is normal with mean $z^\top\beta_i$ and variance $\sigma_c^2+\sigma_i^2$, i.e., $Y_i\sim\mathcal{N}(z^\top\beta_i,\sigma_c^2+\sigma_i^2)$ with $i=1,2,3$. Given two cut points t_1 and t_2 ($t_1<t_2$) and a vector z of covariates values, the TCFs are:

$$\begin{aligned}
\mathrm{TCF}_1(t_1;z) &= \Phi\left(\frac{t_1-z^\top\beta_1}{\sqrt{\sigma_c^2+\sigma_1^2}}\right),\\
\mathrm{TCF}_2(t_1,t_2;z) &= \Phi\left(\frac{t_2-z^\top\beta_2}{\sqrt{\sigma_c^2+\sigma_2^2}}\right)-\Phi\left(\frac{t_1-z^\top\beta_2}{\sqrt{\sigma_c^2+\sigma_2^2}}\right),\\
\mathrm{TCF}_3(t_2;z) &= 1-\Phi\left(\frac{t_2-z^\top\beta_3}{\sqrt{\sigma_c^2+\sigma_3^2}}\right),
\end{aligned}$$

where $\Phi(\cdot)$ is the cumulative distribution function of the standard normal distribution. Plugging the REML estimators $\widehat{\beta}_1,\widehat{\beta}_2,\widehat{\beta}_3,\widehat{\sigma}_c^2,\widehat{\sigma}_1^2,\widehat{\sigma}_2^2,\widehat{\sigma}_3^2$ into these expressions, leads to the estimators $\widehat{\mathrm{TCF}}_1(t_1;z)$, $\widehat{\mathrm{TCF}}_2(t_1,t_2;z)$ and $\widehat{\mathrm{TCF}}_3(t_2;z)$.

3.2 Selection thresholds methods

Under the given model setting, a covariate-specific optimal pair of thresholds (t_1^+,t_2^+) can be obtained by:

(i) maximizing the generalized Youden index $J_3(z)$ (GYI, Nakas et al, 2010), with

$$J_3(z) = \mathrm{TCF}_1(t_1;z) + \mathrm{TCF}_2(t_1,t_2;z) + \mathrm{TCF}_3(t_2;z); \tag{2}$$

(ii) minimizing the Euclidean distance $D_3(z)$ between the perfection point $(1,1,1)$ and $(\mathrm{TCF}_1(t_1;z), \mathrm{TCF}_2(t_1,t_2;z), \mathrm{TCF}_3(t_2;z))$ (CtP, Attwood et al, 2014), with

$$D_3(z) = \sqrt{[1-\mathrm{TCF}_1(t_1;z)]^2 + [1-\mathrm{TCF}_2(t_1,t_2;z)]^2 + [1-\mathrm{TCF}_3(t_2;z)]^2}; \tag{3}$$

(iii) maximizing the volume $V_3(z)$ of the cuboid under the ROC surface (MV, Attwood et al, 2014), with

$$V_3(z) = \mathrm{TCF}_1(t_1;z) \times \mathrm{TCF}_2(t_1,t_2;z) \times \mathrm{TCF}_3(t_2;z). \tag{4}$$

According to (2), (3) and (4), the covariate-specific objective functions $J_3(z)$, $D_3(z)$, $V_3(z)$ and the associated optimal pair of cut points (t_1^+, t_2^+) depend on γ. Plugging the REML estimator $\widehat{\gamma}$ into the expressions of $J_3(z)$, $D_3(z)$ and $V_3(z)$, leads to the estimated versions $\widehat{J}_3(z)$, $\widehat{D}_3(z)$ and $\widehat{V}_3(z)$. The estimators $(\hat{t}^+_{1,\mathrm{GYI}}, \hat{t}^+_{2,\mathrm{GYI}})$, $(\hat{t}^+_{1,\mathrm{CtP}}, \hat{t}^+_{2,\mathrm{CtP}})$ and $(\hat{t}^+_{1,\mathrm{MV}}, \hat{t}^+_{2,\mathrm{MV}})$ are obtained by maximizing $\widehat{J}_3(z)$ and $\widehat{V}_3(z)$, or minimizing $\widehat{D}_3(z)$, under the constraint $t_1 < t_2$. The optimization leads also to the covariate-specific estimated optimality statistics $\widehat{J}_3^+(z)$, $\widehat{D}_3^+(z)$ and $\widehat{V}_3^+(z)$ (e.g., $\widehat{J}_3^+(z)$ is the maximum of $\widehat{J}_3(z)$). Estimators $\widehat{J}_3^+$, $\widehat{D}_3^+$, $\widehat{V}_3^+$, $(\hat{t}^+_{1,\mathrm{GYI}}, \hat{t}^+_{2,\mathrm{GYI}})$, $(\hat{t}^+_{1,\mathrm{CtP}}, \hat{t}^+_{2,\mathrm{CtP}})$ and $(\hat{t}^+_{1,\mathrm{MV}}, \hat{t}^+_{2,\mathrm{MV}})$ are functions of the REML estimators. As a consequence, they are consistent and asymptotically normal. Delta method can be applied to obtain asymptotic variances and covariances (see also Schisterman and Perkins (2007)) as:

$$\mathbb{V}\mathrm{ar}\left(\widehat{H}^+\right) = \left(\frac{\partial H}{\partial \gamma^\top}\right) \Lambda \left(\frac{\partial H}{\partial \gamma^\top}\right)^\top, \tag{5}$$

$$\Sigma_{\hat{t}^+_{1,*}, \hat{t}^+_{2,*}} = \left(\frac{\partial t^+_{1,*}}{\partial \gamma^\top}, \frac{\partial t^+_{2,*}}{\partial \gamma^\top}\right) \Lambda \left(\frac{\partial t^+_{1,*}}{\partial \gamma^\top}, \frac{\partial t^+_{2,*}}{\partial \gamma^\top}\right)^\top, \tag{6}$$

where H stands, in turn, for J_3, D_3 or V_3, and the symbol $*$ stands for the name of the selection method (i.e., GYI, CtP and MV). The involved derivatives are:

$$\frac{\partial t^+_{m,*}}{\partial \beta^\top} = \left(\frac{\partial^2 H}{\partial t^+_{m,*} \partial t^+_{m,*}}\right)^{-1} \left(-\frac{\partial^2 H}{\partial t^+_{m,*} \partial \beta^\top}\right),$$

$$\frac{\partial t^+_{m,*}}{\partial \theta^\top} = \left(\frac{\partial^2 H}{\partial t^+_{m,*} \partial t^+_{m,*}}\right)^{-1} \left(-\frac{\partial^2 H}{\partial t^+_{m,*} \partial \theta^\top}\right),$$

$$\frac{\partial H}{\partial \gamma^\top} = \frac{\partial H}{\partial I}\frac{\partial I}{\partial \gamma^\top} + \frac{\partial H}{\partial t^+_{1,*}}\frac{\partial t^+_{1,*}}{\partial \gamma^\top} + \frac{\partial H}{\partial t^+_{2,*}}\frac{\partial t^+_{2,*}}{\partial \gamma^\top},$$

where I denotes the identity function, with $m = 1,2$. The plug-in method gives consistent estimates of quantities in (5) and (6). Confidence intervals for the entities of interest can be easily constructed by using the normal approximation.

4 Simulation study

We perform several simulation experiments to evaluate the performance of the discussed selection methods. Table 1 gives some results only, referring to the following scenario. The total number of clusters c is taken to be in the set $\{15,30,60\}$. Then, we consider a balanced setting, i.e., an equal size in each cluster, with $n_k \in \{4,10\}$. In the k-th cluster, the disease status of subjects is simulated from a multinomial distribution, $multinomial(n_k,(0.6,0.3,0.1))$. We consider a covariate X simulated from a uniform random variable $\mathscr{U}(-2,2)$. The parameters of model (1) are set to be $\beta_{01}=0.5$, $\beta_{11}=0.5$, $\beta_{02}=2$, $\beta_{12}=0.8$, $\beta_{03}=3.5$ and $\beta_{13}=1.1$. Variances of errors ε_i are set to be $\sigma_1^2=0.3$, $\sigma_2^2=0.8$, $\sigma_3^2=1.3$; σ_c^2, is set to be 0.2 or 1. This choice of variance components allows us to consider two different values for the intra-class correlation coefficient $ICC=\frac{\sigma_c^2}{\sigma_c^2+\sigma_\varepsilon^2}$, with $\sigma_\varepsilon=\frac{\sigma_1+\sigma_2+\sigma_3}{3}$. In particular, ICC equals 0.213 or 0.574, corresponding to the two values of σ_c^2.

Table 1 reports the estimated covariate-specific optimality statistics and the corresponding optimal pairs of thresholds, at $x=1.58$, over 1000 simulations. When the number of clusters and the cluster sizes are small ($c=15,30$ and $n_k=4$), biases are slightly large, but become smaller as the number of clusters and cluster sizes grow larger. The estimated asymptotic standard deviations are comparable with the Monte Carlo ones. Larger ICC values produce larger standard deviations. The empirical coverage probabilities of 95% confidence intervals become close to the nominal level when either the number of clusters or the cluster sizes increase.

Environment, Physics and Engineering

A hidden semi-Markov model for segmenting environmental toroidal data

Un modello a classi latenti semi-markoviane per l'analisi di dati ambientali toroidali

Francesco Lagona and Antonello Maruotti

Abstract Toroidal time series are temporal sequences of bivariate angular observations that often arise in environmental and ecological studies. A hidden semi-Markov model is proposed for segmenting these data according to a finite number of latent classes, associated toroidal densities. The model conveniently integrates circular correlation, multimodality and temporal auto-correlation. A computationally efficient EM algorithm is proposed for parameter estimation. The proposal is illustrated on a time series of wind and sea wave directions.

Abstract *Le serie storiche toroidali sono sequenze di osservazioni circolari bivariate che appaiono di frequente in studi ambientali ed ecologici. Un modello classi latenti semi-markoviane viene proposto per classificare questi dati secondo un numero finito di classi latenti, ognuna associata con una densità toroidale. Il modello è in grado di catturare simultaneamente la correlazione circolare, la multimodalità e l'auto-correlazione temporale dei dati.*

1 Introduction

Bivariate sequences of angles are often referred to as toroidal time series, because the pair of two angles can be represented as a point on a torus. These data often arise in environmental and ecological studies. Examples include time series of wind and wave directions [8], time series of wind mean directions and directions of the

maximum gust observed each day [2] and time series of turning angles in studies of animal movement [10].

The analysis of toroidal time series is complicated by the difficulties in modeling the dependence between angular measurements over time [7]. An additional complication is given by the multimodality of the marginal distribution of the data, because environmental toroidal data are observed under time-varying heterogeneous conditions.

This paper introduces a toroidal hidden semi-Markov model (HSMM) that simultaneously accounts for dependence across circular measurements, temporal autocorrelation, multimodality and latent time-varying heterogeneity. Under this model, the distribution of toroidal data is approximated by a mixture of toroidal densities, whose parameters depend on the evolution of a latent semi-Markov process. While the toroidal density accommodates dependence between two circular variables, a mixture of toroidal densities allows for multimodality and, finally, a latent semi-Markov process accounts for temporal correlation and, simultaneously, for time-varying heterogeneity.

Our proposal extends previous approaches that are based on toroidal hidden Markov models [9, 1]. Under a toroidal hidden Markov model, the data are approximated by a mixture of toroidal densities, whose parameters depend on the evolution of a latent, first-order Markov chain with a finite number of states. The sojourn times of each state of a Markov chain are distributed according a geometric distribution. Hence the most likely dwell time for every state of a hidden Markov model with underlying first-order Markov chain is 1. Our proposal relaxes this restrictive assumption by replacing the latent Markov chain with a latent semi-Markov model, allowing for sojourn times that are not necessarily geometrically distributed.

2 A hidden semi-Markov model for toroidal data

Let $\mathbf{z} = (x, y)$ be a pair of angles, $x, y \in [0, 2\pi)$. Moreover, let $f(x;\alpha)$ and $f(y;\beta)$ be two circular densities, respectively known up to the parameters α and β. Further, let $F(x;\alpha)$ and $F(y;\beta)$ be the two cumulative distribution functions of x and y, defined with respect to a fixed, although arbitrary, origin. Finally, let $g(u;\gamma), u \in [0, 2\pi)$ be a parametric circular density, known up to a parameter γ. Then,

$$f_q(\mathbf{z};\theta) = 2\pi g\left(2\pi\left[F(x;\alpha) - qF(y;\beta)\right]\right) f(x;\alpha) f(y;\beta) \quad q = \pm 1 \tag{1}$$

is a parametric toroidal density with support $[0, 2\pi)^2$, known up to the parameter vector $\theta = (\alpha, \beta, \gamma)$, having the marginal densities $f(x;\alpha)$ and $f(y;\beta)$ [3]. Equation (1) is a typical example of a copula-based construction of a bivariate density, obtained by decoupling the margins from the joint distribution. When the binding density g is the uniform circular distribution, say $g(x) = (2\pi)^{-1}$, then equation (1) reduces to the product of the marginal densities. Otherwise, the dependence between x and y is captured by the concentration of g: when g is highly concentrated, the de-

pendence is high; when g is more diffuse, dependence is low. Finally, the constant $q = \pm 1$ determines whether the dependence between x and y is positive ($q = 1$) or negative ($q = -1$).

The proposed hidden semi-Markov model can be described as a dynamic mixture of copula-based toroidal densities. To illustrate, let $\mathbf{z} = (\mathbf{z}_t, t = 1, \ldots, T)$, $\mathbf{z}_t = (x_t, y_t)$, $x_t, y_t \in [0, 2\pi)$, be a toroidal time series. We assume that the distribution of the data is driven by the evolution of an unobserved semi-Markov process with K states, which represents (time-varying) latent classes and can be specified as a sequence $\mathbf{u} = (\mathbf{u}_t, t = 1, \ldots, T)$ of multinomial variables $\mathbf{u}_t = (u_{t1} \ldots u_{tK})$ with one trial and K classes, whose binary components represent class membership at time t. The joint distribution $p(\mathbf{u}; \pi)$ of the chain is fully known up to a parameter π that includes K initial probabilities $\pi_k = P(u_{1k} = 1), k = 1, \ldots, K, \sum_k \pi_k = 1$, $K^2 - K$ transition probabilities $\pi_{hk} = P(u_{tk} = 1 | u_{t-1,h} = 1), h, k = 1, \ldots, K, \sum_k \pi_{hk} = 1, h \neq k$ (whereas $\pi_{kk} = 0$, $k = 1 \ldots K$), and, finally, p parameters of the dwell time distributions of each state.

The specification of the HSMM is completed by assuming that the observations are conditionally independent, given a realization of the semi-Markov process. As a result, the conditional distribution of the observed process, given the latent process, takes the form of a product density, say

$$f(\mathbf{z}|\mathbf{u}; \theta_1, \ldots, \theta_K) = \prod_{t=1}^{T} \prod_{k=1}^{K} f(\mathbf{z}_t; \theta_k)^{u_{tk}}, \tag{2}$$

where $f(\mathbf{z}; \theta_k), k = 1, \ldots, K$, are the K cylindrical densities defined by (1) and known up to a vector of parameters θ_k.

The likelihood function of the model is therefore obtained by integrating the joint density of the observed data and the unobserved class memberships with respect to the segmentation $\mathbf{u}$, namely

$$L(\pi, \theta; \mathbf{z}) = \sum_{\mathbf{u}} p(\mathbf{u}; \pi) f(\mathbf{z}|\mathbf{u}; \theta_1, \ldots, \theta_K). \tag{3}$$

By computing the maximum likelihood estimate $\hat{\theta}$, the toroidal time series can be segmented according to the posterior probabilities of class membership

$$\hat{\pi}_{tk} = P(u_{tk} = 1 \mid \mathbf{z}; \hat{\theta}), \tag{4}$$

based on $\hat{\theta}$. More precisely, the observation at time t can be allocated to class $k^\star$ if $\hat{\pi}_{tk^\star} \geq \hat{\pi}_{th}$, for each $h = 1 \ldots K$ (maximum a posterior, MAP, allocation).

When the dwell distribution of each latent state is geometric, the model reduces to a hidden Markov model that ignores alternative dwell time distribution. If, additionally, the transition probability matrix of the model has equal rows, the model reduces to a mixture model where observations are clustered by ignoring the information redundancy that is due to temporal correlation.

3 An application to marine data

The proposed methods have been implemented to segment a time series of $T = 1326$ semi-hourly wind and wave directions, taken in wintertime by the buoy of Ancona, which is located in the Adriatic Sea at about 30 km from the coast. Figure 1 displays the scatter plot of the data. Point coordinates indicate the direction (in radians) from which winds blow and waves travel. For simplicity, these bivariate observations are plotted on the plane, although data points are actually on a torus. The interpretation of these data is not easy. While in the ocean wind and wave directions are strongly correlated, this is not necessarily true in the Adriatic Sea, due to the orography of the basin and the location of the buoy. Coastal winds generate synchronized waves only when the waves travel unobstructed, that is, either northwesterly or southeasterly, along the major axis of the basin. When western and south-western winds blow from the coast, waves are not synchronized with wind and travel along the major axis of the Adriatic basin from SE to NW. This explains the clusters shown in Figure 1 and suggests the occurrence of two latent wind–wave regimes. Accordingly, a HSMM with two states have been estimated from these data.

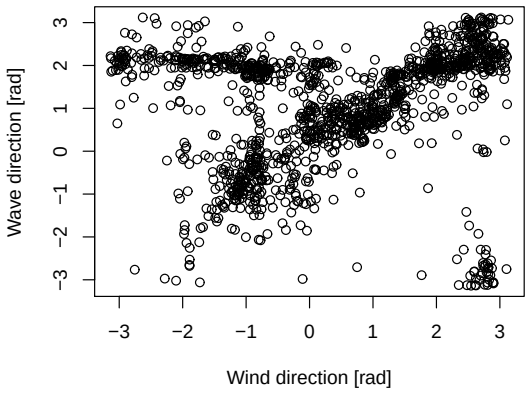

Fig. 1 Wave directions and heights, as observed by the buoy of Ancona in wintertime ($-\pi$, $-pi/2$, 0, $\pi/2$ respectively indicate South, West, North, East). For simplicity, the data are plotted on the plane, although they are points on the torus $[-pi/2, \pi/2)^2$.

The proposed HMM requires a parametric specification of the toroidal density (1), which reduces to the choice of the binding density g and the choice of the marginal densities $f(x;\alpha)$ and $f(y;\beta)$ that respectively model the marginal distribution of the wind and wave direction. However, depending on the choice of the binding density, the density (1) can be multimodal [4]. Using multimodal densities in segmentation and classification problems, such as the one motivating this paper,

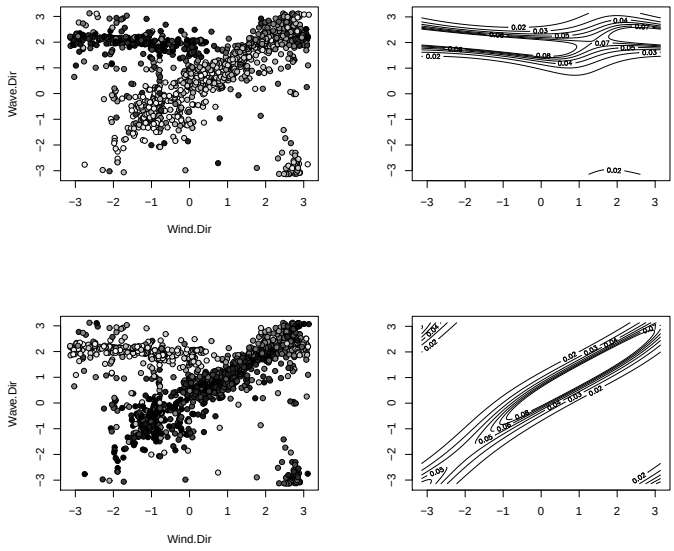

Fig. 2 Segmentation of a time series of wind and wave directions. Left: observations colored with grey levels according to the estimated membership probabilities of each class (black indicates a probability equal to 1). Right: contour plot of state-specific toroidal densities.

may unnecessarily complicate the interpretation of the results. Unimodal densities can however be obtained by using the wrapped Cauchy as a binding density g [4].

Accordingly, for this study, the binding density has been specified as a centered wrapped Cauchy

$$g(u;\gamma) = \frac{1}{2\pi}\frac{1-\gamma^2}{1+\gamma^2-2\gamma\cos(u)} \quad , \quad u \in [0,2\pi).$$

This circular density depends on a single concentration parameter $\gamma \in [0,1)$ and reduces to the uniform circular density when $\gamma = 0$.

Wrapped Cauchy densities that include additional location parameters α_1 and β_1 have been instead exploited to model the marginal distributions of wind and wave direction, say

$$f(x;\alpha) = \tfrac{1}{2\pi}\frac{1-\alpha_2^2}{1+\alpha_2^2-2\alpha_2\cos(y-\alpha_1)} \quad , \quad x \in [0,2\pi); \tag{5}$$

$$f(y;\beta) = \tfrac{1}{2\pi}\frac{1-\beta_2^2}{1+\beta_2^2-2\beta_2\cos(y-\beta_1)} \quad , \quad y \in [0,2\pi). \tag{6}$$

The proposed toroidal density is therefore obtained by taking a wrapped Cauchy density that binds wrapped Cauchy marginals, a model known as the bivariate wrapped Cauchy model [5].

Figure 2 shows the shapes of the two state-specific toroidal distributions and the segmented observations. The model successfully segment the observations according to two clusters, and offers a clear-cut indication of the distribution of the data under each regime. Under state 1, wind and wave directions are essentially independent, because coastal winds do not generate waves. Under state 2, winds blows along the major axis of the Adriatic basin and their directions are highly correlated with the directions of the wave that they generate.

Overall, the model describes the plasticity of the wind–wave interaction in the Adriatic Sea, indicating that the joint distribution of wind and wave data changes under different environmental regimes. Regime switching changes not only the modal directions and concentrations around these modes but also, and more interestingly, the correlation structure of the data. As a result, on the one side, the (marginal) weak correlation between wind and wave directions is explained by the presence of coastal winds (State 1). On the other side, the model indicates that the wind direction is an accurate predictor of the wave direction only under a specific regime (State 2). In summary, wind directions should not be used to predict wave directions, without accounting for the latent, environmental heterogeneity of the data under study.

represent an alternative to the main known BLE (Bluetooth low energy), Bluetooth, RFID (Radio frequency identification) and WIFI communications for short range distances. Scope of our work is very ambitious and aims to represent an interesting challenge path for innovation in data transmission without radio frequency and to analyze and implement relative security approach. A good indoor security level is reached, in fact, these kind of approach allows to border the transmission only to the room instead of radio frequencies (characterized by a better diffusion). Otherwise, these communication approaches can be useful to develop data communication for hostile environments where radio frequency can not be used (e.g. oil and gas environments). Possible applications of these two technologies are for anti-theft, tracking and surveillance purposes for devices, the remote control of mobile objects, the identification of objects using interfaces of internet of things, etc. However, it is important to analyze the possible vulnerabilities of these two technologies considering possible attacks and provide innovative methods for detection and prevention. Also the dynamic combination of these two data transmission mediums considering the environment parameters can be very useful to improve redundancy and reduce errors in data communication.

This paper is structured in four sections. In the second section visible light communication technology and approaches are described considering possible attacks and detection and prevention solutions. The same approach is followed for data over audio technology in the third section of the paper. Experimental results, conclusions and future development application are described in the fourth section.

2 Visible light communication

Visible light communication (VLC) operates, as the name implies, in the portion of the visible spectrum of light.

The visible spectrum is a part of the electromagnetic spectrum (EMI) with a wavelength ranging from ~ 700 (red) to ~ 400 (violet) nanometers with a frequency range between 428THz and 750THz.

The VLC technology has had an exponential growth in recent years, also given by the reduction in costs and the technical evolution of LED such as efficiency and brightness, therefore there is no approved standard defined by the IEEE (Institute of Electrical and Electronic Engineers).

The data are transmitted by modulating the light with a sequence of 0 and 1 through the use of light- emitting diodes (LED) while photodiodes, which are very sensitive to light, are mainly used as the receiver. Unfortunately, at low speeds the human eye will perceive a constant flickering of the light source. However, the LED modulating the light in an ultra- fast way, will be considered as a constant source in time without any variation.

The main data modulation techniques are: OOK (On-Off Keying), VPPM (Variable Pulse Position Modulation), CSK (Color shift keying).

The advantages of using VLC technology over radio frequencies consists in having an unlimited band (400nm - 700nm) without any regulation, it does not generate any electromagnetic interference, it is harmless for the human body and finally it has a higher transmission speed. It has been shown that through the laser diode based on gallium nitride (GaN) it is possible to reach a speed of 15 Gb/s with a distance of 15cm and 197cm respectively. The most commonly used slogan in the security field is "What You See Is What You Send" (WYSIWYS) so if there is an unauthorized device it would be easily recognizable through directionality and visibility. Although there is this assumption, VLC networks are not exempt from potential attacks. “Jamming” is an attack designed to disrupt communication so that the signal-to-noise ratio is reduced. In visible-spectrum communication, the jamming- based attack is easily implemented. To do it, it would be enough to have a higher light source (usually) than the transmitter that would disturb the transmitted data. Unfortunately, with this technique there are no effective solutions, except that of using another transmission medium like DoA in a coupled way. VLC networks can be subject to attacks such as the "man in the middle" (MIM) in which another device is interposed between the sender and the recipient for the purpose of secretly extracting the data and/or altering it by making people believe devices involved to have direct communication. In this case, it is sufficient to insert another device to be able to intercept the flow. The MIM attack can be countered by encrypting the data in both directions. The device that would like to obtain the data will no longer be able to decode them and therefore, it will be removed from the communication.

Arduino-based circuits have been created. The transmitter device is composed of a white LED flanked by a 220 Ohm resistor. On the receiver there are two voltage dividers with two photoresistors, which vary their resistance based on the amount of light that hits it and two 10KOhm resistors. The first photoresistor is directly hit by the LED that deals with transmitting the data, while the second detects the ambient light that will be subtracted from the first. The transmitter adopts an OOK data modulation. The two devices were placed at a distance of about 10cm. By inserting an interfering light source (Jamming) like the torch of the smartphone, it turns out to be very effective to disturb the signal and even to neutralize it. All messages sent were not received correctly.

As regards the MIM connection, another device has been placed in which both a photoresistor and an LED are present, so as to obtain the message from the transmitter and send it to the receiver altering its contents. Even this attack was successful without the devices noticing a third device.

3 Data Over Audio

DoA (Data over audio) is a technology that allows data to be sent between devices via audible or inaudible audio signals to man, maintains the advantages of wired indoor networks allowing the creation of private networks, limited and without

electromagnetic pollution while maintaining convenience of wireless networks based on RF technology.

The information to be transmitted is enriched with information useful for transmission (eg timestamp, sender), followed by encryption to preserve security and subsequently algorithms are used to preserve the loss of information (eg reed-solomon codes). The information is transformed into audio frequencies and then sent. The amount of information that can be sent depends on the frequency range you want to use and on the number of devices you want to communicate simultaneously. Some examples of the communication speed: 7bytes in 3s(ultrasonic, multi-channel), 8bytes in 4s(ultrasonic, single-channel), 32bytes(acoustic, single-channel).
Once the communication is started, algorithms are used to clean up the sound from the background noise and from frequencies not relevant to the communication, finally the sound is saved and transformed back in the original information.

The range of action of the communication depends on the frequencies used, the capacity of the speakers and the background noise. The DDos (Distributed Denial of Service) attack consists of one or more devices within the range of a DoA communication that during this communication send audio signals with the purpose of blocking the transmission of data by interposing its audio signal to that of communication. Algorithms like reed-solomon codes to reduce errors in communication, combined with algorithms to distinguish to noises unrelated to DoA communications, can be useful against DDoS attacks, even though this technology is still weak to such attacks. An interlocutor placed between the DoA-DoA communication (emitter and receiver side) can represent an elusive factor of some systems. The DoA receiver will read the signal through a special microphone and will authenticate. However, if the signal doesn't arrive directly to the receiver but is transmitted remotely, it could be a communication interposed between the emitter and the final DoA receiver (e.g. with the use of RF or VOIP). A method based on a comparison between frequencies constituting an original signal and a radio transmitted signal can be an effective anti-elusive method. An identifying footprint of the real presence of a radio broadcast can be represented by the White Gaussian Noise Additive (AWGN) that is present in every radio broadcast. In the electronic field, a manifestation of these signals is described as thermal noise. The observation of this phenomenon can be physically implemented on the receiving side through a device suitable for monitoring a resistor to which no voltage is applied. Instead with AWGN's presence thermal agitation occurs which generates a noise voltage that varies over time and depending on the temperature. By controlling this resistor is therefore possible to perceive whether the received signal is or is not an attempt to circumvent the DoA system as a function of the voltage at its ends. Thermal agitation is not entirely deterministic, which is why the AWGN is described by a random variable and an average zero value and by its white spectrum as it's flat in a wide range of frequencies. A device equipped with a special anti-elusive system based on scanning and frequency comparison between a reference and the received signal, would make it possible to interpret the incoming signal and perform a check before giving an output. Thus, even managing to evade the first authentication, a second check based on the analysis of the signal spectrum arriving at the receiver would

exclude the possibility of remote elusion; for the prevention of recorded messages, a possible solution concerns the timestamp sent in the encrypted audio message, this added data allows to have an audio sent always different and allows to assign a deadline to the message.

4 Experimental results and conclusions

Real experiments with application of DoA have been conducted for safety in construction site areas (Caldarola patent), in home automation lamps (Thegg Domotica patent) and for coffee vending machines (Coffee Express patent). In the first case study an "ALT" alert is revealed by the fleet in critical areas. The simulation and monitoring of the site areas is made through the use of DoA emitters which allow to have a rigorous control of action areas through augmented reality alerts in the earth moving machinery HMIs. In the second case study the lamp is managed through DoA, in the third case study the vending machine interaction is provided by DoA channel.

Figure 1: DoA experimental Case Study

To provide an extimation of perfomances we have implemented a test scenario with the use of DoA and VLC communication channel. We have used as input the AIN Thesaurus, characterized by over 1200 adjectives and adverbs of Italian language. We have also considered the application of AES cryptography to AIN Theasurus strings. Considering a distance of 0,5 m the DoA performance with a basic microphone (SunFounder Mini Microphone) reaches 97,4%. The transmission rate is 4,52s/32bytes. Some problems of decoding are obtained with the use of AES. In this case the string is characterized by 64 bytes. Different results are obtained with the use of VLC technology, that reaches 99,1% of performance without the use of

cryptography till a distance of 0,5 meters. It represents an emerging challenge to a correct performance estimation.

Table 1: Estimated Performances Results

Input Test Set	Distances	Technology	Estimated Performance
AIN Thesaurus	2 m	DoA	88,3%
AES + AIN Thesaurus	2 m	DoA	56,9%
AIN Thesaurus	0,5 m	DoA	97,4%
AES + AIN Thesaurus	0,5 m	DoA	78,3%
AIN Thesaurus	0,5 m	VLC	99,1%
AES + AIN Thesaurus	0,5 m	VLC	91,5%

These technologies have been the subject of experimental green approaches conducted in some companies of southern Italy. These prototype technologies have represented an important solution in communication field in environments characterized by an explosive atmosphere studied, like in the case of L'Antincendio (Colucci, M., 2019). In this hostile environment there is a mixture of flammable substances in which the radiofrequency can represent a source of ignition. The implementation of an environmental monitoring station that communicates via a VLC-DoA experimental hybrid gateway represented a possible solution for these environments. These technologies represent a considerable commitment in terms of corporate social responsibility (Barile, A., 2019). An other important development is about the communication in a green accommodation area as that of Matera Inerti using a disused aggregate quarry (Antonello Ribba's patent). These case studies represent an evidence of the space available for new challenge in industrial research and experimental development of solutions which require performance estimation.

An improved sensitivity-data based method for probabilistic ecological risk assessment

Un metodo efficiente per la valutazione probabilistica del rischio ecotossicologico basato su dati di sensitivitá

Sonia Migliorati and Gianna Serafina Monti

Abstract Ecological risk assessment procedures are essentially based on Species sensitivity distributions (SSDs), a community-level concentration-response curve. In this contribution we propose a new definition of SSD as a finite mixture of log-logistic distributions, which integrates all the information available in the toxicity dataset, in a conservative perspective. We provide parameter estimation within a Bayesian MCMC approach. Furthermore, we propose the derivation of a more realistic hazardous chemical concentration HCp, the concentration protective of $(1-p)\%$ species in the environment. An application of our methods to real data completes the work.

Abstract *Le distribuzioni di sensibilitá delle specie (SSD) rispetto alle concentrazioni di un certo agente tossico sono sempre piú integrate nelle procedure di valutazione del rischio ecotossicologico. In questo contributo, in un'ottica conservativa nella valutazione del rischio ecotossicologico, viene proposta una nuova definizione di SSD basata su una mistura finita di distribuzioni log-logistiche, in grado di valorizzare il contributo informativo contenuto nei dati, sia a livello di specie testate che di modalitá d'azione delle sostanze tossiche. L'inferenza é condotta secondo un approccio Bayesiano. Viene fornito quindi un modo alternativo per la stima di HCp, ovvero della concentrazione protettiva per l'*$(1-p)\%$ *delle specie nell'ambiente di riferimento, su cui potranno basarsi le decisioni normative. Un caso applicativo mostra l'efficacia del metodo proposto.*

1 Species Sensitivity Distributions in risk assessment

Species Sensitivity Distributions (SSDs) are a widespread method for ecotoxicological risk assessment of chemicals (Posthuma et al., 2002). An SSD model relates the variation in the tolerance of tested species to a specific compound.

Let n denote the number of different species tested with respect to a certain chemical compound $i\,(i = 1,\ldots,k)$, and let $y_{ij}\,(j = 1,\ldots,n)$, denote the effective concentration data, generally log(base 10)-transformed, of the j^{th} species under study. The value y_{ij} refers to a specific toxicity endpoint derived from a single-species toxicity study, for example a median effective/hazardous concentration value (EC50), or a no observed effect concentrations (NOEC). Once the data are arranged in non-decreasing order, let $x_{ij} = i/(n+1)$ indicate the relative rank of each species, also called Weibull plotting positions.

A generic model formulation to fit a probabilistic SSD curve to the observed data can be written as:

$$SSD_i = F_i(y;\boldsymbol{\theta}), \qquad (i = 1,\ldots,k) \tag{1}$$

where $F_i(.;\boldsymbol{\theta})$ is the cumulative distribution function that describes the relationship between the (transformed) species concentration levels, y, and the corresponding plotting positions, whereas $\boldsymbol{\theta}$ is the unknown model parameter vector.

Several distributions were proposed to fit an SSD model. A log-normal distribution is used by the European Commission (Wagner and Lokke, 1991; ECHA, 2008) and it is considered the standard choice for SSD model (Aldenberg and Jaworska, 2000; Posthuma et al., 2002). Though, Newman et al. (2000) pointed out the scarcity of goodness of fit of a log-normal model in several examples. An alternative model is the log-logistic distribution (Aldenberg and Slob, 1993; Wheeler et al., 2002), especially adequate from a conservative perspective, thanks to its extended tails. In this case the parameter vector $\boldsymbol{\theta}$ is equal to (μ, σ), where μ is the location parameter and σ the scale parameter.

SSDs are generally used to assess the degree of hazard posed by a given chemical to species, represented by hazardous chemical concentration (HCp), that is a concentration harmful to the p% of species in a given assemblage. Particular attention is deserved to the estimate of HC5, as it corresponds to an estimate of a predicted no effect concentration (PNEC), frequently used in environmental risk assessment. Several methods are present in literature to obtain HCp estimates. Let's briefly remember the one proposed by Aldenberg and Slob (1993), based on a log-logistic distribution, i.e.

$$\widehat{\text{HC5}}_{AS} = \bar{y} - \kappa_n s \tag{2}$$

where $\bar{y}$ and s are the sample mean and standard deviation of the observed endpoints respectively, and κ_n is an extrapolation factor, tabulated for various sample sizes n.

2 Hierarchical species sensitivity distribution

One of the structural problems when attempting to apply the SSD approach to ecological risk assessment is the scarcity of available data. To overcome this limit, we propose here to incorporate all available information into a hierarchical model for SSDs expressed by

$$\begin{aligned} & y_{ij}|\mu,\delta_i,\gamma_j,\sigma^2 \sim \text{Logistic}(\mu+\delta_i+\gamma_j,\sigma^2), \\ & \mu|\sigma_\mu \sim \text{N}(0,\sigma_\mu^2), \\ & \delta_i|\sigma_\delta \sim \text{N}(0,\sigma_\delta^2), \quad \text{(random substance effect)}, \\ & \gamma_j|\sigma_\gamma \sim \text{N}(0,\sigma_\gamma^2), \quad \text{(random species effect)}, \end{aligned} \tag{3}$$

where y_{ij} is the log-(base 10) toxicity value for compound i, ($i = 1,\ldots,k$), tested on species j ($j = 1,\ldots,n$). Thus, and differently from the standard approach, we let substance and species effects to be represented by random effects with a dedicated variance parameter. Hence, for each substance-species combination (i,j) the residuals are a random sample from a distribution centered about zero with homogeneous variance σ^2 that is independent of experimental conditions, chemical, and species.

In a Bayesian perspective, the (weakly informative) hyper-prior distributions can be assigned as follows:

$$\sigma \sim \text{Uniform}(0,100),\ \ \sigma_\delta \sim \text{Uniform}(0,100),\ \ \sigma_\gamma \sim \text{Uniform}(0,100)\,. \tag{4}$$

furthermore we set σ_u to a high value. The posterior distributions of the parameters of interest are obtained via Markov chain Monte Carlo (MCMC) methods.

By considering substances and species effects as random, we succeed in enriching the model variability structure, usually represented by σ^2 (i.e. the measurement error), by two further components, namely $\sigma_\delta^2, \sigma_\gamma^2$ (Gelman, 2015). The latter account for variability between substances and between species.

Thus, the proposed SSD for substance i, namely $\text{MSSD}_i(y)$, can be expressed in terms of the hierarchical model (3) as a finite mixture of logistic CDFs:

$$\text{MSSD}_i(y) = \frac{1}{n}\sum_{j=1}^{n} F_{ij}\left(y;\mu+\delta_i+\gamma_j,\sigma^2\right). \tag{5}$$

Furthermore, the posterior CDF of the hazardous concentration HCp can be estimated from the posterior of $\text{MSSD}_i(y)$ by observing that, given a value y, the following equality holds

$$P(\text{MSSD}_i(y) \le p) = P(\text{HCp}_M \ge y)\ . \tag{6}$$

Therefore, the CDF of HCp_M at point y can be estimated by the proportion of MCMC sample values of $\text{MSSD}_i(y)$ that are greater than or equal to p. To better

reflect uncertainty in the estimate, essentially due to small sample size, we propose to calculate the lower one-tailed 95% confidence limit.

3 An application to real toxicity data

3.1 Data description

To demonstrate the effectiveness of our procedure we considered data from Versteeg et al. (1999), related to a variety of substances ($k = 11$), including heavy metals, pesticides, surfactants, and general organic and inorganic compounds, tested on several species $n = 56$. This is an unbalanced design, as some species have not been tested on all chemicals. Multiple data for the same species were summarised as geometric means using the NOEC or EC20 concentration.

3.2 Implementation and results

We run three MCMC chains in parallel. For each chain, after a burn-in period of 5,000 samples, to reach stationarity of the chain, 10,000 samples of the random variables were generated with a thinning rate of 50, i.e. we discarded all but every 50-th observation, with the goal of reducing autocorrelation. All analyses were performed using R and OpenBUGS softwares (R Core Team, 2019; Lunn et al., 2000).

In Figure 1 we show the autocorrelation plots and partial time series plots of the parameters σ, σ_γ and σ_δ, which are typical diagnostic tools used to assess convergence.

To appreciate the well-fitting of the $\text{MSSD}_i(y)$, given by (5), let us consider Figure 2, which shows both the MSSD and the standard log-logistic SSD, together with their 90% pointwise confidence bands for three different toxic compounds. The log-logistic SSD confidence bands are obtained using 1000 bootstrap resamples. The proposed model clearly improves the fit of the log-logistic model, as it better captures the variability of sample data gathering information from differences in sensitivity of the selected sample species.

We summarised and compared the results of our analyses by using HC5 point estimates with associated lower 95% confidence intervals (one tailed) (Table 1).

In particular we calculated the sample quantile $\widehat{\text{HC5}}_q$, the HC5 estimated according to Aldenberg and Slob (1993) (see (2)) and its lower left-sided 95% confidence limit (one tailed), i.e. $\widehat{\text{HC5}}_{AS}$ and $\widehat{\text{HC5}}_{ASL}$ respectively, and $\widehat{\text{HC5}}_M$ computed according to (6) along with its lower left-sided 95% confidence limit $\widehat{\text{HC5}}_{ML}$.

As we might expect, the lower left-sided 95% confidence limit of HC5 estimate given by our model gives a reasonable estimate of the PNEC. Indeed, $\widehat{\text{HC5}}_{ML}$ is

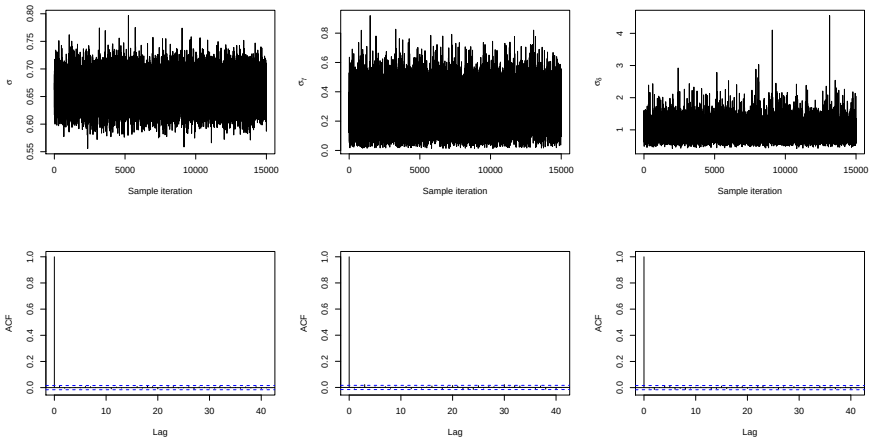

Fig. 1 Diagnostic tools to assess convergence of MCMC samples with respect to the parameters (from left to right) σ, σ_γ and σ_δ. Upper panels: time-series plots (after the burn-in period and thinning regime). Lower panels: autocorrelation functions.

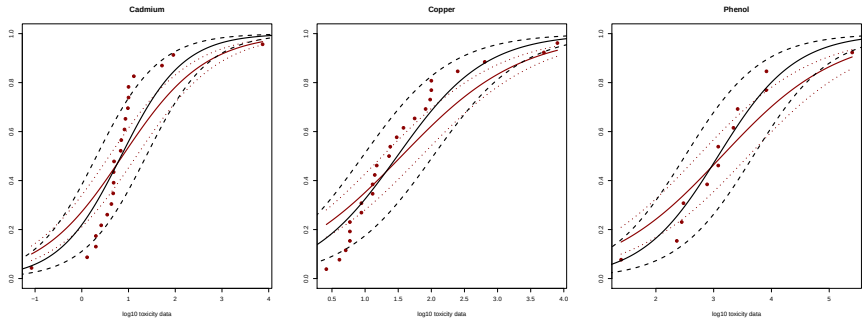

Fig. 2 Fitted SSD curves for three toxic compounds. Log-Logistic SSD with 90% bands (dark red solid and dashed lines), MSSD with 90% pointwise confidence bands (solid and dashed black lines). Points correspond to log-NOEC data of tested species.

always lower than $\widehat{\text{HC5}}_q$, but higher than $\widehat{\text{HC5}}_{ASL}$, thus realizing a good compromise between the two existing proposals.

Comparing predictive distributions in EMOS

Distribuzioni predittive per modelli EMOS

Giummolè Federica and Mameli Valentina

Abstract EMOS models are widely used post-processing techniques for obtaining predictive distributions from ensembles for future weather variables. A predictive distribution can be easily obtained by substituting the unknown parameters with suitable estimates in the distribution of the future variable, thus obtaining a so called estimative distribution. Nonetheless, these distributions may perform poorly in terms of coverage probability of the corresponding quantiles. In this work we propose the use of calibrated predictive distributions in the context of EMOS models. The proposed calibrated predictive distribution improves on estimative solutions, producing quantiles with exact coverage level. A simulation study assesses the goodness of the calibrated predictive distribution in terms of coverage probabilities and also logarithmic score and CRPS.

Abstract *I modelli EMOS forniscono un metodo per ottenere distribuzioni predittive a partire da un insieme di previsioni per una variabile meteorologica di interesse. Una distribuzione predittiva si può ottenere facilmente sostituendo i parametri non noti con delle stime opportune nella distribuzione della variabile futura. Questa procedura dà origine alle cosiddette distribuzioni estimative che però spesso risultano inadeguate in quanto la probabilità di copertura associata ai loro quantili differisce da quella nominale. In questo lavoro proponiamo, nel contesto dei modelli EMOS, una distribuzione predittiva calibrata che fornisce quantili la cui probabilità di copertura coincide con quella nominale. Uno studio di simulazione evidenzia la bontà della predittiva proposta, sia in termini di probabilità di copertura che rispetto alle funzioni di perdita logaritmica e CRPS.*

1 Introduction

In modern society, weather conditions have wide-ranging economic impacts in fields as diverse as aviation, shipping, tourism and agriculture, just to name a few. All these important applications require accurate forecasts of future weather conditions. Weather forecasts are usually provided as forecast ensembles obtained from multiple numerical models achieved using different initial conditions and different numerical representations of the atmosphere [8]. However, such ensemble forecasts are able to capture only part of the forecast uncertainty exhibiting dispersion errors and systematic biases [7], [2]. For this reason, ensemble forecasts are often statistically post-processed to produce calibrated predictive distributions. Many statistical post-processing methods have been proposed in the literature. The most popular are the ensemble model output statistics (EMOS) that allow for probabilistic forecasts of continuous weather variables ([4]). EMOS is nothing but a linear regression model with heteroschedastic Gaussian errors. The EMOS mean is a linear combination of the ensemble member forecasts, with unknown coefficients that represent the contributions of each member of the ensemble to the interest weather variable. The EMOS variance is a linear function of the ensemble variance that accounts for spread relationship. More precisely, it is assumed that a weather continuos variable Y depends on the ensemble forecasts $X_1,\dots,X_m$ in such a way that its mean is equal to $\beta_0+\beta_1X_1+\ldots+\beta_mX_m$ and its variance is equal to $\gamma+\delta S^2$, where $S^2=\frac{1}{m-1}\sum_{i=1}^{m}(X_i-\bar{X})^2$ denotes the ensemble variance and $\beta_0,\dots,\beta_m$, $\gamma>0$ and $\delta>0$ are unknown coefficients. Under normality assumptions, the distribution of Y is $N(\beta_0+\beta_1X_1+\ldots+\beta_mX_m,\gamma+\delta S^2)$. Suitable estimates are then substituted to the unknown parameters, obtaining what is known as an estimative distribution for the future weather quantity Y:

$$N(\hat{\beta}_0+\hat{\beta}_1X_1+\ldots+\hat{\beta}_mX_m,\hat{\gamma}+\hat{\delta}S^2),$$

where $\hat{\beta}_0,\hat{\beta}_1,\dots,\hat{\beta}_m,\hat{\gamma}$, and $\hat{\delta}$ are suitable estimates of $\beta_0,\beta_1,\dots,\beta_m,\gamma$, and δ, respectively.

Unknown parameters can be estimated using the method of maximum likelihood or of minimum Continuous Ranked Probability Score (CRPS), which respectively optimise the logarithmic score and the CRPS, see [5, 6].

Unfortunately, an estimative distribution can lead to poor prediction statements, since it does not take into account for the uncertainty introduced by substituting estimates to the true parameter values. In particular, the coverage of prediction intervals obtained by the estimative distribution does not achieve the nominal coverage level, see [1, 3].

In this work we recommend for the EMOS model the use of a calibrated predictive distribution based on a bootstrap procedure proposed by [3], which improves on the estimative solution. On a simulation study, we compare the Gaussian estimative distributions obtained with minimum CRPS estimates and maximum likelihood estimates with their calibrated counterparts. We show that the calibrated predictive distributions always improve on the estimative ones in terms of coverage of pre-

diction intervals and of logarithmic score. As regards the CRPS, all the considered distributions perform in a similar way.

2 Calibrated predictive distributions

In this section we briefly review, in the context of EMOS models, the calibrating approach proposed by [3], which provides predictive distributions whose quantiles give well-calibrated coverage probability.

Suppose that $\{Y_i\}_{i\geq 1}$ is a sequence of independent continuous random variables with probability distribution specified by the EMOS model:

$$Y_i \sim N(\beta_0+\beta_1 x_{i1}+\ldots+\beta_m x_{im}, \gamma+\delta s_i^2), \quad i\geq 1,$$

where x_{ij} is the i-th value of the ensemble variable X_j, $j=1,\ldots,m$, s_i^2 is the ensemble variance of $x_{i1},\ldots,x_{im}$, and $\theta=(\beta_0,\beta_1,\ldots,\beta_m,\gamma,\delta)$ is the unknown parameter vector. We assume that $Y=(Y_1,\ldots,Y_n)$, $n>1$, is observable, while $Z=Y_{n+1}$ is a future or not yet available variable. We indicate with $\Phi(z;\theta)$ the Gaussian cumulative distribution function of Z.

Given the observed sample $y=(y_1,\ldots,y_n)$, an α-prediction limit for Z is a function $c_\alpha(y)$ such that, exactly or approximately,

$$P_{Y,Z}\{Z\leq c_\alpha(Y);\theta\}=\alpha, \tag{1}$$

for every $\theta\in\Theta$ and for every fixed $\alpha\in(0,1)$. The above probability is called coverage probability and it is calculated with respect to the joint distribution of (Z,Y).

Consider a suitable asymptotically efficient estimator $\hat{\theta}=\hat{\theta}(Y)$ for θ and the estimative prediction limit $z_\alpha(\hat{\theta})$, which is obtained as the α-quantile of the estimative distribution function $\Phi(\cdot;\hat{\theta})$. The associated coverage probability is

$$P_{Y,Z}\{Z\leq z_\alpha(\hat{\theta}(Y));\theta\}=E_Y[\Phi\{z_\alpha(\hat{\theta}(Y));\theta\};\theta]=C(\alpha,\theta) \tag{2}$$

and, although its explicit expression is rarely available, it is well-known that it does not match the target value α even if, asymptotically, $C(\alpha,\theta)=\alpha+O(n^{-1})$, as $n\to+\infty$, see e.g. [1]. As proved in [3], the function

$$G_c(z;\hat{\theta},\theta)=C\{\Phi(z;\hat{\theta}),\theta\}, \tag{3}$$

which is obtained by substituting α with $\Phi(z;\hat{\theta})$ in $C(\alpha,\theta)$, is a proper predictive distribution function, provided that $C(\cdot,\theta)$ is a sufficiently smooth function. Furthermore, it gives, as quantiles, prediction limits $z_\alpha^c(\hat{\theta},\theta)$ with coverage probability equal to the target nominal value α, for all $\alpha\in(0,1)$.

The calibrated predictive distribution (3) is not useful in practice, since it depends on the unknown parameter θ. However, a suitable parametric bootstrap estimator for

$G_c(z;\hat{\theta},\theta)$ may be readily defined. Let y^b, $b=1,\ldots,B$, be parametric bootstrap samples generated from the estimative distribution of the data and let $\hat{\theta}^b$, $b=1,\ldots,B$, be the corresponding estimates. Since $C(\alpha,\theta)=E_Y[\Phi\{z_\alpha(\hat{\theta}(Y));\theta\};\theta]$, we define the bootstrap calibrated predictive distribution as

$$G_c^{boot}(z;\hat{\theta})=\frac{1}{B}\sum_{b=1}^{B}\Phi\{z_\alpha(\hat{\theta}^b);\hat{\theta}\}|_{\alpha=\Phi(z;\hat{\theta})}. \tag{4}$$

The corresponding α-quantile defines, for each $\alpha\in(0,1)$, a prediction limit having coverage probability equal to the target α, with an error term which depends on the efficiency of the bootstrap simulation procedure.

3 A simulation study

In order to assess and compare the performance of the estimative and the calibrated predictive distributions for the EMOS model we perform several experiments with simulated ensembles. The ensemble members are drawn from a m-variate normal distribution with zero mean and identity covariance matrix, with $m=5,10,15$. The i-th observation is generated from a normal random variable with mean $\beta_0+\sum_{j=1}^{m}\beta_j x_{ij}$ where $\beta_j=(j+1)/\sum_k\beta_k$, $j=0,\ldots,m$, and variance $\gamma+\delta s_i^2$, with $\gamma=0$ and $\delta=1$, $i=1,\ldots,n$ with $n=20$. The bootstrap procedure is based on 500 bootstrap samples. The estimation is based on 1000 Monte Carlo replications. We evaluate the estimative and calibrated predictive distributions in terms of coverage probabilities and also using the logarithmic score and CRPS as loss functions, as commonly used in the literature, see [4, 9]. It should be noted that the calibration procedure is based on asymptotic considerations. Thus the improvement over estimative results is more evident with small sample sizes. Here we have chosen $n=20$, having in mind to use the 20 most recent daily observations of a meteorological variable as the training period for estimating the EMOS model parameters, see [4].

Table 1 provides the results of a simulation study for comparing coverage probabilities of 66.7% and 90% central prediction intervals obtained from the estimative and the calibrated distributions with minimum CRPS and maximum likelihood estimates. For this aim, we consider prediction limits of levels $\alpha=0.05,0.167,0.833$, and 0.95. It can be noted that the coverage probabilities associated to the calibrated quantiles almost equal the nominal values, showing accurate coverage. Average width of prediction intervals, not shown here, demonstrates that the calibrated predictive distributions yield slightly longer prediction intervals with respect to the estimative ones, but this can be explained by the greater coverage of these prediction intervals.

We assess the improvement of the calibrated predictive distributions over the estimative ones by computing also the logarithmic score and the CRPS, averaged over 1000 replicates, as shown in Table 2. The superior performance of the calibrated dis-

tributions is reflected in the values of the logarithmic score. Indeed average values of the logarithmic score for estimative distributions are significantly worse with respect to their calibrated counterparts. In terms of the CRPS, the estimative solutions perform similarly to the calibrated ones.

4 Conclusions

This work proposes a comparison between estimative and calibrated predictive distributions based on a bootstrap resampling procedure. The comparison is carried out on a simulation study, where appropriate verification measures, such as the CRPS, logarithmic score and coverage probabilities, are used for assessing the predictive performance of the considered distributions. From the results one can conclude that the calibrated predictive distributions always improve on the estimative ones, in terms of logarithmic score and coverage. Instead, the considered predictive distributions perform similarly with respect to the CRPS. Future development of the work will explore sliding training periods of constant size in the same way as in the work of [4]. Moreover other verification measures will also be considered.

Compositional analysis of fish communities in a fast changing marine ecosystem

Analisi composizionale di comunità ittiche in un ecosistema marino in rapida evoluzione

M. Mingione, P. Alaimo Di Loro, G. Jona Lasinio, S. Martino, F. Colloca

Abstract Concerns about the effects of human activities and climate change on the Mediterranean marine ecosystem are recently demanding new research work on the response of fish communities to environmental pressures to which they are subjected. The main limitation of standard statistical approaches is that they cannot properly account for the complex interactions occurring among sub-populations. In this work, we analyze a community of 129 demersal fish species living in front of the Lazio coast. The goal is to understand if the compositions changed over time and, if so, verify any statistical relationship with changes in water temperature. Results show that this area of Mediterranean Sea is undergoing a slow but progressive meridionalization of the fish inhabiting its waters.

Abstract Le preoccupazioni dovute agli effetti delle attività umane e del cambiamento climatico sull'ecosistema marino del Mediterraneo hanno recentemente richiesto nuovi lavori di ricerca sulla risposta delle comunità ittiche alle pressioni ambientali di cui soffrono. Le limitazioni principali degli approcci statistici standard è che non possono adeguatamente gestire la complessità delle interazioni che si osservano tra sottopopolazioni. In questo lavoro, studiamo una comunità di 129 specie di pesci demersali che abitano la costa del Lazio. Lo scopo principale è quello di capire se le composizioni siano cambiate nel tempo e, nel caso, verificare possibili relazioni statistiche con variazioni della temperatura. I risultati mostrano che questa zona del Mediterraneo sta subendo una lenta ma progressiva meridionalizzazione dei pesci che la abitano.

1 Introduction

A thorough knowledge of fish diversity, distributions and habitat requirements is essential to the management of fisheries and conservation of species. In this respect, several attempts have been made to quantify the abundance of species in specific areas, their distribution and which factors affect the richness and biodiversity of the habitat [4; 3; 8]. In large part of the previous statistical modeling efforts, species have been usually considered individually or biodiversity has been generally quantified in terms of a single summary index. This implicitly neglects the well-established fact that species interact with each other and these interactions influence the assembly of the community. Moreover, analysis in terms of biodiversity indices is not able to detect whether some groups or species replaced others while keeping constant the overall diversity of the community. This means that eventual changes in the structure of the community must be verified considering simultaneously all its components. When dealing with such an high-dimensional outcome, standard multivariate models fail to account properly for the natural relationships among the single components of the response. Furthermore, the information of major interest in this study lies in the relative magnitude between the size of sub-groups, and not in their absolute values. When this is the case case, the outcomes can be expressed as portions of a total and are therefore more adequately modeled through the techniques of compositional analysis [1].

2 Data

We analize data gathered in the context of the MEDITS program [2]. We consider the $n = 40$ fishing stations sampled in front of the Lazio coast (Tyrrhenian Sea) from 1995 to 2015. Locations can be divided into 2 classes according to their depth: the 22 locations at depth $< 200m$ have been classified as *shelf*[1]; the remaining 18 locations at depth $\geq 200m$ have instead been labeled as *slope*. We only consider data for fishes (teleosteans and selaceans) including a total amount of 129 different species. For each of them, the number of sampled individuals and their weight are recorded for each year at each fishing station. The same data have been previously analyzed in [6], which focused on the temporal evolution of the biodiversity in the same area; while this study did not highlight any relevant temporal pattern, we cannot exclude substantial variations in terms of the individual components that constitute the community. In order to reduce the dimensionality of the outcome, species have been grouped together according to the habitat they prefer. This classification identifies 3 different groups: subtropical (S), subtropical-temperate (ST) and temperate (T). T species are the most common in this area of the Mediterranean Sea and it is most represented in the sample with 84 different species ($\approx 64\%$ of the entire catch). S species are the second component in magnitude, counting 38 species ($\approx 32\%$ of the entire catch). ST is a midway class composed only by 7 of the sampled species ($\approx 4\%$), characterised by species with good adaptability to different habitats. Additional information about temperature has been included from MyOcean database [9]. In particular, we added the quarterly average surface temperature recorded each year at each location. Figure 1 shows a progressive increase of the temperature of the four quarters temperatures between 1995 and 2017. In this study, we try to understand if and which groups of species are already (directly or indirectly) affected by the

[1] According to standard nomenclature, this depth class should include both shelf and edge.

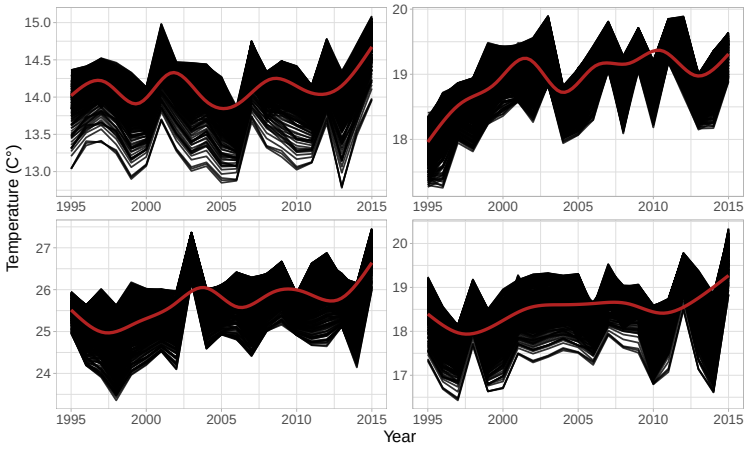

Fig. 1 Time series of the quarterly T1, T2, T3 and T4 average surface temperatures at 40 fishing stations in the study area, from top left panel to right bottom panel respectively.

rapidly evolving climatic condition of the Mediterranean Sea, pushing toward the meridionalization of its habitat and fauna [5].

3 Modeling compositional data

Whenever we are dealing with a collection of variables $\mathbf{s} = (s_1, s_2, \ldots, s_D) \in \mathbb{R}_+^D$ that represent the different parts of a whole, we can treat them as compositions. The compositional approach assumes that the relevant information contained in such data is associated only to the relative magnitude of the parts and not to their absolute value. When this is the case, we can discard all the unimportant information and achieve interpretability in terms of composition by standardizing the collection $\mathbf{s}$ through the closure operator $\mathscr{C}(\cdot)$:

$$\tilde{\mathbf{s}} = \mathscr{C}(\mathbf{s}) = \frac{(s_1, s_2, \ldots, s_D)}{\sum_{i=1}^{D} s_i}.$$

Managing compositions is less straightforward than it seems: the most significant information about compositions is contained in ratios between the components, which are generally difficult to handle; most methods from multivariate statistics developed for real-valued data-sets are misleading or inapplicable to compositions, which belong to the D-dimensional unit simplex $\mathscr{S}^D$. As a matter of fact, the classic algebraic operations used to deal with conventional real vectors are neither subcompositionally coherent nor scaling invariant. Aitchison geometry, introduced by [1], replaces these operators with others that suite the structure of the simplex and allows the development of *compositional analysis*. Let us consider two composition vectors $\mathbf{u}, \mathbf{v} \in \mathscr{S}^D$ and a scalar $\lambda \in \mathbb{R}$.

- *Perturbation*. Corresponds to the sum for compositions and is defined as:

$$\mathbf{z} = \mathbf{u} \oplus \mathbf{v} = \mathscr{C}(u_1 v_1, u_2 v_2, \ldots, u_3 v_3)$$

- *Powering*. Corresponds to the scalar multiplication for compositions and is defined as:

$$\mathbf{z} = \lambda \odot \mathbf{v} = \mathscr{C}\left(v_1^{\lambda}, v_2^{\lambda}, \ldots, v_3^{\lambda}\right)$$

The set of compositions, together with the operations of Aitchison geometry (including also the *compositional scalar product*), builds a $(D-1)$-dimensional Euclidean space structure on the simplex. This means that we can virtually translate any composition to the space of real vectors. One common transformation is the *isometric log-ratio transformation*: $ilr: \mathscr{S}^D \overset{iso}{\to} \mathbb{R}^{D-1}$, which induces an isometric identification of $\mathbb{R}^{D-1}$ and $\mathscr{S}^D$. Perturbation and powering in $\mathscr{S}^D$ are equivalent to sum and scalar product on their real-valued ilr counterparts and this allows to define all the basic probability operations on the simplex by working directly on the ilr space.

This implies that, whenever we define a valid stochastic model on the simplex, we can easily translate it into a standard multivariate regression model in $\mathbb{R}^{D-1}$ through the ilr transformation. In particular, if we consider the *Normal on the simplex* [7] distribution, which is perfectly coherent with the geometric structure induced by Aitchison geometry [1], this would correspond to the standard multivariate Normal in the ilr space. In the domain of this paper, we will focus on how to deal with compositions as dependent variable $\mathbf{y} = \tilde{\mathbf{s}}$ when all the covariates $\{x_k\}_{k=1}^K$ are classic variables. In order to stick with the structure of the data introduced in Section 2, without any loss of generality, we will introduce the regression framework in the context of a fixed effect model.

Let $\mathbf{y}_{it}$ be the $1 \times p$ composition vector and $\mathbf{x}_{it}$ the $K \times 1$ vector of covariates observed on unit i, $i = 1, \ldots, n$ at time t, $t = 1, \ldots, T$. We can express the compositional regression model through the linear Aitchison structure of the simplex as:

$$\mathbf{y}_{it} = \mathbf{a}_i \oplus \bigoplus_{k=1}^{K} \left(x_{it,k} \odot \mathbf{b}_k\right) \oplus \boldsymbol{\varepsilon}_{it}, \quad i = 1, \ldots, n,\ t = 1, \ldots, T, \tag{1}$$

where $\mathbf{a}_i$ is a unit-specific unknown compositional constant, which is perturbed by each covariate $x_{it,k}$ through the powering of the $1 \times p$ compositional vector of coefficients $\mathbf{b}_k$[2]; $\boldsymbol{\varepsilon}_{it}$ are independent compositional random variables with null compositional expectation $\mathbf{1}_D = (1, \ldots, 1)/D$, constant variance $\Sigma_{\mathscr{S}}$ and *Normal distribution on the simplex*. This model can be translated into a multivariate regression problem in $\mathbb{R}^{D-1}$ by applying the ilr transform at both side of Equation (1):

$$\text{ilr}(\mathbf{y}_{it}) = \text{ilr}(\mathbf{a}_i) + \sum_{k=1}^{K} x_{it,k} \cdot \text{ilr}(\mathbf{b}_k) + \boldsymbol{\varepsilon}_{it}, \quad i = 1, \ldots, n,\ t = 1, \ldots, T, \tag{2}$$

where $\boldsymbol{\varepsilon}_{it} \overset{iid}{\sim} \mathscr{N}_{D-1}(\mathbf{0}, \Sigma_{\text{ilr}})$. We can then fit the model using standard linear multivariate regression techniques, and then transform back the parameters in their simplicial counterparts in order to interpret their effect in terms of composition. The estimated intercepts $\hat{\mathbf{a}}_i$ can be interpreted as the expected composition for $x_{it,k} = 0$, $\forall k$; the slope $\mathbf{b}_k$ may be interpreted as the perturbation applied to the composition if $x_{it,k}$ increases by 1 unit. It is important to point out that the neutral element of

[2] Each element $b_{k,j}$ of $\mathbf{b}_k$ represents the effect of covariate x_k on the jth component

perturbation is the vector $\mathbf{1}_D$: values of $\mathbf{b}_{k,j}$ greater (lower) than $1/D$ have a positive (negative) effect on component j.

4 Application

In according to the notation introduced in Section 3, let us denote outcome and covariates related to the ith fishing stations at tth time points as $\{(\mathbf{y}_{it}, \mathbf{x_{it}}),\}_{i,t=1}^{n,T}$. The response variable $\mathbf{y}_{it}$ has been transformed into compositions through $\tilde{\mathbf{y}}_{it} = \mathscr{C}(\mathbf{y}_{it})$. We assume that the resulting compositions are the realizations of model (1), where individual fixed effects $\mathbf{a}_i$ have been assigned to each fishing haul. Variables referred to the geographic position of the stations (longitude, latitude and depth) have been excluded from the analysis (individual fixed effects already account for the spatial variability). Six hauls widely change their position along the years and they have been excluded from the analysis because such movements would negatively affect the proper estimation of the respective fixed effects. Furthermore, in order to highlight temporal variation with respect to the first year of observation, all the temperatures have been centered with respect to the ones observed in 1995, which is taken as a baseline. The model can be estimated exploiting its ilr counterpart expressed in Equation (2). The fit produced an $R^2 \approx 0.54$, which is a good fit considering the dimensionality of the outcome and the few predictors considered. Nevertheless, the major interest of this analysis is directed toward the interpretability of the estimated coefficients. Figure 2 shows the estimates of simplicial coefficients for all the statistically significant variables ($p < 0.1$). The values of the fixed effects highlight a large variability between shelf and slope stations (respectively characterized by the dominant presence of S species and of T ones), but also a non-negligible variability within class, that justifies the utilization of individual fixed effects. The bars on the right summarize the effect of time (expressed in years) and of the yearly temperature trend referred to the first quarter. As discussed in Section 3, those values must be interpreted in terms of *perturbation*. From a graphical point of view, the time effect seems to be very close to the neutral element. However, the numeric values of the coefficients are $\mathbf{b}_{year} = (0.3343, 0.3369, 0.3287)$ (respectively for S, ST and T species), which correspond to a slight but general increase of the S and ST component at the expense of the T one. Consider that on the 21st year, through the operation of powering, we get an effect of $21 \odot \mathbf{b}_{year} = (0.3474, 0.4088, 0.2436)$. In particular, the slow transition to the benefit of specifically S species is extremely evident in the years where the temperature of the first quarter was greater than the one of the baseline. Indeed, the estimated coefficient for such co-variate has been estimated to be $\mathbf{b}_{T1} = (0.4108, 0.3084, 0.2807)$.

5 Conclusions and further development

Compositional analysis revealed to be a very useful tool in understanding and modeling the structure of a community by simultaneously taking into account all its parts. While the available time window is still too short for making claims about phenomena that usually evolve at a slow pace and take place along decades, this preliminary regression model already highlighted a slow but progressive meridionalization of the fauna inhabiting the portion of Mediterranean sea in front of the Lazio coast. This may be interpreted as an effect of water temperature increase, which may affect directly or indirectly the indigenous fish community. However, further studies that consider other relevant

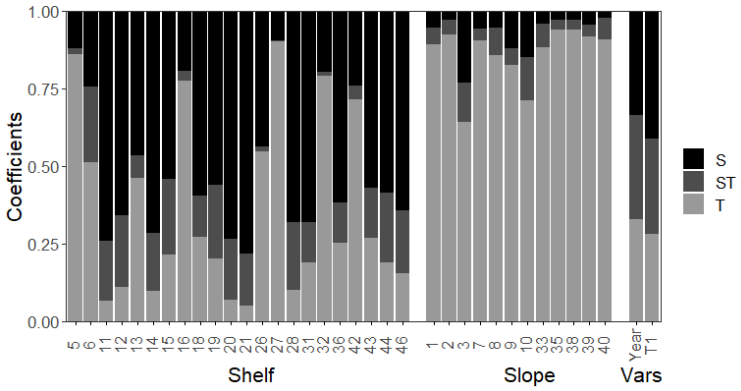

Fig. 2 Barplot of the estimated $\hat{a}_i$'s and $\hat{b}_k$'s arranged from the left to the right: fixed effect (shelf and slope) and variables coefficients.

pressure factors on the fish population (fishing, pollution etc.) are required in order to establish an effective causal effect. A more extensive study on this topic would consider alternative species classifications that may be finer or possibly include exotic individuals.

Tecniche di riduzione della dimensionalità e di separazione di componenti nell'analisi di dati funzionali di spettroscopia infrarossa in trasformata di Fourier

Francesca Di Salvo, Elena Piacenza , Delia Francesca Chillura Martino

Abstract FTIR spectroscopy is a measurement technique used to obtain an infrared spectrum of absorption of a solid (or a liquid or a gas), for the characterization of specific chemical components of materials. When repeated measures are taken on samples of materials, the result is a collection of spectra representing a set of samples from continous functions (signals) defined in the domain of the frequencies. An unifying approach to the study of a collection of FTIR spectra is proposed to deal with the presence of random shifts in the peaks, the identification of representative spectra and finally the characterization of the observed differences: in the functional data framework, the performance of a new proposal for alignment of curves and their assignment to clusters of shapes with an intrinsic order is presented and discussed.
Abstract *La spettroscopia FTIR è una tecnica mediante cui si acquisisce uno spettro di assorbimento di una sostanza, contenente informazioni per la caratterizzazione dei materiali e per lo studio dei legami chimici. Effettuando misurazioni ripetute su campioni di materiali, si osserva una collezione di spettri che per la loro struttura rappresentano le realizzazioni campionarie di curve continue definite sul dominio delle frequenze. Si propone un approccio statistico unitario per lo studio di collezioni di spettri che affronti il problema della presenza di traslazioni casuali nei picchi delle curve, dell'identificazione di curve rappresentative e della interpretazione delle dissimilaritá osservate. L'approccio proposto per l'allineamento e la separazione degli spettri in cluster intrinsecamente ordnati é presentato nel contesto dei dati funzionali.*

1 Introduction

The motivation of this contribution is the attempt to give answers to the interpretation of a collection of Fourier Transform InfraRed (FTIR) spectra, for which the core of the study is a chemical analysis, but a better synthesis of the most meaningful information is achieved by statistical methods.
FTIR spectroscopy is a label-free and non-destructive technique based on the absorption of electromagnetic waves in the infrared region of the spectrum [1]; the absorption bands originate from fundamental transitions of molecular vibrations, that are highly characteristic of specific chemical components. A collection of IR spectra represents a set of samples from continous functions defined in the domain of the frequencies: each spectrum can be visualized in a graph of infrared light absorbance on the vertical axis vs frequency or wavelength on the horizontal axis. Typical units of IR frequency are reciprocal centimeters (called wave numbers, with the symbol cm^{-1}). Units of IR wavelength are given in micrometers (microns with symbol μm, which are related to wave numbers in a reciprocal way. The mid-infrared, approximately 4000–400 cm^{-1} (or 2.5–25μm), may be used to study the fundamental vibrations and their associated structure. After having processed the data by chemical analysis, a statistical approach is adopted in order to sinthetize the most meaningful information from the spectral results.

The procedure allows a complementary analysis of the similarities, or differences, among the curves; the presence of random shifts in the peaks, due to variability in measurements and equipment, introduces the warping as a tool to align the observed spectra and reduce their variance [6], [7] and [8]. The alignment problem and assignment of curves to clusters of shapes is handled with principal component technique in order to characterize and correlating the morphological differences, and a natural order among the members of the clusters, can be obtained in terms of their cohesiveness.

2 The methodology

The goal of any absorption spectroscopy is to measure how much light a sample absorbs at each wavelength and to relate this with chemical composition. The raw data are collected rapidly repeating the measurements many times over a short timespan and afterwards, an algorithm takes all this data and works backward to infer what the absorption is at each wavelength. In this process, from recording the raw data to converting into the light absorption, the resulting curves are affected by noise. The couple $(w, Y_i(w))$ denotes respectively the wavelength and the observed inten-

sity for $w \in W = [4000\text{–}400]cm^{-1}$, $W \subset R^+$. In the observed spectrum, the points are separated by equal frequency intervals. The curves are standardized by the linear transformation:

$$Y_i^s(w) = \frac{Y_i(w)}{max_{w \in W}(Y_i(w))}, \tag{1}$$

Because of their structure, tha IR spectra can be represented as a realization of a univariate functional random field:

$$Y_i^s(w) = X_i(w) + \varepsilon_i(w) \tag{2}$$

$X_i(w)$ is the signal and $\varepsilon_i(w)$ is the random component. From a chemical point of view, the focus is on the shape of the curves, independently from their height, as the differences in height are produced by different intensities, while the study aims to compare loci of peaks, independently from their intensities. For this reason, a non linear transforms of the curves is considered, the square root slope functions: this transformation introduces the problem of separation of the phase and amplitude components of variability of the functional data; the phase variability (variability along the x axis) is here interpreted as a negligible inherent variability in the underlying process itself that needs to be separated from the amplitude variability along the vertical axis; the effect of the reduction of phase variability is considered facing the basic questions of interest:

1. estimation of the central tendency
2. estimation of the variability among the curves and the identification of clusters (location and shape types)
3. detection of outlying curves
4. description of the essential modes of variability

Several methods pursue one of these goals, but separately; alternative proposals approaches the basic questions $1-4$ in an unitary framework: a complete overview of the goals, challenges and contributes in literarure is in [5], where methods based on the square root slope functions are presented. Different the approaches performs these tasks, sequentially, [6] and [7] or jointly [9]. For the goal of this analysis, the algorithm presented provides cluster-wise alignment accounting for the phase variability and discovering the principal modes in the square root slope function (SRSF) framework:let $X_i(w)$ be differentiable almost everywhere on W, with derivative denoted by $\dot{X}$, the square root sope function is defined as:

$$q(w) = sign(\dot{X})\sqrt{|\dot{X}|} \tag{3}$$

An agglomerative hierarchical clustering of the SRSF's of the curves provides an optimal configuration, and inside each cluster a dimension-reduction tool to approximate the two components, phase and amplitude (elements of infinite-dimensional spaces), as elements of finite-dimensional spaces is performed: a general model, that takes into account clusters effects and simultaneously represents the i^{th} SRSF of the j^{th} cluster, j from 1 to J, in the finite-dimensional space, is derived by the Karhunen-Loéve expansion:

$$q_{ij}(\gamma_i(w)) = \mu_q(w) + \sum_{h=1}^{\infty} u_{ij_h}\xi_{j_h}(w) \tag{4}$$

where $\gamma_i(w)$ are the warping function, a deformations of the domain W, such that the original functions composed with these warpings are optimally aligned; $\mu_q(w)$ is the Karcher mean, whose amplitude and relative phase denote the sample means of amplitudes and relative phases; u_{ij_h} and $\xi_{j_h}(w)$ are respectively the h^{th} Principal score for the i^{th} curve and the h^{th} eigenfunction inside the j^{th} cluster. The alignment of the coefficients of principal component analysis (FPCA) on the space of the first derivatives

$$(\hat{\gamma}, \hat{\mu_q}, \hat{u}, \hat{\xi}) = argin f_{\gamma,\mu,u,\xi} \left(\sum_{i=1}^{n} |q_{ij} \circ \gamma_i - \mu_q - \sum_{i=1}^{H} u_{ij_h}\xi_{j_h}|^2 \right) \tag{5}$$

A suitable algorithm implements the estimation problem iteratively. On the current estimated curves, the clustering is repetead until the convergence is obtained. Results derived in terms of principal modes of variations inside the clusters, describe the main cluster-effects on the shape of the curves group-wise registered, while the detection of outlying curves with respect to the centre of the cluster is performed by mean of measures based on the modified band depth [4].A previous paper [2] introduced an algorithm based on the notion of Modified Band Depth for improving the clustering of the curves.

3 Data and results

The dataset consists in a collection of 24 absorbance spectra recorded in the mid-infrared range of wavelength $[4000-400]cm^{-1}$. Here results are presented for a smaller range of wavelength, $[3770-2770]cm^{-1}$, characterized the presence of peaks of interest. The original data standardized in the range $[0,1]$ are in Fig.1 (top-left). The focus of the analysis, implementing the techniques described in Section 2, is to determine homogeneous clusters of curves with respect their shape. The optimal number of clusters is determined by hierarchical clustering with agglomerative algorithms and the optimal number of clusters k is selected by maximizing the average silhouette Fig.1 (top-right, bottom-left); as preliminary results, the Fig.1 (bottom-right) reports four well separated clusters. Another goal is finding a representative shape for each cluster. A data depth algorithm, based on the concept of modified band depth [4], measures the centrality of an observation within a cluster and allows the definition of a natural ordering from center outwards, allowing reallocation of the most external curves. In Fig.2 the structure of the four groups is presented, the inner curves (75% of the cluster) and the external curves (the remaining 25%).

4 Conclusion

This study represents a functional data analysis of spectroscopic investigation carried out with the FTIR thecnology. The analytical approach allowed to compare information from a large number of spectra, leading to an in-depth knowledge of the materials. Shapes of the curves are the essential difference between clusters and the comprehensive approach proposed deals with the problem of registering and modeling them in a joint framework working on the spaces of their derivatives. The results obtained are characterized by groups of peculiar shape with peaks located at specific wavelength providing chemical interpretation in terms of composition of the materials.

Functional Data Analysis for Spectroscopy Data

Analisi di Dati Funzionali per Dati di Spettroscopia

Mara S. Bernardi, Matteo Fontana, Alessandra Menafoglio, Diego Perugini, Alessandro Pisello, Marco Ferrari, Simone De Angelis, Maria Cristina De Sanctis, Simone Vantini

Abstract We propose a functional data analysis approach for the study of spectroscopy data. The applicative problem concerns the characterization of the spectral response of silicate glasses in order to infer the chemical composition of the materials from spectral data, which can be remotely collected. The analysis performed aims at characterizing the phase variability and the amplitude variability of the data in order to extract meaningful information. The technique used is k-mean alignment.
Abstract *Proponiamo un approccio di analisi di dati funzionali per lo studio di dati di spettroscopia. Il problema applicativo riguarda la caratterizzazione della risposta spettrale di vetri silicati al fine di dedurre la composizione chimica dei materiali a partire da dati spettrali, che possono essere raccolti in remoto. Lo scopo dell'analisi è la caratterizzazione della variabilità di fase e della variabilità di ampiezza dei dati al fine di estrarre informazioni significative. La tecnica utilizzata è il k-mean alignment.*

1 Introduction

Silicates are the main constituents of terrains on terrestrial planets in the solar system. Silicate glasses represent the amorphous phase of silicate crystals, and they are widely present in natural volcanic rocks, in which amorphous phases can be present as a small fraction or as the only constituent. Since it is known that terrestrial planets are largely covered by volcanic products, it is of great importance to study the spectral response of glasses to better interpret available and future remotely sensed spectra from past and future missions [5, 3, 2]. Spectral characterization of crystalline materials is usually made through pointing peaks position, intensity, and FWHM (full width at half maximum). Since amorphous material spectral response does not represent a clear set of peaks, but a series of "bulges" and "valleys" whose shape is blurred, a new approach has to be found. To tackle this problem, we propose to apply advanced statistical techniques in the framework of Functional Data Analysis. The advantage of such techniques is the possibility to consider in the analysis the whole spectrum, while classical approaches based on multivariate statistic rely on a dimensionality reduction step (such as the extraction of features characterizing the peaks), thus losing information from the original data.

Functional data analysis [6] is the branch of statistical analysis that considers functional data (such as curves, surfaces, spectra, etc.) as statistical units. In recent years, many functional data analysis techniques have been proposed and applied to many different fields of application. Functional data analysis is suitable for the analysis of the data considered in this work as the underlying phenomenon is continuous in nature (continuous curves on the frequency domain). Resorting to a functional representation of the data allows to automatically extract characterizing features and to properly describe the shape of the curves.

The dataset analyzed in this work, described in Section 2, concerns the spectral response of 4 different magmatic series and natural rocks. The statistical analysis of the data is described in Section 3. Section 4 draws the conclusions of the work and outlines possible directions of future research in this context.

2 Dataset

In order to build up an exhaustive database of amorphous, four different series of silicate glasses were produced, with the aim of reproducing the widest possible chemical variability, according to what we find on Earth. Each series of glasses was produced by crushing, melting and mixing two natural endmembers from different areas, whose volcanic products have different chemical variability: Vulcano (Aeolian islands, Italy) Snake River Plain (USA) Etna (Sicily, Italy) and Pantelleria (Mediterranean Sea, Italy). The resulting series of glasses present a range of chemical compositions that is covering the majority of rocks on planet Earth. Of peculiar interest are the variations in SiO2 content (linked to evolution of magma) and alkaline content (linked to geodynamic setting). Samples were analyzed using

electron probe microanalyses, and spectroscopically characterized in reflectance at the INAF-IAPS in Rome in the mid- infrared range (2-14 micron). Figure 1 shows the data.

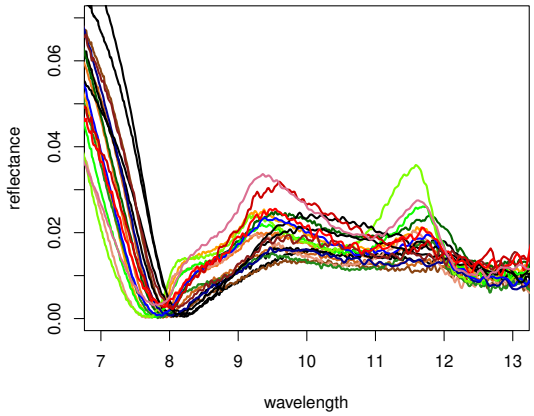

Fig. 1 Plot of the original data.

3 Statistical analysis

The available data are considered as a discrete noisy sampling of an underlying smooth function. Therefore, as a preprocessing step, spline smoothing is applied to the rough data represented in Figure 1 to obtain a smooth functional representation of the data and to remove sampling error and spurious oscillations that are not of interest for the analysis of the phenomenon. The smoothed curves are represented in Figure 2. Spline smoothing is performed using the R package fda [7].

As can be seen in Figure 2, the variability among the data is characterized by an horizontal displacement and a difference in the shapes (peaks more or less pronounced). To properly account for these features of the data, we resort to functional alignment (also called functional registration), a technique to decompose phase variability and amplitude variability. This technique is particularly suitable for the analysis of these data as the horizontal displacement and the shape of the curves are meaningful for inferring the chemical composition of the material.

The technique applied is k-mean alignment [8, 9, 10], an algorithm that simultaneously aligns and clusters curves through an iterative procedure. The use of this technique is motivated by the practical interest in grouping samples of materials with similar spectral characteristics, as this could imply similar chemical compositions.

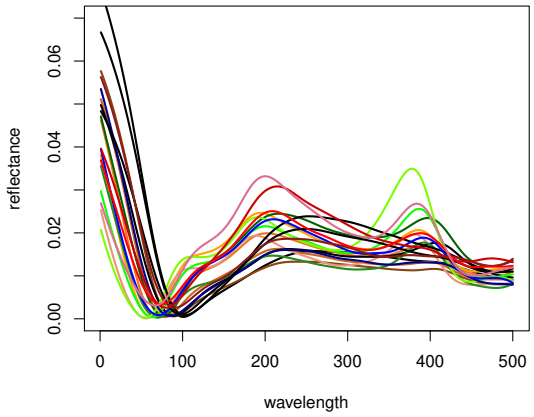

Fig. 2 Plot of the smoothed data.

Functional alignment requires a proper choice of similarity index and class of warping functions. Indeed, aligning a curve $f(s)$ to a reference consists in finding a warping function of the abscissa $h(s)$ such that the curve $f(h(s))$ is the most similar to the reference.

Regarding the choice of the similarity index, in this work we use the following similarity index, which measures the cosine of the angle between the derivatives of two functions g and g:

$$\rho(f,g) = \frac{< f', g' >_{L^2}}{\|f'\|_{L^2}\|g'\|_{L^2}} = \frac{\int_{\mathbb{R}} f'(s)\, g'(s)\, ds}{\sqrt{\int_{\mathbb{R}} f'(s)^2\, ds}\sqrt{\int_{\mathbb{R}} g'(s)^2\, ds}}.$$

This choice reflects the need to analyze the shape of the curves, neglecting their magnitudes. Indeed, the similarity index chosen considers as identical two curves that differ for vertical shifts and vertical dilations:

$$\rho(f,g) = 1 \iff \exists a \in \mathbb{R}^+, \exists b \in \mathbb{R} : f = ag + b.$$

Regarding the choice of the class of warping functions, we consider in our analysis the following three classes:

$$W_{shift} = \{h : h(s) = s + q \text{ with } q \in \mathbb{R}\}.$$
$$W_{dilation} = \{h : h(s) = ms \text{ with } m \in \mathbb{R}^+\}.$$
$$W_{affine} = \{h : h(s) = ms + q \text{ with } m \in \mathbb{R}^+, q \in \mathbb{R}\}.$$

The best results in terms of similarity were obtained with the classes W_{shift} and W_{affine}, with no significant difference between these two classes, meaning that the actual phase variability is well captured by a simple translation.

The results of the analysis highlight a strong correlation between the values of the shifts and the silica content of the materials. Moreover, the clustering obtained by k-mean alignment provides meaningful information about the total alkali-silica composition of the materials. These results demonstrate the importance of the analysis of both phase and amplitude variability as they are both informative for the goals of the analysis.

Further details about this analysis can be found in [1]. K-mean alignment is performed using the R package fda [4].

4 Conclusions and future work

The analysis performed in this work shows the usefulness of functional data analysis techniques for the study of spectral data and the relevance of the information extracted from the data through k-mean alignment in retrieving the chemical composition of the material.

Directions of future research concerns the development of a functional regression model to predict the chemical composition using the spectral data as covariates. In this model, the response is a compositional data, while the covariate is a bivariate functional data composed by the warping function (describing the phase variability) and the aligned data (describing the amplitude variability).

Functional graphical model for spectrometric data analysis

Modello grafico funzionale per l'analisi di dati spettroscopici

Laura Codazzi, Alessandro Colombi, Matteo Gianella, Raffaele Argiento, Lucia Paci and Alessia Pini

Abstract Motivated by the analysis of spectrographic data, we introduce a functional graphical model for learning the conditional independence structure of spectra. Absorbance spectra are modeled as continuous functional data through a cubic B-spline basis expansion. A Gaussian graphical model is assumed for basis expansion coefficients, where a sparse structure is induced for the precision matrix. Bayesian inference is carried out, providing an estimate of the precision matrix of the coefficients, which translates into an estimate of the conditional independence structure between frequency bands of the spectrum. The proposed model is applied to the analysis of the infrared absorbance spectra of strawberry purees.

Abstract Motivati dall'analisi di dati spettroscopici, introduciamo un modello grafico funzionale per l'apprendimento della struttura di indipendenza condizionale degli spettri. Gli spettri di assorbimento sono modellati come dati funzionali continui attraverso una espansione in base B-spline cubica. Un modello grafico gaussiano è utilizzato per i coefficienti dell'espansione di base, attraverso il quale viene indotta una struttura sparsa per la matrice di precisione dei coefficienti. L'inferenza bayesiana del modello permette di ottenere una stima della struttura di indipendenza condizionale tra le bande di frequenza degli spettri. Il modello proposto è applicato all'analisi degli spettri di assorbimento infrarosso di puree di fragole.

1 Introduction

Spectrography is a technique that is used to summarize all the molecular components of a substance. Using this technique, for each substance it is possible to acquire an absorbance spectrum, that is a signal containing detailed information about the substance composition. From a mathematical point of view, the spectrum is a continuous function of the wavelength. To make this signal more meaningful it is important to understand which wavelength bands are related to the different components. The dependency structure between the signal at different wavelenghts is particularly informative in this sense: if two different bands of the spectrum are dependent, we can conclude that they refer to the same components, or to two closely related components. Our goal is then to investigate the dependence among different portions of an absorbance spectrum.

Let $y_i(s)$ be the absorbance at wavelength $s \in [l,u]$ for unit i, $i = 1,\dots,n$, where $[l,u] \subset \mathbb{R}^+$ is the common domain of all curves. The whole curve $y_i(s)$, $s \in T$ is the absorbance spectra of unit i. Using standard smoothing techniques of functional data analysis, the model that we assume for the i-th spectra is:

$$y_i(s) = \sum_{j=1}^{p} \beta_{ij}\varphi_j(s) + \varepsilon_i(s), \quad s \in [l,u]$$

where $\varphi_1,\dots,\varphi_p$ are suitable B-spline basis, $\beta_i = (\beta_{i1},\dots,\beta_{ip})$ is the individual-specific spline coefficients' vector and $\varepsilon_i(s) \overset{\text{iid}}{\sim} \mathrm{N}(0,\tau_\varepsilon^2)$. Within the Bayesian setting a customary prior for the β_i coefficients is:

$$\beta_1,\dots,\beta_n \mid \mu,\Sigma \overset{\text{iid}}{\sim} N_p(\mu,\Sigma), \tag{1}$$

where μ is the prior mean vector and Σ is the prior covariance matrix.

In this framework, the dependence between two bands of the spectrum is reflected in the relationship among the corresponding smoothing regression parameters. Hence, our goal boils down to the study of the dependence structure of the β's, that is on matrix Σ, or on its inverse Σ^{-1}, that is called precision or concentration matrix.

2 Functional graphical model

We employ a graphical modeling approach for learning conditional independence structures among the coefficients. Let $G = (V,E)$ be the graph defined by the node set $V = \{1,\dots,p\}$ representing the coefficients and by the edge set $E \subset V \times V$. In practice, the graph is unknown and must be estimated. For Gaussian graphical models, the problem translates in assuming that the precision matrix Σ^{-1} in (1) is Markov with respect to G. In other words, coefficients β_{ij} and β_{ik} are conditionally

independent given all the remaining variable $\beta_{\setminus\{j,k\}}$ whenever $\{j,k\} \notin E$, if and only if the corresponding entry in matrix Σ^{-1} is zero, i.e., $\beta_{ij} \perp \beta_{ik}|\beta_{\setminus\{j,k\}} \Leftrightarrow \Sigma^{-1}_{j,k} = 0$; see Figure 1 for an example.

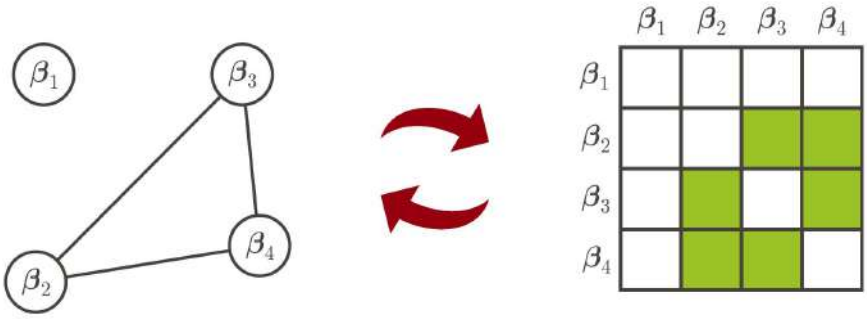

Fig. 1 Example of a Gaussian graphical model with 4 nodes. On the left, the graph with 4 nodes and, on the right, the corresponding precision matrix where green cells represent nonzero entries.

Hence, the Bayesian hierarchical model becomes

$$\begin{aligned} y_i \mid \beta_i, \tau^2_\varepsilon &\overset{\text{iid}}{\sim} \mathrm{N}_r\left(\Phi\beta_i, \tau^2_\varepsilon \mathbf{I}_r\right) \\ \beta_1, \ldots, \beta_n \mid \mu, \Sigma &\overset{\text{iid}}{\sim} \mathrm{N}_p\left(\mu, \Sigma\right) \\ \mu &\sim \mathrm{N}_p\left(\mathbf{0}, \sigma^2_0 \mathbf{I}_p\right) \\ \Sigma^{-1} \mid G &\sim \text{G-Wishart}\left(d_0, \Sigma_0\right) \\ G &\sim \pi\left(G\right) \\ \tau^2_\varepsilon &\sim \mathrm{IG}\left(a, b\right) \end{aligned} \tag{2}$$

where Φ is the matrix collecting the B-spline basis. The G-Wishart distribution has density

$$p\left(\Sigma^{-1} \mid G, d_0, \Sigma_0\right) = I_G\left(d_0, \Sigma_0\right)^{-1} |\Sigma^{-1}|^{\frac{d_0-2}{d_0}} \exp\left(-\frac{1}{2} tr\left(\Sigma^{-1}\Sigma_0\right)\right), \quad \Sigma^{-1} \in P_G$$

where $d_0 > 2$ are the degree of freedom of the parameter, Σ_0 is a $p \times p$ positive definite symmetric matrix, I_G is the normalizing constant and P_G is the set of all the $p \times p$ positive definite symmetric matrices constrained by G. A noninformative prior is placed on graph G that is, the prior probability of any edge ξ to be present in the graph is $\pi(\xi) = 0.5$.

A Monte Carlo Markov Chain (MCMC) algorithm is employed to approximate the full joint posterior probability of model (2). In particular, we adopt a Gibbs sampling strategy to sample from the posterior distribution of the β's, τ^2_ε and μ, while the covariance matrix Σ and the graph G are sampled using a birth-death step as implemented in the `R package BDgraph` [2]. As a result, the vector of

all the visited graph is returned along with the associated weight that provide an approximation of the posterior inclusion probability of each edge ξ.

Given the MCMC output, a variety of summaries can be adopted to estimate the graph. Here, we employ a Bayesian version of the (approximate) expected false discovery rate (FDR; [3]), i.e., we estimate the graph considering those edges whose posterior probability of inclusion is greater than$1-r$, where r is determined so that the FDR is at most 5%.

3 Analysis of fruit purees data

We analyze the spectrum of absorbance of 351 fruit purees prepared using exclusively fresh whole strawberries (without the addition of adulterants) measured on an equally-spaced grid of 235 wavelengths levels and then normalized with respect to the area under the curve; see the left panel of Figure 2. A description of the data can be found in [1]. The goal of the analysis is to provide useful insights about which wavelength bands are related to the different components of the purees, and more specifically about the dependency structure between wavelength bands.

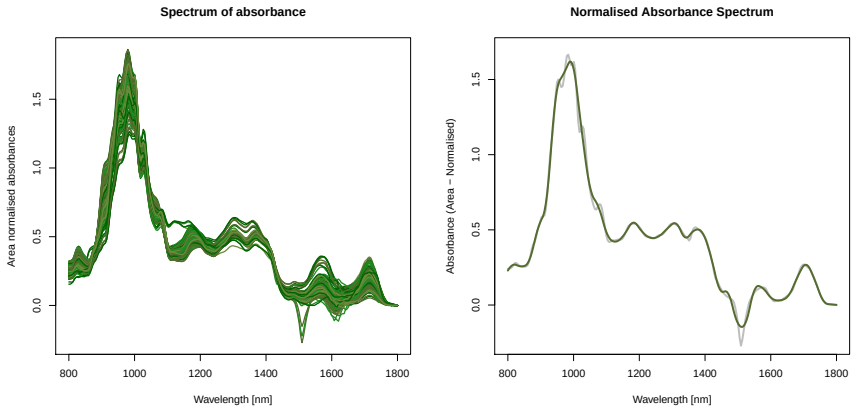

Fig. 2 Plot of 351 spectra of absorbance measured in 235 different wavelengths in left panel and an example of a smoothed curve in the right panel.

We fit model (2) by assuming $p = 40$ B-spline cubic basis functions. The right panel of Figure 2 presents an example of a smoothed curve (green) compared to the original one (gray). Observe that the smoothed curve follows precisely the shape of the original one, smoothing away some pointwise variability.

The left panel of Figure 3 shows the posterior mean of the coefficients while the right panel displays the estimated graph. As expected, the underlying graph is quite sparse and characterized by a block structure. The identified blocks are located

mainly close to the diagonal, with some extra-diagonal exceptions. The prevalence of blocks close to the diagonal is expected, since close wavelength bands are likely to be associated to similar components. The blocks far from the diagonal are also of great interest, since they suggest that components associated to very different wavelengths are strongly related according to their presence in the strawberry purees.

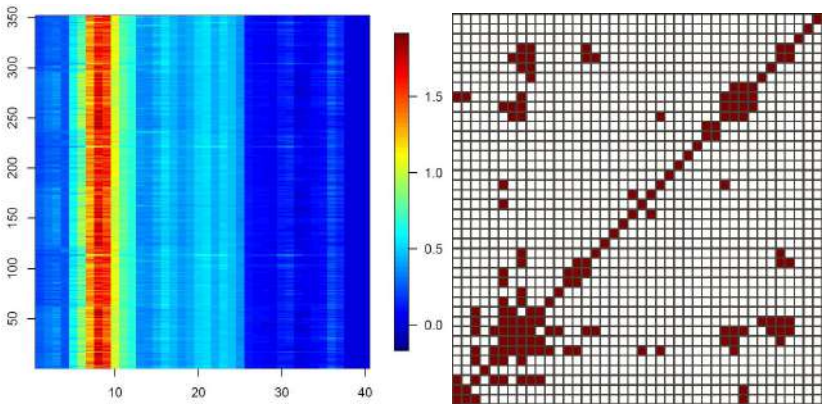

Fig. 3 Posterior mean of all β coefficients (left panel) and the estimated graph (right panel).

Local LGCP estimation for spatial seismic processes

Stima di LGCP locali per processi sismici spaziali

Nicoletta D'Angelo, Marianna Siino, Antonino D'Alessandro, Giada Adelfio

Abstract Using recent results for local composite likelihood for spatial point processes, we show the performance of advanced and flexible statistical models to describe the spatial displacement of earthquake data. Local models described by [1] allow for the possibility of describing both seismic catalogs and sequences. When analysing seismic sequences, the analysis of the small scale variation is the main issue. The interaction among points is taken into account by Log-Gaussian Cox Processes models through the estimation of the parameters of the covariance of the Gaussian Random Field. In their local version these parameters are allowed to vary spatially, and this is a crucial aspect for describing and characterizing the study area through a multiple underlying process.

Abstract *Sulla base di recenti risultati per la verosimigianza locale composita per i processi di punto spaziali, in questo lavoro si analizza la performance di modelli statistici avanzati al fine di descrivere la dislocazione spaziale di dati sismici. I modelli locali descritti da [1] risultano adatti per la caratterizzazione di cataloghi e sequenze sismiche. Per quanto riguarda le sequenze, l'analisi della variazione a piccola scala è cruciale. L'interazione fra i punti è considerata dai modelli Log-Gaussian Cox Processes attraverso la stima dei parametri della covarianza del Gaussian Random Field. Nella loro versione locale questi parametri sono assunti variabili nello spazio, il che rappresenta un aspetto chiave nella descrizione e rapprensentazione della zona analizzata, caratterizzata da processi multiscala sottostanti.*

1 Local composite likelihood for Poisson Models

When dealing with the analysis of spatial point processes, spatial log-linear model are often used. Although, for these for models, parameters are usually assumed to be constant across the entire study region, this assumption may be too simplistic in contexts that are characterised by multiscale and fractal features, like the seismic one. The relationship between the intensity of earthquakes and other possible characteristics of the area where events occur, can be described by a log-linear model with spatial varying coefficient. That is:

$$\lambda(\mathbf{u}) = \lambda(\mathbf{u};\theta(\mathbf{u})) = \exp(\theta(\mathbf{u})^{\top} Z(\mathbf{u}) + B(\mathbf{u})) \tag{1}$$

where $\theta(\cdot)$ is a function of the spatial location $\mathbf{u} \in D$. In the local context, the template model is the one in Equation (1) and the local log-likelihood associated with location $\mathbf{u}$ is $\log \mathrm{L}(\mathbf{u};\theta) = \sum_{i=1}^{n} w_h(\mathbf{u}-u_i) \log \lambda(u_i;\theta) - \int_D \lambda(v;\theta) w_h(\mathbf{v}-\mathbf{u}) dv$ where $w_h(\mathbf{u}) = h^{-d} w(\mathbf{u}/h)$ is a weight nonparametric function, and $h > 0$ is a smoothing bandwidth [5]. Maximising the local likelihood provides spatial varying parameter estimates, confidence intervals, hypothesis tests and other standard tools [1].

1.1 Spatial Log-Gaussian Cox Processes

Cox processes are models for point phenomena that are environmentally driven and have a clustered structure. Let N be a point pattern defined on a spatial region D. N is said to be a Cox process driven by Λ, if its conditional distribution, given a realisation $\Lambda(\mathbf{u}) = \lambda(\mathbf{u})$, is a Poisson process on D with intensity function $\lambda(\mathbf{u})$. Following the inhomogeneous specification in [7], the Log-Gaussian Cox Process (LGCP) for a generic point in space has the following intensity $\Lambda(\mathbf{u}) = \lambda(\mathbf{u}) \exp\{S(\mathbf{u})\}$ where S is a Gaussian Random Field (GRF) with $E(S(\mathbf{u})) = \mu = -\frac{\sigma^2}{2}$ and so $E(\exp\{S(\mathbf{u})\}) = 1$ and with variance-covariance matrix $C(S(\mathbf{u}), S(\mathbf{v})) = C(||\mathbf{u}-\mathbf{v}||) = \sigma^2 R(r)$ under the stationary assumption, where $R(\cdot)$ is the correlation function of the GRF, completely specified by its first and second moments. A LGCP is completely determined by $(\mu, \sigma^2, R(\cdot))$ of the GRF of the point process. It is isotropic if and only if the underlying Gaussian process is isotropic. Several authors have discussed on the issue of separability of LGCPs in space and time [6]. We only refer to models where C is isotropic, i.e. only depends on the distance $r = \|u-v\|$ between locations u and v, with exponential isotropic structure for the covariance function as in [4]. The default template used in this paper is $R(r) = \exp(-r)$ which rises to the exponential covariance function

$$C(r) = \sigma^2 \exp\left(-\frac{r}{\alpha}\right) \tag{2}$$

depending only on α and σ^2 that are the scale parameter for the spatial distance and the variance respectively. The effect of increasing σ^2 is to generate higher peaks in the surface intensity which leads to clusters of points. Increasing the spatial scale parameter α, the underlying GRF presents a strong spatial correlation and it corresponds to a diffuse aggregation of points of the LGCP [9]. Estimation of local LGCP models che be performed by the adaptation of the Palm likelihood to a general non-stationary point process, because of its formal similarity to the Poisson likelihood, though minimum contrast estimation is also possible [1].

2 Application to seismic data

The used catalogue data (1105 events) concern earthquakes occurred in Greece between 2005 and 2014. Only seismic events with a magnitude larger than 4 are considered in this study, and the analyses are marginal with respect to time, focusing on the spatial dependence of events. Starting from the information of the area under study, we are interested in assessing if local characteristics are present in the observed area and if the presence of seismic sources can affect the intensity of the process, that is if the effect of the available covariates can improve the fitting of the model. Therefore, the considered explanatory variables are the Distance from the faults D_f, Distance from the plate boundary D_{pb} and the Distance from volcanoes D_v, computed as the Euclidean distances from the spatial location u of events and the map of the available geological information [3]. Earthquakes, together with plate boundary (in red) and faults (in blue), are displayed in Figure 1 (a). Several models are fitted, with different specifications of the linear predictor. Diagnostics and model selection are carried out through the inspection of the smoothed raw residuals and the inhomogeneous K-functions, but these are not reported here for the sake of brevity. The chosen local Poisson model is

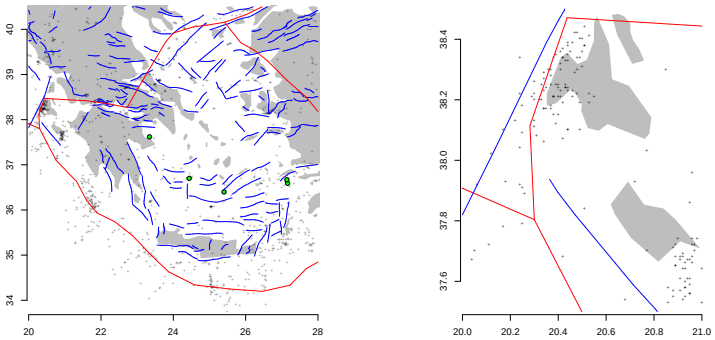

Fig. 1 Left panel: Earthquakes occurred in Greece between 2005 and 2014 (a). Right panel: Earthquakes occurred in Ithaki, Kefalonia and Zakynthos between 2005 and 2014 (b). Volcanoes, in green, faults, in blue, and plate boundary, in red.

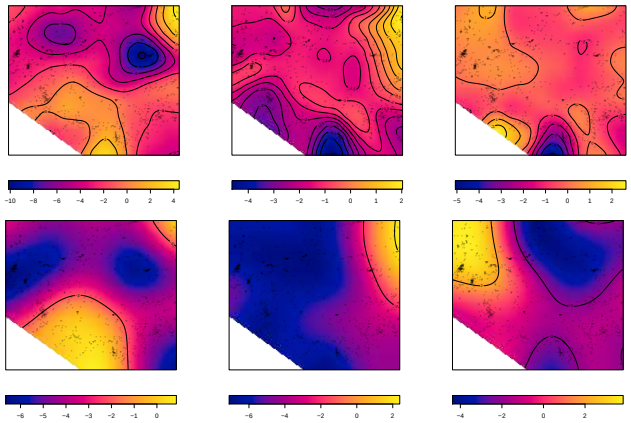

Fig. 2 Top three panels: Spatial varying estimated coefficients $\hat{\beta}_1(\mathbf{u})$, $\hat{\beta}_2(\mathbf{u})$ and $\hat{\beta}_3(\mathbf{u})$ of the local Poisson model in Equation (3). Bottom three panels: the corresponding T-tests.

Table 1 Summary of the spatial varying estimated coefficients of the local Poisson model in Equation (3).

	Min.	1st Qu.	Median	Mean	3rd Qu.	Max.
Intercept	-0.8465	3.7821	4.6536	4.7818	5.4126	13.7942
D_f	-10.3862	-4.0474	-2.3888	-2.4529	-0.6133	4.6906
D_{pb}	-4.735	-1.925	-1.413	-1.448	-1.04	2.17
D_v	-5.3552	-0.6595	-0.2799	-0.2987	0.2351	2.9546

$$\lambda(\mathbf{u}) = \exp(\beta_0(\mathbf{u}) + \beta_1(\mathbf{u})D_f(\mathbf{u}) + \beta_2(\mathbf{u})D_{pb}(\mathbf{u}) + \beta_3(\mathbf{u})D_v(\mathbf{u})) \tag{3}$$

The maps of the varying estimated coefficients $\hat{\beta}_1(\mathbf{u})$, $\hat{\beta}_2(\mathbf{u})$ and $\hat{\beta}_3(\mathbf{u})$ are shown on the top three panels in Figure 2. Their summary statistics are reported in Table 1. The corresponding T-tests are reported on the bottom three panels, where the level curves correspond to the ± 1.96 threshold, associated with a 0.95 confidence level. The blue regions are those in which the null hypothesis does not hold, and so where the coefficients are significantly different from zero. For more details see [1]. As expected, the estimated coefficients are negative quite in all the area, since usually, the intensity decreases as the distance from the seismic source increases, but it is important to notice how the coefficients take quite different values along the whole areas. The lowest values are found exactly in correspondence of earthquakes occurred along the seismic source. These previous analyses of the entire catalogue highlighted the need to focus the analysis on a smaller region. Therefore we move to the analysis of a seismic sequence. The chosen area, that displays an inhomogeneous behaviour, is situated in the Ionian Sea, and it comprehends three of 'the Seven Islands', namely Ithaki, Kefalonia and Zakynthos, from North to South. In this area, earthquakes appear to be clustered in the Western area of Kefalonia island and South to the Zakynthos island. For this analysis, the variables D_f and D_{pb} are taken into account, in order to get an interpretation of the two effects. In Figure 1 (b)

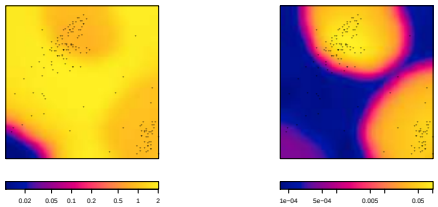

Fig. 3 Spatial varying estimated coefficients $\hat{\sigma}(\mathbf{u})$ and $\hat{\alpha}(\mathbf{u})$ of the local LGCP model in Equation (4).

Table 2 Summary of the spatial varying estimated coefficients of the local LGCP model in Equation (4).

	Min.	1st Qu.	Median	Mean	3rd Qu.	Max.
sigma	0.000105	0.802612	2.451644	2.192861	3.627219	4.157830
alpha	0.00001	0.00009	0.00012	0.01988	0.03764	0.11281

earthquakes, together with plate boundary (in red) and faults (in blue), are displayed. In this application we first consider a local Poisson model with:

$$\lambda(\mathbf{u}) = \exp(\beta_0 + \beta_1 D_f(\mathbf{u}) + \beta_2 D_{pb}(\mathbf{u}) + \beta_3 D_f(\mathbf{u}) D_{pb}(\mathbf{u})) \tag{4}$$

and then it considered as the deterministic part of a local LGCP model, trying to analyse interaction features among points of the selected sequence. The local version of the LGCP model estimates the spatial varying additional parameters $\sigma^2(\mathbf{u})$ and $\alpha(\mathbf{u})$, relaxing the usual assumption that in LGCP models the underlying process is unique and therefore one could obtain only a single value of the covariance of the process describing the correlation among points of the process. With the local version of the LGCP model it is now possible to spot those regions in which, combining together the two additional parameters, the covariance is higher, and therefore it is possible to identify regions in which different processes generate the observed events. Recalling the formula of the covariance of the process from Equation (2), we can introduce the modification of the latter $C(r,\mathbf{u}) = \sigma^2(\mathbf{u}) \exp\left(\frac{-r}{\alpha(\mathbf{u})}\right)$ that is, now the covariance depends also on the location and it is not constant. Basically, while usually it is assumed that the process generating the events is unique, the local approach allows for the assumption that the events may be generated from multiple processes. This is particularly useful since we are able to describe areas where points show different correlation patterns, fitting a unique model. The estimates $\hat{\sigma}^2(\mathbf{u})$ and $\hat{\alpha}(\mathbf{u})$ are displayed in Figure 3 and their summary statistics are reported in Table 2. The results are coherent with the estimated coefficients $\hat{\sigma}^2$ and $\hat{\alpha}$ of the global LGCP model that are respectively equal to 1.92 and 0.2. From Equation (2) we know that a unit increase of $\alpha(\mathbf{u})$ has a grater effect on the computation of the covariance, if compared to a unit increase of $\sigma^2(\mathbf{u})$. Therefore, from Figure 3, we know that the difference in the correlation among points is evident. In particular, this is higher in those areas in which cluster of events occurred, i.e. on the top of the region and on the bottom-right.

3 Conclusions

In this article the local models described by [1] are applied for the description of the seismic events occurred in Greece. This is an area of high seismic hazard that has been characterised by many destructive earthquakes in the last century. In [8], Hybrid of Gibbs models [2] are used to describe the same Hellenic catalogue. In this paper, interaction among points, crucial in the context of the analysis of seismic events, has been taken into account by fitting the local version of LGCP models. This approach makes possible to account both for the effect of covariates and also for the interaction among points, as function of the spatial location. From our application, local models provide good inferential results. It seems that fitting parameters that vary locally leads to more parsimonious models, explaining the spatial underlying variation of the phenomenon. One limit of the provided study is that the local composite likelihood works well if kernel smoothing well performs. Dealing with earthquake data, this is not always true, since their well known features of inhomogeneity and clustering in space. Finally, another important limit of this work is the neglected time component. Indeed, when analysing seismic data, often the focus is on the time sequence data analysis, since aftershocks are the proof of the dependence of earthquakes from the past. One possible future development could take into account both the spatial component, treated through local methods, such as the locally weighted regression, and the time component, moving in the context of space-time point processes.

Observation-driven models for storm counts

Modelli observation-driven per il conteggio delle tempeste

Mirko Armillotta, Alessandra Luati and Monia Lupparelli

Abstract New technologies have made available rich datasets of counts and binary data, focusing attention on time series models for discrete-valued processes. From the recent establishment of their theory, not much has been said about the practical usefulness of these data. Here, to partially address this task, an illustrative example on number of storm detected in the North Atlantic is presented.

Abstract *Nuove tecnologie hanno reso disponibile un ricco ammontare di dati binari e di conteggio, concentrando l'attenzione sui modelli di serie storiche per processi discreti. Dal recente sviluppo della loro teoria, non molto è stato detto riguardo l'utilità pratica di questi dati. Qui, per svolgere parzialmente questo compito, è presentato un esempio illustrativo sul numero di tempeste rilevate nel Nord Atlantico.*

1 A general framework for discrete-valued observation-driven models

Let us consider $\{Y_t\}_{t\in\mathbb{Z}}$ as a discrete-valued time series process. We define a class of observation-driven models such that:

$$Y_t \,|\, \mathscr{F}_{t-1} \sim q(\cdot;\mu_t)\,, \tag{1}$$

Mirko Armillotta, Alessandra Luati
Department of Statistical Sciences, University of Bologna, Via Belle Arti 41, 40126, Bologna, e-mail: mirko.armillotta2@unibo.it, e-mail: alessandra.luati@unibo.it

Monia Lupparelli
Department of Statistics, Computer Science, Applications, University of Florence, Viale Morgagni 59, 50134, Florence, e-mail: monia.lupparelli@unifi.it

$$g(\mu_t) = \alpha + \sum_{j=1}^{k} \gamma_j g(\mu_{t-j}) + \sum_{j=1}^{p} \phi_j h(Y_{t-j}) + \sum_{j=1}^{q} \theta_j \left[\frac{h(Y_{t-j}) - \bar{g}(\mu_{t-j})}{s_{t-j}} \right] \quad (2)$$

where $\mathscr{F}_{t-1} = \sigma(Y_{t-s}, s > 0)$, with. It is assumed that $q(\cdot; \mu_t)$ is a density (or mass) function whose dynamic is captured by the parameter μ_t. We define $g(\cdot)$, $h(\cdot)$ and $\bar{g}(\cdot)$ some one-to-one monotonic functions with range $\mathbb{R}$. The process s_t is some scaling sequence, usually $s_t = \sqrt{\mathrm{V}[h(Y_t)|\mathscr{F}_{t-1}]}$. The parameters ϕ_j measure an autoregressive effect of the observations; γ_j state the long memory dependence of the process (since μ_{t-j} depends on past observations Y_r, $r < t-j$); θ_j represents the analogous of a moving average part. In general, all the functions involved are not constrained to assume the same shape. This leads to a quite general and flexible framework which encompasses the most frequently used models on discrete-valued observation processes. Ergodicity conditions for model (1, 2) has been found in [1]. In [2] the same authors proved consistency and asymptotic normality of the quasi maximum likelihood estimator (QMLE), as defined in [7]. Once inference theory is established, we present an application.

2 Named storms in the North Atlantic Hurricane Basin

Here, by using (1, 2), we analyse the annual number of named storms in the North Atlantic Hurricane Basin (1851-2018) . In the label "named storm" are counted tropical storms, hurricanes and subtropical storms, from HURDAT database. The time series, with $n = 168$, is plotted in Figure 1 along with its autocorrelation function. There is a temporal correlation which spread over several lags in the past; this suggest the use a long memory feedback mechanism. We decided to fit models coming from two different distributions; the Poisson distribution:

$$q(Y_t, \mu_t) = \mathrm{P}(Y_t = y|\mathscr{F}_{t-1}) = \frac{\exp(-\mu_t)\mu_t^y}{y!}, \quad (3)$$

and the Negative binomial distribution (NB, henceforth):

$$q(Y_t, \mu_t) = \mathrm{P}(Y_t = y|\mathscr{F}_{t-1}) = \frac{\Gamma(\nu + y)}{\Gamma(y+1)\Gamma(\nu)} \left(\frac{\nu}{\nu + \mu_t} \right)^{\nu} \left(\frac{\mu_t}{\nu + \mu_t} \right)^{y}, \quad (4)$$

where $\nu > 0$ is the dispersion parameter and μ_t is the conditional expectation; the latter is the same for both distributions; in fact (4) is defined in terms of mean instead of probability parameter $p_t = \frac{\nu}{\nu + \mu_t}$ and it accounts for overdispersion in the data, since in the Poisson (3) mean and variance are the same, whereas in (4), $\mathrm{V}(Y_t|\mathscr{F}_{t-1}) = \mu_t(1 + \mu_t/\nu) \geq \mu_t$. We define a model selection procedure by estimating the following sub-models of (2). For simplicity, all the models include only the first lag. The log-linear autoregression (log-AR [8]):

$$\log(\mu_t) = \alpha + \phi \log(y_{t-1} + 1) + \gamma \log(\mu_{t-1}). \quad (5)$$

is obtained from (2) when the index $q = 0$, $g(\mu_t) = \log(\mu_t)$ and $h(y_t) = \log(y_t + 1)$. The Generalized ARMA model (GARMA, [3]):

$$\log(\mu_t) = \alpha + \phi \log(y^{\star}_{t-1}) + \theta \left[\log(y^{\star}_{t-1}) - \log(\mu_{t-1})\right] \tag{6}$$

is defined here from (2) with $k = 0$, $g \equiv \bar{g} \equiv h = \log(\cdot)$, where $y^{\star}_{t-1} = \max\{y_t, c\}$ and $c = 0.1$. The Generalized linear ARMA model (GLARMA, [6]) can be derived by (2) with $p = 0$, $g(\mu_t) = \log(\mu_t)$, $h(y_t) = y_t$ and $\bar{g}(\mu_t) = \mathrm{E}(Y_t|\mathscr{F}_{t-1})$:

$$\log(\mu_t) = \alpha + \gamma \log(\mu_{t-1}) + \theta \left(\frac{y_{t-1} - \mu_{t-1}}{s_{t-1}}\right) \tag{7}$$

where $s_t = \sqrt{\mu_t}$ for the Poisson distribution and $s_t = \sqrt{\mu_t\,(1 + \mu_t/\nu)}$ for the NB. A more general model is also introduced:

$$\log(\mu_t) = \alpha + \gamma \log(\mu_{t-1}) + \phi \log(y_{t-1} + 1) + \theta \left[\frac{\log(y_{t-1} + 1) - \bar{g}(\mu_{t-1})}{s_{t-1}}\right] \tag{8}$$

where $\bar{g}(\mu_t) = \mathrm{E}\left[\log(Y_t + 1)|\mathscr{F}_{t-1}\right]$ and $s^2_t = \mathrm{V}\left[\log(Y_t + 1)|\mathscr{F}_{t-1}\right]$. These conditional moments are computed by using the second order Taylor expansion. The score functions written in terms of predictor $x_t = \log \mu_t$ are:

$$\chi_n(\rho) = \frac{1}{n} \sum_{t=1}^{n} \Big(y_t - \exp x_t(\rho)\Big) \frac{\partial x_t(\rho)}{\partial \rho} \tag{9}$$

$$\chi_n(\rho) = \frac{1}{n} \sum_{t=1}^{n} \left(y_t - \frac{(y_t + \nu)\exp x_t(\rho)}{\exp x_t(\rho) + \nu}\right) \frac{\partial x_t(\rho)}{\partial \rho} \tag{10}$$

The solution of the system of non-linear equations $\chi_n(\rho) = 0$, if it exists, provides the QMLE of ρ (denoted by $\hat{\rho}$). In NB models, the estimation of ν is required. We used the moment estimator, as in [4]:

$$\hat{\nu}_1 = \left\{1/n \sum_{t=1}^{n} \left[(y_t - \hat{\mu}_t)^2 - \hat{\mu}_t\right] / \hat{\mu}^2_t\right\}^{-1} \tag{11}$$

where $\hat{\mu}_t = \mu_t(\hat{\rho})$ from the Poisson model. Then, with $\nu = \hat{\nu}_1$ we estimate the NB model and obtain the new estimates for $\hat{\mu}_t$, plug them into (11), obtain a new value for $\hat{\nu}_1$, and repeat the procedure until desired convergence.

Clearly, we replaced each quantity with the sample counterparts computed at $\hat{\rho}$. The results of the analysis are summarized in Table 2. The intercept is not significant, at a 5% level, for the General models and the NB log-AR and GARMA models. The same can be said for the parameter $\hat{\gamma}$ in the NB General model. All the other coefficients are significant. The parameter $\hat{\nu}$ is generally around 5. Both AIC and BIC select the Pois GLARMA model as the best, in goodness-of-fit sense.

We then assess the adequacy of fit. We check the behaviour of the standardized Pearson residuals $e_t = [Y_t - \mathrm{E}(Y_t|\mathscr{F}_{t-1})] / \sqrt{\mathrm{V}(Y_t|\mathscr{F}_{t-1})}$ which is done by taking the

empirical version $\hat{e}_t$ from the estimated quantities. If the model is correctly specified, the residuals should be white noise sequence with constant variance. The ACF in our case appear quite uncorrelated (not presented for space constraints).

Another check comes form the probability and marginal calibrations (mc), as defined in [9]. In particular [5] introduced a Probability Integral Transform (PIT) for discrete data. It can be build by the following conditional distribution function

$$F(u|y_t) = \begin{cases} 0, & u \leq P_t(y_t - 1) \\ \frac{u - P_t(y_t-1)}{P_t(y_t) - P_t(y_t-1)}, & P_t(y_t) \leq u \leq P_t(y_t - 1) \\ 1, & u \geq P_t(y_t) \end{cases} \tag{12}$$

where $P_t(\cdot)$ is the cumulative distribution function (CDF) at time t (in our case Poisson or NB). If the model is correct, $u \sim Uniform(0,1)$ and the PIT (12) will appear to be the cumulative distribution function of a Uniform(0,1). the PIT (12) is computed for each realisation of the time series $y_t, t = 1\ldots,n$ and for values $u = j/J, j = 1,\ldots,J$, where J is the number of bins (usually equal to 10 or 20); then its mean $\bar{F}(j/J) = 1/n\sum_{t=1}^{n} F(j/J|y_t)$ is taken. The outcomes are probability mass functions, which are obtained in terms of differences $\bar{F}(\frac{j}{J}) - \bar{F}(\frac{j-1}{J})$ plotted in Figure 2. The Poisson PIT's appear to be closer to Uniform(0,1).

The marginal calibration is defined as in [9] and [4]. Practically, it compares the average of CDF selected, $\bar{P}(x) = 1/n\sum_{t=1}^{n} P_t(x)$, against the average of the empirical CDF, $\bar{G}(x) = 1/n\sum_{t=1}^{n} \mathbf{1}(y_t \leq x)$; the difference $\bar{P}(x) - \bar{G}(x)$ is plotted in Figure 1 for GLARMA model and the model (8). In the other models the results are similar to those of GLARMA. Clearly, the nearer the difference to zero axis, the better. A far better concordance with empirical distribution for the Poisson case is found in the mc plot in Figure 1.

In order to assess the power of prediction we refer to the concept of sharpness of the predictive distribution defined in [9]. It can be measured by some average quantities related to the predictive distribution, which take the form $1/n\sum_{t=1}^{n} d(P_t(y_t))$, and $d(\cdot)$ is some function called scoring rule. We used some of the usual scoring rules employed in the literature: the logarithmic score (logs) $-\log p_t(y_t)$, where $p_t(\cdot)$ is the probability mass at the time t; the quadratic score (qs) $-2p_t(y_t) + \|p\|^2$, where $\|p\|^2 = \sum_{k=0}^{\infty} p_t^2(k)$; the spherical score (sphs) $-p_t(y_t)/\|p\|$ and the ranked probability score (rps) $\sum_{k=0}^{\infty}[P_t(k) - \mathbf{1}(y_t \leq k)]$, for different models and distributions. The results are summarized in Table 1. The Poisson General model have the best predictive performance for all the scoring rules. This shows the usefulness of our framework for the model selection in the existing literature as well as different new models which lead to improved performances.

Statistical control of complex geometries, with application to Additive Manufacturing

Controllo statistico di geometrie complesse, con applicazioni all'Additive Manufacturing

Riccardo Scimone, Tommaso Taormina, Bianca Maria Colosimo, Marco Grasso, Alessandra Menafoglio, Piercesare Secchi

Abstract New production processes, as Additive Manufacturing (AM), allow the production of objects and shapes characterized by a growing complexity, especially when compared with those normally manufactured in traditional production processes. It is thus necessary to develop methods which can be applied to the study of the variability of a dataset whose elements are manufactured realizations of the same nominal model, which can carry a very high degree of complexity. In the present work, we propose a method allowing modeling a wide variety of possibly local geometric deviations of the manufactured object with respect to the nominal model. A way of identifying and monitoring these kind of deviations, based on Principal Component Analysis in Hilbert spaces, is proposed as well. The proposed method is tested on a real datased of items produced via AM.

Abstract Lo sviluppo di nuovi metodi di produzione, quali l'Additive Manufacturing (AM), rende realizzabili forme geometriche sempre più articolate e molto più complesse di quelle normalmente realizzate in processi produttivi più tradizionali. Si rende dunque necessario lo sviluppo di metodi statistici applicabili all'esplorazione della variabilità di dataset in cui ogni osservazione è una realizzazione effettiva-

mente prodotta di un modello nominale, che può presentare un elevato grado di complessità. Nel presente lavoro viene proposto un metodo che consente, in linea di principio, di modellare un insieme molto ampio di deviazioni geometriche, anche locali, degli oggetti prodotti rispetto al modello nominale, e di rilevare successivamente tali deviazioni via Analisi delle Componenti Principali in spazi di Hilbert. Tale metodo viene altresì testato su un dataset di oggetti reali prodotti via AM.

1 Introduction

Additive Manufacturing processes are becoming more and more important, since they are facing a continuous technological improvement, and they allow the realization of a wide variety of shapes and geometries. The production of complex shapes (e.g, objects with a complete asimmetry, or with an internal lattice structure) constitutes an interesting challenge for Statistical Process Control. The necessity of adequate methods, suitable to the statistical control of this kind of objects, is moreover driven by the fact that the industrial sectors in which AM presents the greatest potentialities are the aerospace and the biomedical sectors ([10]), both areas in which the identification of production errors is foundamental.
After the manufacturing phase, data usually come as reconstructed shapes (e.g., via tomography), in the form of a point cloud, possibly associated to a triangulated mesh. Point clouds are a class of data whose statistical process monitoring has been studied by several authors ([6], [7], [11], [12]). In all cited works, points in the reconstructed point cloud were associated with their deviation from the nominal geometry (usually a CAD model), hence producing a *deviation map*. However, the deviation map generated by the distances of the points in the reconstructed point cloud is usually different from the deviation map generated by the distances of the points in the nominal point cloud from the reconstructed object. Different information are, in general, carried by the corresponding deviation maps, as follows from the formal definition of Hausdorff distance between subsets of a metric space, which was firstly introduced, in a completely different context, by Hausdorff in [1]. In [15] we propose to summarize all the information content about the differences between an object and its corresponding model using two *deviation maps*. These maps are then used in a monitoring method based on a functional Principal Component Analysis for compositional data (SFPCA, [8]), allowing to exploit this information content completely. In this communication, performances of the method shall be showcased on a dataset of manufactured objects, produced via Additive Manufacturing at the Department of Mechanical Engineering at Politecnico di Milano. These objects will be briefly introduced in the next section.

2 Test Dataset: a motivating example

The dataset on which all the analyses are carried out consists of a sample of 16 meshes, resulting from the tomography of plastic objects produced via Additive Manufacturing at the Department of Mechanical Engineering of Politecnico di Milano. These objects are trabecular egg-shaped shells, and they constitute a quite realistic example of the geometric complexity that can be achieved by Additive Manufacturing processes. We show the nominal model in Fig. 1.

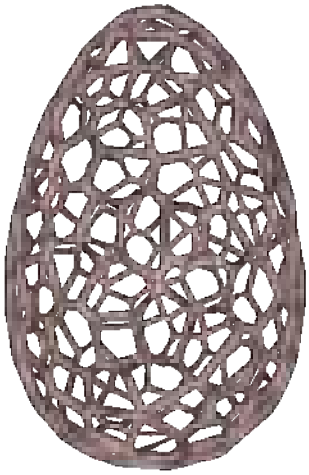

Fig. 1 Nominal CAD model for the produced trabecular structures.

Among the sixteen produced items, we have objects with no evident defects (In Control), as well as items affected by different kinds of geometrical deviations (Out of Control). In Fig. 2 we show two realizations of defective elements, on the left an item affected by irregularities on the geometrical structure, on the right a case in which a struct is missing.

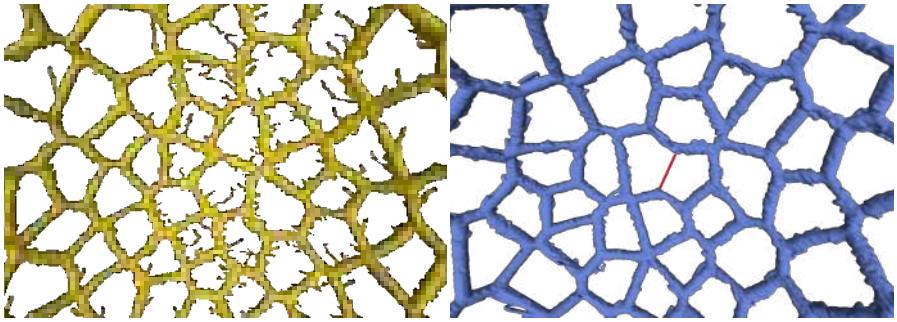

Fig. 2 Different kind of geometric deviations in the manufactured objects

It is worth noting that these geometrical deviations are an example of the complementariety of the two deviation maps mentioned in Section 1. Indeed, while the local irregularities can be detected if one measures the distance of points of the manufactured object from the nominal model, a missing struct is visible only when considering distance of points of the nominal model from the manufactured object.

3 Methodology: a density representation of Hausdorff maps

The general problem of analyzing the differences between two meshes or point clouds can be efficiently stated by referring to the definition of Hausdorff distance, given below (see [2] for a deeper insight).

Definition 1. Let X, Y be two closed, bounded, non-empty subsets of a metric space (U, d). Their Hausdorff distance is defined as

$$d_H(X,Y) := \max \left\{ \sup_{x\in X} \inf_{y\in Y} d(x,y), \sup_{y\in Y} \inf_{x\in X} d(x,y) \right\} \tag{1}$$

This definition implicitly introduces two maps, which are

$$d_X : Y \to \mathbb{R}^+, d_X(y) := \inf_{x\in X} d(x,y) \tag{2}$$

and

$$d_Y : X \to \mathbb{R}^+, d_Y(x) := \inf_{y\in Y} d(x,y) \tag{3}$$

which will be called, as already done, *deviation maps*. A key idea underlying the method we propose in [15] is that both deviation maps should be analyzed to re-

trieve all possible differences between a reconstructed geometry and the nominal one. In the case of a dataset of point clouds, these maps are easily computed, since they are represented by finite, discrete sets. From each map we estimate a density obtained by dropping the spatial information carried by the data. These are f_X and f_Y, representing the PDFs of the values of d_X and d_Y respectively (or of a monotone transformation of these). The dataset of PDFs can be analyzed on the common support of the densities through SFPCA ([8]), which extends Functional Principal Component Analysis ([3]) to probability density functions. The natural space in which PCA of density functions can be coherently performed has been defined by ([4]), and laterly studied in other works ([5], [9]). It is the space $B^2(a,b)$, defined as the set (of equivalence classes) of positive functions with square-integrable logarithms

$$B^2(a,b) := \{f > 0 \text{ s.t. } \log f \in L^2(a,b)\} \tag{4}$$

where the equivalence relation is defined as

$$f_1 = f_2 \iff \exists c > 0 \text{ s.t. } f_1 = c f_2 \text{ a.e..} \tag{5}$$

In $B^2(a,b)$, operations and inner product are defined as

$$f_1 \oplus f_2 = f_1 f_2, \tag{6}$$

$$\alpha \odot f_1 = f_1^{\alpha}, \alpha \in \mathbb{R} \tag{7}$$

$$\langle f_1, f_2 \rangle_{B^2} = \frac{1}{2(b-a)} \iint \log \frac{f_1(x)}{f_1(y)} \log \frac{f_2(x)}{f_2(y)} \, dx \, dy. \tag{8}$$

This space is a useful extension of the Aitchison geometry (see [13] for a complete reference), in which PCA can be applied in the form of SFPCA ([8]), and it can be practily applied relying on the centered log-ratio transformation, as in [14]. Dimensionality reduction via SFPCA allows reducing the monitoring problem to a multivariate one based on the scores along the first K principal components. In [15], we build a control chart scheme based on the scores vectors, which allows detecting out of control conditions for the produced objects.

4 Results and conclusion

SFPCA, based on a geometric structure coherent with the features of probability density functions, provides interpretation tools which are quite powerful when coupled with the geometric iterpretation of the introduced deviation maps. This dimensional reduction technique provides a very good compromise between spatial simplification (all spatial information is dropped) and loss of information (the functional approach allow to performs data analysis directly on density functions). The control chart scheme based on SFPCA proves to be very effective in detecting out-of-control conditions deriving from either widespread or localized defects. Indeed,

the method performs well also in presence of local defects affecting just a small part of the whole point cloud, exhibiting then good detection power.

Tree attributes map by 3P sampling in a design-based framework

Mappa degli attributi forestali attraverso il campionamento 3P in un approccio basato sul disegno

Lorenzo Fattorini and Sara Franceschi

Abstract As mapping is becoming a burning issue in environmental and forest surveys, the estimation of marks for a finite population of points (e.g. trees) scattered onto a survey region when a 3P sampling is adopted is here considered. The estimation is approached in a design-based setting, consequently avoiding the massive modelling usually involved in model-based framework to handle with marked point processes. Since 3P sampling involves marks prediction for each population unit, prediction errors are here interpolated instead of marks in order to better meet design-based consistency requirements. The effectiveness of the proposed strategy is checked theoretically and by means of a simulation study performed on both artificial and real populations.

Abstract *La mappatura di attributi ecologici costituisce un argomento di notevole interesse nelle indagini di carattere ambientale e forestale. In questo lavoro è stato affrontato quindi il problema della stima degli attributi di una popolazione finita di punti (ad esempio alberi) collocati in un'area di studio qualora venga adottato un campionamento 3P. La procedura di stima è stata considerata in un approccio basato sul disegno, evitando dunque la modellistica solitamente utilizzata qualora si lavori in un contesto da modello. Al fine di soddisfare più facilmente le condizioni necessarie alla coerenza, sono stati interpolati gli errori di previsione piuttosto che l'attributo di interesse. Al fine di verificare empiricamente le proprietà teoriche, è stato effettuato uno studio di simulazione sia su popolazioni reali che artificiali.*

Key words: 3P sampling, marked point populations

1 Introduction

Wall-to-wall mapping of spatial pattern of ecological attributes is becoming a burning issue in forest surveys and inventories, since it represents a crucial information for environmental managing.

Maps of interest attributes are usually obtained in a model-based approach (see e.g. [5], [7], [8]) supposing that units are outcomes of a marked point process in the plane. However, in the last years the issue has been addressed in a design-based framework ([1], [3], [4]) where, contrary, marks are treated as fixed characteristics and properties of the resulting maps are determined by the probabilistic sampling scheme adopted to select units on which marks are recorded. The authors exploited the very simple Tobler's first law of geography as assisting model and accordingly, they adopted the so-called inverse distance weighting (IDW) interpolator in which the marks at un-sampled units are estimated by a weighted sum of the sampled marks with weights inversely decreasing with distances to the unit under estimation.

Nevertheless, as to concern natural finite populations of marked points such as trees or shrubs, maps are rarely possible owing to the prohibitive acquisition of units' locations. In most cases, natural populations are sampled without knowing their lists, by means of plots or transects located in the study area according to a suitable probabilistic design.

Probably, the unique relevant case in which the mapping of natural populations becomes possible is under the so called 3P sampling. Indeed, under 3P sampling all the units of the population are visited by a crew of experts in such a way that population list together with predictions of the survey variable for each population unit can be obtained. Then, units are independently selected with probabilities proportional to prediction (3P) as in the Poisson sampling. In this context, for the sampled units, both predictions and actual values are known, in such a way that also the prediction errors are known for them. Therefore, prediction errors can be interpolated by IDW, in such a way that the interpolated values are given by the predictions plus the interpolated errors. Fattorini et al. [8] pointed out that this strategy is likely to provide considerable improvement with respect to the direct interpolation of marks.

The goal is now to pursue this strategy and to check its effectiveness.

2 Notations and theoretical results

Let $\mathcal{A}$ be a survey region and suppose a discrete population U of N points $p_1,\ldots,p_N$ scattered onto $\mathcal{A}$. For brevity denote points by their indices $1,2,\ldots,N$. For each point $j\in\mathsf{U}$ let y_j be the amount of the survey variable Y, usually referred to as the mark of unit j. The interest is to reconstruct the marked population of points on the basis of the values recorded in a sample S of n points selected from U by means of 3P

sampling. Exploiting the Tobler law of geography in a model-assisted framework, Bruno et al. [1] propose to estimate the y_j s by means of the IDW interpolator

$$\hat{y}_j = Z_j y_j + (1 - Z_j) \sum_{i \in U} w_{ij} y_i$$

where Z_j is the random variable equal to 1 if $j \in S$ and 0, otherwise

$$w_{ij} = \frac{Z_i \phi(d_{ij})}{\sum_{l \in U} Z_l \phi(d_{lj})}$$

is the weight attached to the mark of unit *i* to estimate the mark of unit *j*, d_{ij} represents the Euclidean distance between points *j* and *h* and $\phi : [0, \infty) \to \Re^+$ is a not increasing function on $]0, \infty)$, with $\phi(0) = 0$ and $\lim_{d \to 0^+} \phi(d) = \infty$.

Fattorini et al. [8] derived conditions under which 3P sampling ensures design-based asymptotic unbiasedness and consistency of the IDW interpolator. Furthermore, they propose to interpolate predictions errors rather than marks. Indeed, for the sampled trees, both predictions, here indicated by y_j^0, and actual values y_j are known, in such a way that also the prediction errors $e_j = y_j - y_j^0$ are known for each sampled point. Therefore, the IDW interpolator can be used for interpolating the prediction errors for any population unit by means of

$$\hat{e}_j = Z_j e_j + (1 - Z_j) \sum_{i \in U} w_{ij} e_j$$

As to the mean squared error estimation, following [8], a simple estimator is

$$\hat{V}_j = (\hat{e}_j - e_{near(j)})^2$$

where *near*(*j*) is the label of the sampled unit nearest to point *j*.

In this way the interpolated marks are given by the predicted values plus the interpolated errors, that is

$$\hat{y}_j = y_j^0 + \hat{e}_j, \quad p_j \in U$$

It can be proven that smoothness assumptions for marks, necessary for ensuring design consistency, are more realistic when considering prediction errors. Indeed, jumps and irregularities of marks throughout $\mathcal{A}$ are presumably absorbed by similar jumps and irregularities in the corresponding predictions. As consequence, if predictions are good, prediction errors turn out more smoothed than marks.

Following [2] and [6], it is reasonable to assume that there exists a maximum error rate of predictions $r \in (0,1)$ that occurs at the extremes of marks, in such a way that small values near the lower bound *l* are over-evaluated and large values near the upper bound *L* are under-evaluated. If for simplicity we further assume that the predictions increase linearly with marks, then

$$y_j^0 = a + b y_j, \; p_j \in U$$

where

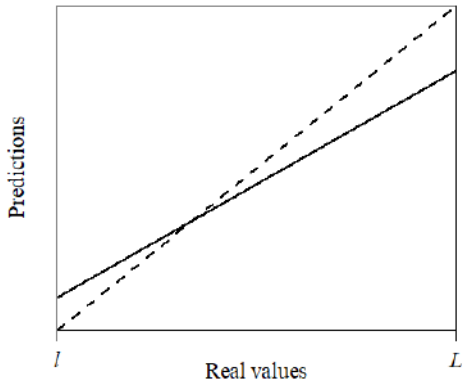
$$b = 1 - r\frac{L+l}{L-l}, \quad a = (1+r)l - bl$$

with $r < (L-l)/(L+l)$ in order to ensure a slope $b \in (0,1)$ in such a way that the prediction line increases less slowly than the line of perfect predictions (see Figure 1).

In such a situation it has been proven that, under some conditions, if prediction errors are interpolated instead of marks, the gain in precision is expected to be about

$$(1-b)^{-1} = \frac{L+l}{(L-l)r}.$$

Figure 1: The continuous line shows predictions as linear function of the true values with maximum error rates occurring at the extremes. The dotted line is the line of perfect predictions



3 Simulation study

A simulation study is performed on a set of artificial nested populations of points located in a unit square in accordance with different spatial patterns in order to check the gain provided by the error interpolation with respect to the direct interpolations of marks under predictions of different precision. The same comparison is performed on a real population of about 1400 trees within a stand of 9*ha* located in Monte Cimino (South Italy).

For any considered population, 10000 samples were selected according to 3P sampling and absolute relative bias, relative root mean squared error and absolute bias of the relative root mean squared error estimator were computed from the resulting Monte Carlo distributions of the density estimates and of the relative root mean squared error estimates.

Results, not reported here for sake of brevity, completely confirm the theoretical finding of section 2.

4 Conclusion

Theoretical and simulation results highlight the failure of IDW technique in the direct interpolation of marks under 3P sampling. This problem tends to disappear when prediction errors are interpolated instead of marks. In this case, under good predictions, prediction errors are much more smoothed than marks. Therefore, the interpolation gains a satisfactory level of accuracy and precision notwithstanding the unbalanced selection provided by 3P sampling.

In conclusion, in accordance with the results of this study, when the purpose is simply to produce a map of a mature population of trees without giving explanation about the process that dislocated trees and generated volumes, the complex task of modelling the marked point process and estimating its parameters can be avoided and we can opt to produce the map in a design-based framework adopting 3P sampling and the IDW interpolation of prediction errors: under reliable predictions, the resulting map has the potential of being a reliable picture of the actual map.

Unsupervised classification of texture images by gray-level spatial dependence matrices and genetic algorithms

Classificazione di immagini attraverso matrici di dipendenza spaziale dei livelli di grigio e algoritmi genetici

Roberto Baragona[1] and Laura Bocci[2]

Abstract Recognition of objects and regions of interest in digital image processing often relies on texture classification. The source image is divided according to a rectangular grid to form textured regions each of which is characterized by some numerical significant measure called feature. A new approach is introduced that uses the gray-level spatial dependence matrices and the genetic clustering with unknown *K* algorithms to locate sets of homogeneous regions and enhance the discrimination amongst them. There is no need to select and compute complicated features transforms as the procedure is based on the optimal weighting of the simple basic features. A simulation experiment is performed using the well-known Brodatz textures to demonstrate that the new procedure is able to define well separated clusters according to the principle of strong internal cohesion and high inter-clusters separation.

Abstract *Nell'elaborazione di immagini digitali il riconoscimento di oggetti e di regioni di interesse si basa spesso sulla classificazione delle trame. L'immagine viene divisa secondo una griglia rettangolare individuando regioni caratterizzate da una specifica caratteristica. Allo scopo di individuare nell'immagine insiemi di regioni omogenee si presenta un approccio basato sulle matrici di dipendenza spaziale dei livelli di grigio e sugli algoritmi genetici di clustering con numero di gruppi K incognito. Secondo questo approccio non è necessario selezionare e calcolare complicate trasformazioni di funzioni poiché la procedura si basa sulla ponderazione ottimale delle semplici funzioni di base. Un esperimento di simulazione che utilizza le note trame di Brodatz dimostra che la nuova procedura è in grado di definire gruppi ben definiti secondo il principio di forte coesione interna ed elevata separazione tra i gruppi.*

1 Introduction

A large amount of digital imagery data is available from uncountable sources within continuous processes. A thorough examination of even a single image by human visual inspection is often practically impossible and therefore discovering some characteristics of interest hidden in a noisy framework is challenging. Examples may be found in aerial photograph, photo micrograph, satellite and/or medical images.

In this paper we are concerned with the task of texture classification in a given 2-dimensional image, which consists in identifying and portraying, using a gray-scale (or a colormap), the features occurring in the image in terms of the object or type of land cover these features actually represent on the ground. Many problems in image processing may be handled conveniently by texture analysis. Recognition of objects and regions of interest in digital texture processing mainly relies on either supervised or unsupervised texture classification. Uniform textured regions are usually identified by defining and computing numerical significant measures of certain characteristics of the image. Relevant applications may be found in surface recognition and medical imagery framework. Dealing with textures often means that a 2-dimensional image is available that contains important information about the structural arrangement of surfaces and their relationship to the surrounding environment. From the visual image of a texture special characteristics of interest have to be extracted to draft a kind of 3-dimensional picture of reality. Methods for describing image textures (see e.g. Depeursinge et al., 2017) may be approximately divided in geometrical, model based, signal processing and statistical.

In this paper we concentrate on the statistical method based on Gray-Level Spatial Dependence Matrix (GLSDM) (Haralick et al., 1973). Spatial statistics are commonly used within this approach. Such texture features summarize the spatial gray level co-occurrence in an image. Actually the image is an array of gray levels, one gray level for each and every pixel. Each entry of the associated GLSDM is the frequency of the pair of gray levels that distance apart and oriented according to that angle. Several image texture properties may be estimated from spatial dependence matrices and homogeneous regions may be identified and classified accordingly.

Our contribution for improvement mainly resides in using two devices: 1) the discrimination enhancement problem as stated by Zizzari (2003) is solved by using genetic algorithms instead of numerical optimization; specially for large equation systems numerical algorithms may not converge to the optimal solution; 2) the genetic clustering for unknown K (Bandyopadhyay and Maulik, 2002, GCUK) is used to overcome the limitation to only 3 clusters in the early formulation of the discrimination enhancement problem.

The plan of the paper is as follows. In the next Section 2 the feature extraction from GLSDM procedure is summarized and the discrimination enhancement problem is stated formally. In Section 3 the genetic algorithms solution to the discrimination enhancement problem is presented. A Monte Carlo simulation experiment is described in Section 4 which aims at demonstrating the capability of the genetic algorithm-based procedure in the recovering of textures in an image.

2 The discrimination enhancement problem

An image in its digital form is usually recorded as an $L_x \times L_y$ matrix $\mathbf{R}$ of resolution cells, or pixels. Any of the elements r_{pq} (p = 1,…, N_x, q=1,…, N_y) of the matrix $\mathbf{R}$ is a pixel with gray tone $g \in G$, $G = \{1, \dots, N_g\}$.

The Gray-Level Spatial Dependence Matrix (GLSDM) $\mathbf{P}_{(d,\theta)}$ related to the matrix $\mathbf{R}$ and for displacement (d, θ) as defined in Haralick et al. (1973) is a square symmetric matrix, with row and column dimensions equal to the number of discrete gray levels (intensities) N_g in the image being examined, for each distance d and orientation θ. The generic element of $\mathbf{P}_{(d,\theta)}$ in row i (gray tone i) and column j (gray tone j) is the frequency of pairs (r_{pq}, r_{st}) of pixels distance d far apart along direction θ and such that $r_{pq} = i$ and $r_{st} = j$. The dependence spatial matrix reveals certain properties about the spatial distribution of the gray levels in the texture.

Considering that all texture information is contained in $\mathbf{P}_{(d,\theta)}$ related to the image $\mathbf{R}$, a set of textural features can be extracted from GLSDM. These features may be defined as possibly non-linear real functions of the elements $p(d, \theta)_{ij}$. Though any feature contains information about the textural characteristics of the image, the interpretation may not be as easy to perform. One may be often left in doubt what characteristic or property it is exactly concerned with. Moreover, the result is strongly affected by the ability of the feature functions to map the underlying structures of an image in order to identify objects or regions of interest in the image itself. This task is strictly dependent on the discriminatory power of the chosen feature functions, in the sense that the functions have to assign very different values to different types of image blocks.

Let $\mathbf{W} = [w_{ij}]$ $(i, j = 1, \dots, N_g)$ be the $N_g \times N_g$ matrix of weights associated to the GLSDM $\mathbf{P}_{(d,\theta)}$, we introduce the features functional form as follows

$$f(\mathbf{W}) = \mathbf{1}'_{N_g}\left(\mathbf{W} \odot \mathbf{P}_{(d,\theta)}\right)\mathbf{1}_{N_g}\,, \tag{1}$$

where $\mathbf{1}_{N_g}$ denotes the column vector with N_g ones and $\odot$ is the Hadamard product (i.e. the entry-wise product). The discrimination power of the feature f in (1) will depend directly on how well each of the individual elements w_{ij} $(i, j = 1, \dots, N_g)$ discriminate between spatial gray tone related to clusters of pixels. The purpose is to find the weights w_{ij} associated to each element of $\mathbf{P}_{(d,\theta)}$ that are large for those elements which produce good discrimination, while are small (ideally zero) for the elements giving poor discrimination.

Often a real problem consists in distinguishing textures within the same textural image. Let $\mathbf{R}$ be divided in n sub-matrices (blocks) $\{\mathbf{R}_1, \dots, \mathbf{R}_h, \dots, \mathbf{R}_n\}$ each of dimension $L_x^h \times L_y^h$ (h = 1, . . . , n). For each and every block $\mathbf{R}_h$ (h = 1,…, n) a gray-level spatial dependence matrix $\mathbf{P}_h$ for given (d, θ) may be computed and features f_h evaluated as in (1)

$$f_h(\mathbf{W}) = \mathbf{1}'_{N_g}(\mathbf{W} \odot \mathbf{P}_h)\mathbf{1}_{N_g}\,, \qquad (h = 1,\dots, n). \tag{2}$$

Each one of the n blocks $\mathbf{R}_h$ may be assigned to one of K clusters $C = \{C_1, \dots, C_k, \dots, C_K\}$ using the block feature. Let T_k be the cardinality of the discrete set C_k, the $n = \sum_{k=1}^{K} T_k$.

The objective is the improvement of such a discriminatory power of textural features by identifying an optimal set of weights **W** which solves the problem of maximizing this level of separation among clusters of pixels. The criterion is to enhance the separation amongst feature values that may be associated to different classes of pixels and simultaneously improve internal cohesion. The optimization problem that allows the set of weights **W** to be computed is called *discrimination enhancement problem* (Zizzari, 2003). This way the functional form itself is determined by the data and is not imposed arbitrarily.

The requirement of greatest separation amongst clusters C_k (k = 1,…, K) may be conveniently achieved by maximizing the total *inter - cluster separation measure*

$$TISM(\mathbf{W}) = \frac{1}{2}\sum_{k=1}^{K}\sum_{v=1}^{K}\left(\bar{f}(\mathbf{W})^{(k)} - \bar{f}(\mathbf{W})^{(v)}\right)^2$$

where $\bar{f}(\mathbf{W})^{(k)} = \frac{1}{T_k}\sum_{h\in C_k} f_h(\mathbf{W})$ (k = 1,…, K), f_h defined by Equation (2).

For maximizing internal cohesion the total *within - cluster scatter measure*

$$TWSM(\mathbf{W}) = \frac{1}{2}\sum_{k=1}^{K}\sum_{h\in C_k}\left(f_h(\mathbf{W}) - \bar{f}(\mathbf{W})^{(k)}\right)^2$$

The discrimination enhancement problem consists in searching for optimal weighting parameters **W** so that $(TWSM - TISM)$ is minimized. Note that the features themselves depend on the weights and their values are involved as well within the optimization procedure, so usual optimization may not be used directly.

The number of clusters K is either known or may be assumed known from some preliminary analysis, but it seems preferable that the number of clusters be included as an additional parameter within the optimization procedure. A measure of cluster validity which is in close agreement with the principles of the discrimination enhancement problem is the Davies - Bouldin index (Bezdek and Pal, 1998).

3 A Genetic algorithm for texture analysis

The optimization problem described in Section 2 may be decomposed in two steps. The first step is concerned with the estimation of the weighting parameters. The second step regards the allocation of the blocks to clusters. The genetic clustering with unknown K (GCUK) algorithm (Bandyopadhyay and Maulik, 2002) is adapted to implement both steps sequentially in each iteration. The GCUK algorithm is a natural choice, as it minimizes both the chromosome length and the execution time, and uses as optimality criterion a transform of the Davies-Bouldin index.

A GCUK algorithm is a population based meta-heuristic that starts from a set of tentative solutions, called chromosomes, to the optimization problem and proceed for a pre-specified number of iterations in each of which the set of tentative solutions in the current population are updated to produce a new set of improved tentative solutions that replace the current one. Each iteration is composed of three steps usually called selection, crossover and mutation.

A crucial point in the definition of a genetic algorithm is the choice of the encoding of a tentative solution. In this framework, any tentative solution to the discrimination enhancement problem is coded as a chromosome of length $N_g^2 + K_{\max}$. The chromosome has two parts: 1) a sequence of N_g^2 real numbers that are assumed as the weights $\{w(i,j)\}$ $(i,j = 1,\dots,N_g)$; 2) a sequence of length $K_{\max}$ which may include either real numbers or # symbols, the former are a centre of a non-empty cluster, the latter represents an empty cluster; the number of non-empty clusters K is required to take value in the interval $[K_{\min}, K_{\max}]$.

A disadvantage in operating with the whole chromosome resides in that the chromosome itself may be too large for the genetic algorithms to be able to output a reliable solution in a reasonable time. In addition, the two parts of the chromosome may happen to be unbalanced, i.e. one part may be larger than the other in such a way that the genetic algorithm works essentially on the longer part and neglects the shorter. Then we may run the procedure in two steps: 1) weights estimation: the second part of the chromosomes is assumed constant, and chromosomes are evolved by improving their fitness function only using the first part of the chromosome; 2) allocation of the blocks to clusters: changes are allowed only in the second part of the chromosome. In this second step the optimal allocation of blocks to clusters takes place by using the weights obtained in the first step.

Should the number of weights be excessively large we could resort to maximum likelihood estimation of the weights assuming normality and using Monte Carlo methods. In this case only step 2 would be executed achieving a significant reduction of computations.

4 A Monte Carlo experiment

To check the effectiveness of the genetic algorithm-based procedure for unsupervised classification of textures some Monte Carlo simulations have been performed. We downloaded all 111 Brodatz textures from D1.gif to D112.gif (texture D14.gif is missing). These are 75×75 pixels images. In the present simulation experiment 49 textures selected at random were arranged in a 7×7 grid to assemble a 525×525 pixels mosaic. The random selection has been replicated 1000 times to yield 1000 texture mosaics. Three levels of noise have been considered, 1%, 5% and 10%, that is pixels in each image have been altered at random according to the given percentage. For each texture mosaic the genetic algorithm-based clustering procedure has been used to recover the right classification of the original textures.

For the computation of the gray-level spatial dependence matrices and the features extraction the Matlab Image Processing Toolbox has been used, available in the version R2017b or higher.

Results from the complete Monte Carlo experiment are reported in Table 1 where the well-known corrected Rand index (CRI) and number of cluster bias (difference between actual and estimated number of clusters) are averaged across 1000 replications. The standard errors are enclosed in parentheses. The genetic algorithm parameters have been: population size 10; number of generations 20; crossover probability 0.7; mutation probability 0.01; interval where the number of clusters has to be searched ($K_{\min} = 2$, $K_{\max} = 10$). Ng = 16 gray levels have been used (bit depth = 4 bits) and features have been computed averaged across angles $\theta = (0, \frac{\pi}{4}, \frac{\pi}{2}, \frac{3}{4}\pi)$ for each of three distances $d = (1, 2, 3)$. As a matter of fact, angular dependencies should be invariant under rotations. This condition may be fulfilled by using some suited functions of the angularly dependent features (Haralick et al., 1973, p. 615), for instance their average.

Table 1: Assessment of the two steps genetic algorithm-based procedure for texture analysis: Corrected Rand index and number of cluster bias, averaged across 1000 replications of Monte Carlo simulation experiment. The standard errors are enclosed in parentheses.

Level of noise	*Corrected Rand index*	*Number of cluster bias*
1%	0.8451 (0.1480)	- 0.5420 (2.0298)
5%	0.8247 (0.1495)	- 0.2950 (2.0600)
10%	0.8099 (0.1556)	- 0.2090 (2.0453)

According to the CRI values shown in Table 1 the genetic algorithm-based procedure seems able to recognize the different textures. It has to be expected that, increasing the noise level, the agreement between the actual and estimated partitions deteriorates while the variability of the estimates increases. Nevertheless, the figures reported in Table 1 suggest that the loss of precision is rather small. The bias of the estimates of the number of clusters is always negative, that is the procedure estimates in general more clusters than the actual ones. However, the standard errors of the estimates are large as maybe often a cluster is split into two similar clusters.

A discrete choice approach to analyze contractual attributes in the durum wheat sector in Italy

Un approccio a scelte discrete per l'analisi degli attributi contrattuali nel settore del grano duro in Italia

Stefano Ciliberti[1] and Simone Del Sarto[1] and Giulia Pastorelli[1] and Angelo Frascarelli[1] and Gaetano Martino[1]

Abstract This study investigates the preferences of durum wheat farmers as regards the characteristics of a contract, considering this tool as a mechanism for transferring decisions and property rights. To this aim, a sample of durum wheat Italian farmers is interviewed for expressing their preferences about some contractual features, such as price, production and quality rules and sustainable environmental techniques. Using a discrete choice analysis through a multinomial logistic model, results shows how contracts, in addition to price stabilization, are relevant for their impact on technology, quality, and the environment.

Abstract *Questo lavoro indaga le preferenze degli agricoltori di grano duro circa i termini contrattuali di un contratto, considerato come meccanismo di trasferimento delle decisioni e dei diritti di proprietà. A tale scopo, è stato intervistato un campione di agricoltori italiani di grano duro, i quali hanno espresso le loro preferenze inerentemente al prezzo, regole di produzione e di qualità e tecniche ambientali sostenibili. I risultati ottenuti mediante modelli a scelta discreta mostrano come i contratti, oltre alla stabilizzazione dei prezzi, siano rilevanti per il loro impatto sulla tecnologia, sulla qualità e sull'ambiente.*

Key words: Discrete choice models, contracts, contractual terms, uncertainty

1 Introduction

Contracts between farmers and agri-food processors have received increasing attention in different theories and by policy-makers. Recent developments in Transaction Cost Economics have shed light on the possibility of analyzing the contracts in terms of the allocation of rights between transacting parties [2]. This new perspective allows for a model of contract analysis to be developed which, on one hand, connects

[1] Department of Agricultural, Food and Environmental Sciences, University of Perugia

the contract with the organization and provides a detailed perspective and, on the other, highlights the transfer of rights between the parties and the role this plays in organizing the transaction. The three basic components (the transaction, the property and decision rights, and the contract) are analytically interconnected in the golden triangle and provide key "tools to investigate the institutional dimensions framing the economies" [3]. This approach conceives the contract as the way to organize the transfer of rights between the parties to a transaction [2].

Moreover, the theory states that the choice of governance structure is made by aligning the attributes of the transaction (asset specificity, uncertainty, and frequency) with the attributes of the governance structures [10]. Transaction attributes determine the costs associated with each organizational form and agents seek to choose an efficient organization to minimize these costs. According to empirical studies on contract farming [1, 5], uncertainty plays the major role in this background of contractual choice. From a general standpoint, uncertainty incurs higher governance costs when coordination is decentralized. As a consequence, an agent would exclude a contractual term/condition when faced with a high level of uncertainty. By keeping the decision rights in his/her own hands and out of the contract, the costs of adaptation are reduced compared to the case of a low level of uncertainty in which the decision rights are allocated in the contract. In this regard, the concept of uncertainty can be split into three subcategories: market uncertainty ("unpredictability of demand and inability to accurately forecast and schedule production" [4]), technological uncertainty (acceleration of technological changes that increase the rate of obsolescence in assets [7]) and behavior uncertainty ("the difficulty of observing and measuring the adherence of the transacting parties to the contractual arrangements and the difficulty of measuring the performance of these parties" [6]).

Against this backdrop, the present paper aims at testing the main hypothesis that the transaction attribute of uncertainty affects the allocation of decision rights within a contract. In more details, the contractual attributes related to the three types of uncertainty are: price (market uncertainty), rules of production, quality levels and sustainable cultivation techniques (technological uncertainty), and forms of payment and technical assistance (behavioral uncertainty).

The durum wheat sector in Italy certainly represents an interesting case study for testing the above hypothesis. In fact, durum wheat is usually seen as a commodity market and this context enables us to put less emphasis on asset specificity and more focus on the uncertainty attribute. Moreover, despite contracts have not been traditional largely used in this sector as a means of decision coordination, they have gained momentum even in order to address the different type of uncertainties that have negatively affected the stability of exchanges between farmers and processing companies.

To this aim, we analyze data coming from questionnaires administrated to farmers. They have to choose among several contracts, specified in terms of various attribute levels (contractual terms) that reflect the three uncertainties just mentioned. In particular, a choice-based conjoint analysis is performed by means of an extended multinomial logit model [9].

This article is organized as follows. Section 2 describes the way we obtained data and the statistical method employed for our analysis. Results are shown in Section 3, while some concluding remarks are given in Section 4.

2 Material and methods

We use data from questionnaires administrated during the period October 2019-February 2020 to farmers from several regions that represent the main areal of production of durum wheat in Italy. In these questionnaires, different potential contracts are proposed, characterized by six attributes (each one with three levels), reflecting different types of uncertainties (Table 1).

For investigating the farmers' preferences as regards contractual terms, a discrete choice experiment is carried out. A full factorial design is obtained by combining the levels of all the attributes. Hence, $3^6 = 729$ different contracts may arise, but this amount is too hard to handle in a single experiment. For this reason, a fractional factorial design is created and contracts are randomly distributed into 18 choice sets, each of them with three possible contracts (alternatives) plus the no-choice option, that is, "none of the previous contracts". Ultimately, the farmer randomly faces three out of these 18 choice sets and, for each one, the choice is among four alternatives: either one of the three proposed contracts or the no-choice option.

Let us suppose that decision-maker $i = 1,\dots,n$ has to choose among J alternatives (i.e., contract profiles in our case). According to the random utility modeling framework, he/she will choose the alternative that maximizes his/her utility, U_{ij}, with $j = 1,\dots,J$. Then, the probability of choosing alternative l is

$$P_{il} = Prob(U_{il} > U_{ij}, j \neq l). \tag{1}$$

Decision-maker's utility can be decomposed as $U_{ij} = V_{ij} + \varepsilon_{ij}$, where V_{ij} is function of known covariates (alternative and/or decision-maker specific), while ε_{ij} represents the impact of all the unobserved factors (not included in V_{ij}) on the utility of selecting a particular alternative. In this work, we assume that V_{ij} contains only alternative specific variables (i.e., alternative attributes) and can be specified linearly, i.e., $V_{ij} = \boldsymbol{x}_j^\top \boldsymbol{\beta}$, where $\boldsymbol{x}_j$ is a vector of p attributes of alternative j and $\boldsymbol{\beta}$ is the p-dimensional parameter vector. Moreover, we suppose that the random component is independently, identically extreme value distributed. Hence, we can derive the multinomial logit choice probabilities as follows [8]:

$$P_{il} = \frac{\exp(\boldsymbol{x}_l^\top \boldsymbol{\beta})}{\sum_{j=1}^{J} \exp(\boldsymbol{x}_j^\top \boldsymbol{\beta})}. \tag{2}$$

Model parameters $\boldsymbol{\beta}$ are estimated through maximum likelihood methods (see [8] for further details). Finally, in this work we consider the extended no-choice multi-

nomial logit (ENCMNL) [9], where an extra dummy variable is added to $\boldsymbol{x}_j$ for taking into account the no-choice option.

3 Results

In this section we report the results obtained on a final sample of 191 questionnaires, related to farmers who completely fulfilled the questionnaire (i.e., without missing values in the choices). As each farmer has to express three choices (three choice sets), a total of 573 choices are available, of which 117 (20.4%) consist in the no-choice option. The remaining choices are summarized in Table 1, in which the raw choice relative frequency is shown for each attribute level. As we can see, most of farmers chooses contracts with a guaranteed minimum price (36.3%), more than twice with respect to those selecting contracts with 100% open price. Moreover, as far as the techniques of sustainable cultivation are concerned, the choices are equally distributed over the three possible techniques.

Table 2 shows the results of the ENCMNL model estimated on the data at issue. Estimates for price attribute reveal that the presence of a 100% opened price in a

contract negatively affects (-0.690 on the logit scale) the probability of choosing a contract with respect to a contract having the guaranteed minimum price, other things being equal. The same also applies for a mixed price, even if the magnitude is lower. This result shows that farmers rely on contracts in order to reduce market uncertainty, thanks to a guaranteed minimum price that – compared to open price and mixed price – is not influenced by market price volatility.

As regards the technique attribute, results show that the presence of technical requirements imposed by the industry significantly hinders the probability of choosing a contract, with reference to contracts where farmers are free to decide. Therefore, what emerges is that durum wheat producers prefer to maintain decisional rights on technique in their hands, in order to autonomously address technological uncertainty.

Furthermore, the quality threshold attribute significantly influences the probability of choosing a contract only as regards the highest content of protein ($>$14.5%): in particular, a higher quality requested by the contract discourages farmers from a potential choice.

Lastly, the presence of service of technical assistance impacts on the probability of adopting a contract with reference to the no technical assistance option. Such a result confirms that farmers are willing to share their decision rights with the counterpart to share technological uncertainty, with a direct positive impact on behavioral uncertainty as well.

4 Conclusions

The main purpose of the present paper is to investigate the hypothesis that the transaction attribute of uncertainty affects the allocation of decision rights within a contract. To this aim, a choice-based conjoint analysis is performed through a multinomial logistic model in order to investigate how several contractual terms (considered as proxies of different types of uncertainty) influence the potential contract choice by durum wheat farmers. Main findings reveal that a guaranteed minimum price is preferred by farmers so as to decrease market uncertainty. Moreover, farmers are discouraged from a higher product quality requested by the contract, but are potentially interested in a contract with technical assistance, in order to share technological uncertainty with the counterpart.

A fuzzy approach to the measurement of the employment rate

Un approccio sfocato alla misura del tasso di occupazione

Bruno Cheli, Alessandra Coli, Andrea Regoli

Abstract The computation of employment and unemployment rates is conditioned by the rigid classification of labour force into the mutually exclusive groups of people in employment and people not in employment. This implies a relevant loss of statistical information and wipes out all the nuances that exist between fully employed people and those ones who work only occasionally, while needing to work more. In our view employment should not be considered as a simple attribute that is present or absent but rather as a matter of degree. The aim of this paper is to define and compute fuzzy measures of employment by considering both the number of hours actually worked and wished.

Abstract *Il calcolo dei tassi di occupazione e di disoccupazione è condizionato dalla rigida ripartizione delle forze di lavoro nei due gruppi mutuamente esclusivi degli occupati e dei non occupati. Ciò conduce ad una rilevante perdita di informazione statistica e non consente di cogliere le sfumature che esistono tra la condizione di occupato a tempo pieno e quella di chi, pur risultando occupato, lavora meno ore rispetto a quanto desiderato. In realtà, l'occupazione non dovrebbe essere considerata un semplice attributo di cui rilevare la presenza o l'assenza ma piuttosto una grandezza presente con livelli di intensità diversi. Lo scopo di questo articolo è quello di definire e calcolare misure sfocate di occupazione, tenendo conto sia del numero di ore effettivamente lavorate che della quantità desiderata di ore di lavoro.*

Key words: employment rate, fuzzy approach, labour force survey

1 Introduction

The analysis of the labor force is traditionally based on the clear contrast between the two complementary sets of employed and unemployed. This classification, however, appears too rigid since it neglects all the nuances that exist between those who work full-time and those who, on the other hand, work only occasionally even if they wish to work more. Furthermore, this way of proceeding involves a significant loss of statistical information which could instead be used for a more accurate representation and measurement of the phenomenon considered. For this purpose, it is necessary to stop treating employment and unemployment as simple binary attributes that manifest themselves in terms of presence or absence and instead treat them as quantitative variables that can assume different degrees or intensities. On a logical level, this implies the passage from a boolean conception to a "fuzzy" one. The fuzzy set theory of (Zadeh, 1965) has been widely applied in the most varied research fields. One of the areas in which it has been most successful is that of poverty analysis (Cerioli and Zani, 1990; Cheli and Lemmi, 1995; Betti et al., 2006). Apparently, however, no application has yet been registered for the analysis of the labor force. The aim of this paper is to define fuzzy measures of employment using available information on the number of hours weekly worked and about the fact that part-time workers may not be satisfied of their condition and wish to work more. In a future development of this research, we intend to extend the same approach to the measurement of unemployment.

2 Employment and unemployment rates in official statistics

According to the International Labour Organization directives (ILO 1982), working age population (persons aged 15 and older) can be split into three mutually exclusive groups: employed, unemployed and inactive population. The way in which these groups are identified affects the value assumed by unemployment and employment rates. In fact, the unemployed rate is defined as the proportion of unemployed persons in the total labour force population whereas the employment rate expresses the number of employed persons as a percentage of the working age population. Employed, unemployed and inactive population groups are identified on the basis of information collected by labour force surveys (e.g. the European Union Labour Force Survey) and following a hierarchical process, which first identifies the employed persons, then the unemployed ones and eventually the inactive population.

In line with the ILO guidelines, an employed person is a person aged 15 and over who meets one of the following conditions: i) during the reference week he/she performed some work - even if for just one hour - for pay, profit or family gain; ii)

he/she was not at work but had a job or business from which he/she was temporarily absent.

The unemployed population comprises all the persons in working age who: i) were without work during the reference period, ii) are currently available for work, and have taken concret actions in a specified recent period to seek paid employment or self-employment.

Finally, the inactive population includes persons in working age who are neither employed, nor unemployed.

3 The fuzzy measure of employment

The fuzzy measure of employment intends to overcome the sharp distinction between persons in employment and persons not in employment. The application of the fuzzy set theory (Zadeh, 1965) to the concept of employment rejects the definition of employment as a binary status identified by the one-hour criterion. This concept would include among the employed every individual who performed some work during the reference week, regardless of the number of hours worked. Instead, we define a membership function in the fuzzy subset of the employed, which is measured on a scale from 0 to 1, whereby 1 means full membership to the set of the employed persons and 0 full non-membership.

A fuzzy measure of employment is able to reflect the unmet need for working additional hours among the employed, thus accounting for the labour under-utilization. The concept of labour under-utilization encompasses both time-related underemployment and involuntary part-time. These groups include persons who share some characteristics with the unemployed though they are officially included among the employed. In the fuzzy approach that we propose, we treat them as employed to a certain degree: the lesser the time they work, the lower their degree of employment.

4 Empirical application on Italian data

The fuzzy approach for measuring employment has been implemented on the 2018 yearly Italian data of the EU Labour Force Survey (Eurostat, 2019).

People who are not employed (i.e. unemployed and inactive population) are assigned a membership function equal to 0.

Employed people (according to ILO working status), are assigned a membership value that ranges from 0 (excluded) to 1. Fig. 1 sketches the assumptions underlying the membership function for persons in employment and shows some results.

Membership function is set equal to 1 in case of: i) full-time workers working no less than a specified threshold (defined as we explain below) who represent the 67.6% of the employed population, ii) full-time workers who do not wish to work more, even if employed for less than the specified threshold (13.4%), iii) volun-

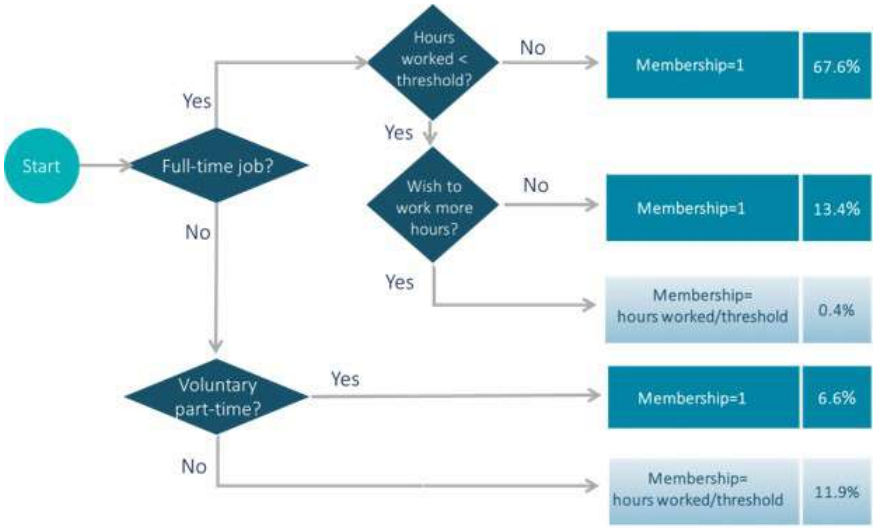

Fig. 1 Membership to the employment set

tary part-time workers (6.6%). The threshold acts as a limit set by statutory or collectively agreed standards and corresponds approximately to the number of hours worked on average by full-time workers. In particular it has been set equal to 40 weekly hours for workers of the private sector (employees, self-employed and family workers) and to 36 weekly hours for employees of the public sector. We have verified that these figures represent the modes of the distribution of the hours worked for the two groups. For both of them, the mode is equal to the median value, which supports the choice of the mode as a suitable measure of central tendency.

In the middle, with membership values greater than 0 and lower than 1, we find the underemployed workers. The largest part of them (11.9%) is composed by involuntary part-time workers, i.e. workers who could not find a full-time job, because of aggregate demand problems (linked with the lack of full-time jobs) or supply side problems (due for example to the lack of qualifications for the available full-time jobs). The remaining part consists of full-time workers who have worked less than the specified threshold and are willing to work additional hours. Their membership function has been defined as the ratio of the hours actually worked to the threshold value.

Finally, the fuzzy measure of employment results from the weighted mean of the individual membership values. As such, it can be compared with the traditional employment-to-population ratio (Table 1). The results show that, with reference to the total population between 15 and 64 years, the fuzzy rate is 55.2%, smaller by 5.6% compared to the official rate. The downward correction is more marked among females (9.3%) compared to males (2.8%), which proves that the unmet need for working more hours is by far stronger among the female workers compared to the male ones. Young adults (aged less than 35 years) and workers with a low educa-

tion level emerge as the groups of workers who are the most severely penalized by labour under-utilization. With reference to the geographical area of residence, the downward correction of the fuzzy measure is slightly above the average in the Southern regions and in the Islands and slightly below the average in the Northern regions.

Table 1 Employment-to-population ratio (15-64 years)

	Traditional measure (T)	Fuzzy measure (F)	F/T(%)
Total	58.5	55.2	94.4
Male	67.6	65.7	97.2
Female	49.5	44.9	90.7
15-24 years	17.7	15.8	89.3
25-34 years	61.7	57.3	92.9
35-44 years	73.4	69.4	94.6
45-54 years	72.3	68.6	94.9
55-64 years	53.7	51.4	95.7
Lower secondary education	43.8	40.7	89.3
Upper secondary education	64.3	60.9	92.9
Third secondary education	78.7	75.4	95.8
North-West	66.8	63.5	95.1
North-East	68.1	65.0	95.4
Centre	63.2	59.0	87.0
South	44.9	41.9	93.3
Islands	43.7	40.3	92.2

A proposal to model credit risk contagion using network count-based models

Un approccio network basato su dati di conteggio per modellizzare il rischio di contagio nel credito

Arianna Agosto and Daniel Felix Ahelegbey

Abstract Interconnectedness between institutions and between economic sectors is known to be the main source of systemic risk, and was recognised as a trigger of the great financial crisis in 2008-2009. In this paper we study contagion effects between corporate sectors using a financial network model where the significant links are identified through conditional independence testing.
While the existing financial network literature is mostly focused on Gaussian processes, our approach is based on discrete data. We indeed assess pairwise dependence of default counts in different economic sectors, finding several contagion channels in both the conditional mean and the shocks of the corporate credit risk dynamics.
Abstract *Le interconnessioni tra imprese e tra settori economici sono note come la principale causa del rischio sistemico e hanno contribuito in modo decisivo alla diffusione della crisi finanziaria globale degli anni 2008-2009. Nel presente lavoro studiamo gli effetti di contagio tra settori economici con una metodologia network, in cui i link significativi sono individuati mediante test di indipendenza condizionale. Mentre la letteratura dei network finanziari utilizza prevalentemente processi gaussiani, il nostro approccio è basato su dati discreti. Testando le interdipendenze nella dinamica dei conteggi di default di diversi settori di impresa, troviamo possibili canali di contagio significativi sia nella media condizionata sia nella componente di shock della dinamica del rischio di credito.*

1 Introduction

The increase in credit risk arising from interconnectedness between institutions and individuals, commonly referred to as *contagion*, is known as one of the main sources of systemic risk. Contagion channels originate from the inter-linkages between companies, sectors, and countries. Corporate default dependency can be conditional on the business cycle, affecting all companies in a financial system, or arise from trading and legal relationships. Studying interconnections and their changes is of major interest for both policy makers and lending institutions. Correlation network models have been recently proposed in the econometric literature to study systemic risk. In particular, [1] and [3] derived contagion measures based on Granger causality tests and variance decompositions. More recently, [2] and [6] extended the methodology introducing stochastic correlation networks. So far, stochastic correlation network models have been based on Gaussian processes, a natural approach when data are market prices. Several works have instead applied discrete data models to analyse possible dependence between default events. For example, [5] tested conditional independence of default times based on the Poisson assumption, while [4] applied Poisson autoregressive models with exogenous covariates to the US default count time series.

In this work we combine the financial network approach with the default count modelling. We indeed estimate a network representing pairwise conditional dependencies between corporate sectors based on their default count dynamics, modelled through log-linear Poisson autoregressive processes.

2 Data

We focus on the default dynamics of Italian non-financial companies.
In particular, as a proxy of default counts we consider the quarterly bad loans flow provided in Bank of Italy statistical database[1] for the period 1996-2018. Using the classification provided in the dataset, we divide corporates into the following sectors: Commerce, Energy, Manufacturing, Primary, Real Estate (including both constructions and real estate corporates), Transports, Information and Communication Technologies, Services. Figure 1 plots the default count time series, showing an increase in level and variability starting from 2008, with the mean returning close to the pre-crisis level after 2015. All the eight series confirm the empirical evidence that defaults cluster in time and show peaks during economic downturns.

[1] http://www.bancaditalia.it/statistiche.

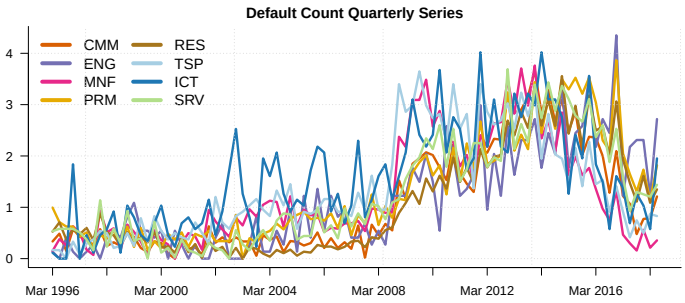

Fig. 1 Normalised quarterly default counts in the Italian credit system (March 1996 - June 2018) by economic sector (CMM = Commercial, ENG = Energy, MNF = Manufacturing, PRM = Primary, RES = Real Estate, TSP = Transports, ICT = Information and Communication Technologies, SRV = Services).

3 Model

3.1 Log-linear Poisson autoregressive model

We assume the conditional distribution of the default counts in economic sector i at time t to be Poisson distributed with a log-linear autoregressive intensity:

$$\begin{aligned} Y_{it}|\mathscr{F}_{t-1} &\sim Poisson(\lambda_{it}) \\ \log(\lambda_{it}) &= \omega_i + \sum_{j=1}^{p} \alpha_{ij} \log(1+y_{it-j}) + \sum_{j=1}^{q} \beta_{ij} \log(\lambda_{it-j}) \end{aligned} \tag{1}$$

where
$\omega_i \in \mathbb{R}$, $y_{ij} \in \mathbb{N}$, $\alpha_i \in \mathbb{R}^p$, $\beta_i \in \mathbb{R}^q$, $\forall i = 1,...,k$ with $k = 8$ sectors.

In Model 1, whose properties and inference theory were studied by [8], both the α_i and the β_i coefficients express dependence of the expected number of defaults on past default counts.
For each of the considered sector, we estimate Model 1 by maximum likelihood, choosing the number of p and q lags between 1 and 4 which minimises the Akaike Information Criteria (AIC). The estimated default intensities are the expected number of defaults in a given quarter.
In this framework, the error component is instead the difference between the observed counts and the estimated intensity, scaled to take into account the time-varying variance: the so-called Pearson residuals $e_{it} = \frac{y_{it}-\hat{\lambda}_{it}}{\sqrt{\hat{\lambda}_{it}}}$.

In the following sections, we estimate inter-sector linkages through testing dependencies in both the intensity ($\hat{\lambda}_{it}$) and the shock (e_{it}) processes.

3.2 Network model

We use the estimates obtained from application of the log-linear Poisson model to build two networks, where the nodes are the considered sectors and the directed edges represent significant dependencies between the default counts of different sectors.
The first network is made up of the links between the estimated default intensities and represents lagged effects between sectors, while the second one is based on the shock component of the default count processes.

3.2.1 Inter-sector network based on lagged effects

We use the default intensities estimated in Section 3.1 to investigate interdependencies in the conditional mean (and variance) of different economic sectors by testing conditional Granger causality [7].

To perform the Granger causality test, we consider the following 8-variate Vector AutoRegressive (VAR) specification:

$$\Delta\lambda_t = \Phi_0 + \sum_{k=1}^{p} \Phi_k \Delta\lambda_{t-k} + u_t, \qquad u_t \sim \mathcal{N}(0,\Sigma) \tag{2}$$

where the lag order p is chosen through model selection based on the Bayesian Information Criteria (BIC). In this setting, the hypothesis that a change of default intensity in sector l does not Granger cause a change of default intensity in sector i can be verified by testing the restriction $\phi_{il,j} = 0$ for $j = 1,...,p$.

Once the test is performed for each of the ϕ_{il} coefficients, we are able to build the A_λ adjacency matrix with binary entries such that $A_{\lambda,il} = 0$ if $\Delta\lambda_{lt-j}$ does not Granger cause $\Delta\lambda_{it}$, 1 otherwise. This defines a directed network where an edge from node l to node i is drawn if changes in the expected number of defaults in sector i are conditionally dependent on changes in the expected number of defaults in sector l.

Figure 2 plots the network structure in two sub-periods: 1996-2007 (*pre-crisis*) and 2008-2018 (*post-crisis*). To aid interpretation, we distinguish the links using the signs of estimated coefficients: positive dependencies are depicted in green and negative in red. It can be seen from Figure 2 that the networks based on lagged effects in the conditional mean are sparse. In the first subsample (1996-2007) the only positive edge is directed from the commerce sector to ICT, while a negative link is present between Energy and the commerce sector. The period during and following the global financial crisis (2008-2018) shows instead three positive connections,

all involving the energy sector, which turns out to affect Primary, Real Estate and Commerce.

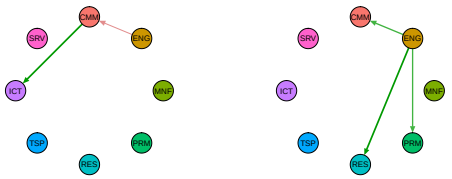

Fig. 2 Inter-sector network based on the quarterly expected number of defaults (left: March 1996 - December 2007; right: January 2008 - June 2018; CMM = Commercial, ENG = Energy, MNF = Manufacturing, PRM = Primary, RES = Real Estate, TSP = Transports, ICT = Information and Communication Technologies, SRV = Services).

3.2.2 Inter-sector network based on contemporaneous effects

Credit risk contagion can also spread through shocks in the default dynamics, generating contemporaneous systemic effects. We thus consider conditional inter-sector dependencies between the residuals of the log-linear models, corresponding to the random (Poisson) part of the default count dynamics.

In order to estimate directed links between sectors based on the estimated shocks, we employ the PC algorithm, which is a constrained-based network inference developed by [10] for learning partially directed networks. We thus build an adjacency matrix called A_e with binary entries such that $A_{e,il} = 0$ if e_{it} does not depend on e_{lt}, 1 otherwise. This way we draw a directed network where an edge from node l to node i means that shocks in the number of defaults in sector i are conditionally dependent on shocks in the number of defaults in sector l.

The networks of connections in default count shocks are shown in Figure 3. Many connections - all with positive sign - can be found in both sub-periods. This indicates that shocks in the default dynamics of different sectors are highly and positively correlated, acting as possible contagion channels. It can also be noticed that the period including the financial crisis is characterised by a larger number of inter-sector links and, as expected, a higher centrality of the real estate sector, which is strongly infected.

4 Conclusions

In this paper we have considered inter-sector contagion effects in corporate default counts, combining Poisson dynamic models with the financial network approach. We estimated directed links between corporate sectors based on their default dy-

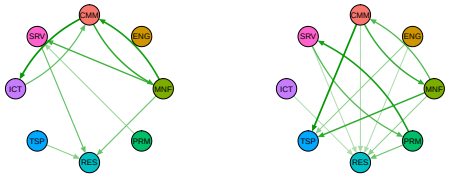

Fig. 3 Inter-sector network based on shocks to the quarterly number of defaults (left: March 1996 - December 2007; right: January 2008 - June 2018; CMM=Commercial, ENG=Energy,MNF=Manufacturing, PRM=Primary, RES=Real Estate, TSP=transports, ICT=Information and Communication Technologies, SRV=Services).

namics, considering both lagged and contemporaneous effects.
Focusing on Italian corporate default counts in eight economic sectors from 1996 to 2018 we found evidence of a high inter-sector vulnerability especially in the global financial crisis period and in the following years. Several significant links between corporate sectors were found in both the mean and the shock component of the default count dynamics.

A similarity matrix approach to empower ESCO interfaces for testing, debugging and in support of users' experience

Le matrici di similarità a sostegno della fruizione delle interfacce di ESCO per il test, il debug e il miglioramento delle esperienze di utilizzo

Adham Kahlawi, Cristina Martelli, Lucia Buzzigoli, Laura Grassini[1]

Abstract This paper intends to apply the Latent Semantix Indexing approach to ESCO, the European language for labour description and coding, overcoming the limits attributable to the current querying instruments. This objective is strategic to bridge the gap existing between ESCO repository, whose richness and granularity suggests to adopt it as a current operative language for labour processes management, and the users' current language, not always able to select the proper keywords to satisfy their information needs. The paper also discusses an application of the proposed approach to testing and debugging of ESCO linguistic objects, intending to identify redundancies and anomalies in the overall knowledge base.

Abstract *Questo lavoro applica l'approccio Latent Semantic Indexing a ESCO, il linguaggio europeo del lavoro, per rafforzarlo e migliorarne la fruizione, superando alcuni limiti degli strumenti di interrogazione della piattaforma. Si tratta di un obiettivo strategico per colmare il divario esistente tra la grande granularità e ricchezza espressiva del repository di ESCO, che ne suggeriscono l'utilizzo nei processi di gestione del lavoro, e le capacità linguistiche degli utenti, non sempre in grado di individuare le parole chiave più adeguate. Questo lavoro discute, inoltre, un'applicazione del metodo al problema del collaudo e del debug del repository di ESCO, per individuarne eventuali ridondanze ed anomalie.*

Keywords: ESCO, labor market, natural language interfaces, similarity measures.

1 Introduction

The dynamism of the current labour market and the rapid changes to which it is subjected require specific attention for the role of skills (competences and knowledge) in the professional placement / re-placement of workers, and for the preparation of training offers consistent with the market demands.

For years, numerous international organizations have reported the problem with the identification of megatrends and critical issues (WEF, 2018; ILO, 2019; OECD, 2019). The European Union, in particular, has stressed the role of skills in the program of the European Pillar of Social Rights (European Commission, 2016b, European Commission 2017) and in 2016 adopted the New Skills Agenda for Europe (European Commission, 2016a), which outlines the strategic role of skills in supporting employment, growth and competitiveness.

In this framework, which is part of Europe 2020 strategy (European Commission, 2010), a specific project was aimed at the implementation of an operational tool that establishes a European common language for the classification of Skills, Competences, Qualifications and Occupations, named ESCO (European Commission, 2019).

The main scope is to organize the knowledge on the European labour market and also on the sector of education and training, to improve both the matching between qualifications and labour market needs, and the matching between jobseekers and employers.

ESCO combines the assets of (i) a rigorous official coding standard and (ii) of a specialized language. Thanks to its high granularity, it can be used, in fact, also to provide a clear description of job profiles for job seeking or CV writing. Therefore, according to the most accredited information systems approaches, ESCO can be used for generating administrative data sets, easily suitable to be used as statistical registers.

This work intends to empower the ESCO functionalities in labour market governance and management, proposing a new approach to improve its capability of crossing users' natural language; the proposed approach also intends to support in ESCO components testing and debugging.

In particular, we intend to apply the Latent Semantic Indexing (LSI) approach to measure the similarity between ESCO objects descriptions; the aim is to allow explorative pathways for queries optimization and for identifying relations and redundancies among ESCO descriptive elements.

2 The current version of ESCO

The current full version, ESCO v1, can be freely consulted on the dedicated portal since 2017 and is published as Linked Open data. The classification is available in 27 languages and is organized in three interlinked ‘pillars’: occupations (2942 entries), skills, competences and knowledge (13485 entries) and qualifications (9457 entries).

The first two pillars have a rich and articulated content, while the qualifications pillar is not as well populated (European Commission, 2015). This is also due to the different methods of development: the pillars of occupations and skills are developed by ESCO contributors (sectoral reference groups and online consultations), managed and coordinated by the Commission, while for the qualifications pillar only external sources are used (typically national qualifications databases of the member states).

In our study we will focus on the first two pillars.

The pillar of occupations is organized hierarchically: the top four levels coincide with those of the international standard classification of occupations ISCO08 (ILO, 2012); the lower levels are specific to ESCO (ESCO occupations). For each occupation, ESCO provides a description, a set of alternative labels, the position in the hierarchy, and – only for the fifth level or lower, organized by means of broader/narrower relation – the essential or optional skills, competences and knowledge required for the occupation. Consequently, a connection is created between the pillars.

The pillar of skills, competences and knowledge, is usually called simply the skills pillar because in ESCO the concept of Skill is a general class that includes skill, competences and knowledge, that are different concepts. Nevertheless, it does not distinguish between skills and competences.

ESCO provides various criteria that the user can apply to classify what is generally called Skill. A first simple criterion is the distinction between skills (denoted by a verb) and knowledge (denoted by a noun), called *type*. Another criterion is the reusability level, which in the intentions of the ESCO drafters should be "crucial for supporting occupational mobility" (European Commission, 2019): each Skill is labelled as transversal, cross-sector, sector-specific and occupation-specific. Other distinctions arise on the basis of the "Skills to occupations" and "Skills to Skills" relationships. In both cases, each Skill can be defined 'essential' or 'optional' for other specific Skills or for specific occupations (another way to generate the interlinking among pillars).

The organization of the skills pillar is therefore not hierarchical, but a sort of hierarchy among Skills is made indirectly by the broader/narrower relation. In brief, for each Skill ESCO provides a description, a set of alternative labels, the Skill type, the reusability level, the occupations for which the Skill is essential/optional, the relationship with other Skills (essential/optional, broader/narrower).

All this information produces a rich database which lists occupations, skills, knowledge and qualifications that are relevant for the European labor market showing the relationships among them, that can be used in other European platforms for labour: for instance, it is the standard language expected for exchange of information in EURES, the network of European employment services (European Commission, 2016c).

Any ESCO object, both skill, competence or occupation is structured in a label and a description (Figure 1).

Up to now, ESCO is queryable only using keywords applied to the object labels: the only way to get an answer to users' need is to use the exact keyword that individuates the required object. This fact represents a major limitation to the usage of ESCO for administrative and management purposes: in practice, it is impossible to

perform evolutive queries that, starting from a fuzzier request, allow aiming to the needed answer.

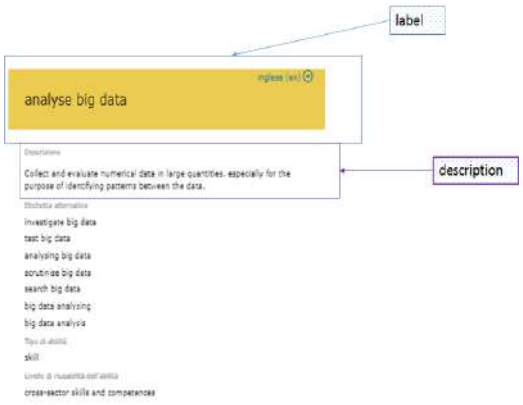

Figure 1: ESCO objects structure

Another aspect that hampers the current usage of ESCO in labour market management and governance is attributable to the redundancy of descriptions' contents. It is a sort of side effect of the impressive richness of ESCO knowledge base: sometimes it is not an easy task to discriminate between different elements, which appear quite similar even if allocated in very different areas of ESCO base.

3 The LSI approach to ESCO interface empowerment

In the application, we analyse similarity between every couple of skills by two different approaches.

Firstly, the similarity between the ESCO descriptions of two different skills is measured using LSI, and this measure is applied to all possible pairs of skills. LSI is an indexing and retrieval technique known for years in the literature on information retrieval, that is able to project queries and documents into a space with latent semantic dimensions (Rosario, 2000) exploring the co-occurrence of each word with every single word. In synthesis, LSI is a text mining processing that produces a corpus-based similarity measure for each pair of descriptions. The measure ranges from 0 to 1 (the greater the more similar).

Secondly, we calculate a use/connection-similarity index. This index is based on the connection between occupations and Skills.

Each ESCO occupation is described by a set of skills. The similarity indicator measures the extent to which a pair of skills are used together. In the specific:
N_x indicates the number of occupations requiring Skill x
N_y indicates the number of occupations requiring Skill y
N_{xy} indicates the number of occupations requiring both Skill x and Skill y
$Sim_{x|y}$ and $Sim_{y|x}$ are defined as follows:

$$Sim_{x|y} = \frac{N_{xy}}{N_y} \qquad Sim_{y|x} = \frac{N_{xy}}{N_x}$$

Note that an index similar to $Sim_{y|x}$ has been used in Opik, et. al. (2018) to measure, in their case, the similarity between two occupations.

The analysis of the different indicators (LSI, $Sim_{x|y}$ and $Sim_{y|x}$) shows a number of interesting cases, some of which are presented in table 1.

Table 1. Some preliminary results

Case	Skill *x* (label)	Skill *y* (label)	$Sim_{x|y}$	$Sim_{y|x}$	LSI
Case 1	IBM Informix	DB2	1.0	1.0	0.9999
Case 2	liaise with union officials	perform internal investigations	0.0	0.0	1.0000
Case 3	provide health psychological concepts	Health psychology	1.0	0.5	1.0000
Case 4	assess chiropractic intervention	prescribe treatments related to surgical procedures	1.0	1.0	0.2181

Case 1 refers to skills that are always required together to describe an occupation; on the other hand, they have two almost identical descriptions. This observation puts the issue whether these skills have an own separate identity.

Case 2 refers to a pair of skills that are never required together to describe an occupation, even if they have identical descriptions. This situation encourages to check whether errors or inaccuracies may have occurred while describing the Skills.

Case 3 refers to a pair of skills that have identical descriptions; on the other hand, when a specific occupation requires Skill *x*, also Skill *y* is required but the opposite is not true. As a result, this is an indication of a possible hierarchy among skills.

Case 4 refers to skills that are always required together to describe an occupation but, as opposed to Case 1, they have two different descriptions. ESCO querying approach can take advantage of this occurrence: at present, it is impossible to perform incremental querying protocols, and the success of an interrogation relies only on the keywords' exact match. Embedding these indicators in ESCO interface it will be possible to move from a skill to the closer ones.

4 Conclusion

This paper intends to expand the information potentialities of ESCO repository, using also the description field as a query target, overcoming the limitations actually in place which limit to the labels the target of the queries.

The proposed approach relies on the LSI methodology which allows evaluating the similarity among textual objects: in this case, ESCO skills descriptions. These

preliminary results encourage to pursue the strategy of embedding the proposed indicators in ESCO interfaces, to empower queries protocols and to test and debug the repository contents on automatic ground.

Adding MIDAS terms to Linear ARCH models in a Quantile Regression framework

Regressione quantilica con l'aggiunta di termini MIDAS per modelli Linear ARCH

Vincenzo Candila, Lea Petrella

Abstract Recent financial crises have placed an increased accent on methods dealing with risk management. Despite some critiques, the Value-at-Risk (VaR) still plays today a leading role among the risk measures. For this reason, the financial econometrics literature has been involved in proposing as much as possible accurate VaR models. Recently, the quantile regression (QR) approach has been used to directly forecast the VaR measures. Within such a QR framework, we add a (MI(xed)-DA(ta) Sampling) term to the well known Linear ARCH (LARCH) model. The MIDAS term allows the inclusion of macroeconomic variables usually observed at low frequencies (monthly, quarterly, and so forth) in contexts where the dependent variable is generally observed at higher frequencies (mainly, daily). The resulting model, named Quantile LARCH-MIDAS (Q–LARCH–MIDAS), is the first model incorporating the MIDAS approach within the QR framework.

Abstract *Le recenti crisi finanziarie hanno portato un enorme interesse verso i metodi per la gestione del rischio. Nonostante alcune critiche, il Value-at-Risk (VaR) ha ancora oggi un ruolo primario tra le misure di rischio. Per questa ragione, la letteratura econometrica-finanziaria ha posto l'attenzione sui modelli per la stima del VaR. Recentemente, la regressione quantilica (QR) è stata usata per calcolare direttamente il VaR. In questo contesto di QR, un termine MIDAS (MI(xed)-DA(ta) Sampling) è aggiunto al noto modello Linear ARCH (LARCH). Il termine MIDAS permette l'inclusione di variabli macro, solitamente osservate a frequenza mensile o quadrimestrale, in contesti dove, di solito, la variabile dipendente è osservata a cadenza giornaliera. Il modello risultante, chiamato Quantile LARCH-MIDAS (Q–LARCH–MIDAS), è il primo modello che incorpora l'approccio MIDAS all'interno di un contesto di QR.*

Key words: Value-at-Risk, Quantile Regression, MIDAS term.

1 Introduction

During the last decades, financial econometrics literature has paid particular attention to the methods for risk management. Among the different risk measures proposed in the literature, the Value-at-Risk (VaR) plays still today a leading role. Despite some criticisms (Artzner et al., 1999), according to the Basel frameworks, the VaR measures are fundamental in order to set aside risk capital adequately (Burchi and Martelli, 2016). The methodology used to obtain the VaR measures can be broadly divided into three main categories: parametric, non-parametric, and semi-parametric (Jorion, 1997). The parametric approach requires the estimation of the volatility of the asset under investigation as a primer step. Typically, the GARCH (Bollerslev, 1986) class of models is used. Secondly, the VaR measures are indirectly obtained by considering these volatility estimates and the quantile at a fixed level of the presumed distribution of the asset. Usually, the Normal distribution is taken into account. Contrary to the parametric approach, the non-parametric technique does not make any distribution assumption concerning the daily returns. The semi-parametric technique specifies the updating dynamics of the model but does not require any distributional assumptions. Contributions based on the quantile regression (QR) (Koenker and Bassett, 1978; Engle and Manganelli, 2004) framework belong to the class of semi-parametric methods for the estimation of the VaR measures. Recent works employing the QR methods are Laporta et al. (2018); Bernardi et al. (2015), among others. Within the QR context, this paper aims to investigate the profitability of including a MIDAS (MI(xed)-DA(ta) Sampling) (Ghysels et al., 2007) component in the well known Linear ARCH (LARCH) (Taylor, 1986) model. The MIDAS component allows to filter the information coming from variables observed at lower frequencies (say, monthly, quarterly) in contexts where the dependent variable is usually observed daily. In this respect, many contributions (Amendola et al. (2019) and Conrad and Loch (2015), among others) highlight that the macroeconomic variables, which are typically observed at a monthly or quarterly frequencies, are driving forces of (daily) assets' variability. To the best of our knowledge, this is the first time that the MIDAS approach is incorporated within the QR framework. Therefore, the advantage of using the proposed Quantile LARCH–MIDAS (Q–LARCH–MIDAS) model to estimate the VaR measures is that these latter values are directly obtained as conditional quantiles of the daily return process, which in turn may depend on some exogenous variables observed at lower frequencies.

The rest of the paper is organized as follows. Section 2 introduces the Q–LARCH–MIDAS model and Section 3 is devoted to the empirical application.

2 Q–LARCH–MIDAS model

Let r_i be a (log-) return of an asset observed at time i, with $i = 1, \cdots, N$. Usually, i represents a day, but sometimes it can refer to periods observed at lower frequencies. In the general heteroskedastic framework, it is assumed that:

$$r_i = \sigma_i z_i, \tag{1}$$

where σ_i denotes the standard deviation, conditionally to the information set $\mathscr{F}_{i-1}$, and z_i is an *iid* random variable with $E(z_i) = 0$ and $Var(z_i) = 1$.

The conditional (one-step-ahead) VaR for day i, at τ level, is defined as VaR_i, and represents the quantity such that

$$Pr(r_i < VaR_i | \mathscr{F}_{i-1}) = \tau. \tag{2}$$

Therefore, by definition, the VaR at time i is the $\tau-$th conditional quantile of the series r_i, given $\mathscr{F}_{t-1}$. For this reason, the VaR can be also expressed as $Q_{r_i}(\tau|\mathscr{F}_{i-1})$.

Within the parametric context, VaR_i can be (indirectly) obtained once got an estimate of the (one-step-ahead) conditional standard deviation, $\hat{\sigma}_i$ and once a distribution function $F(\cdot)$ for z_i is assumed. That is:

$$VaR_i = F(z_i;\tau)\hat{\sigma}_i, \tag{3}$$

where $F(z_i;\tau)$ denotes the quantile at $\tau\%$ of z_i. Many options are available for the conditional standard deviation of r_i. For instance, it can be estimated by means of a specification belonging to the GARCH class of models. The density function of z_i is usually assumed Normal, as in the seminal work of Engle (1982). Instead of following a parametric approach to obtain the VaR measures, the goal of this paper is to directly estimate the VaR by means of the quantile regressions, in a semi-parametric context.

In the linear regression model, the relationship between a dependent variable y_i, at time i, and a set of covariates $\boldsymbol{x}_i$ is represented by the following equation:

$$y_i = \boldsymbol{x}_i^{'}\boldsymbol{\beta} + u_i, \tag{4}$$

where the vector $\boldsymbol{x}_i$ includes an intercept and $k-1$ covariates, while the zero mean *iid* error term u_i, with quantile function $Q_u(\tau)$, is left with an unspecified distribution. As demonstrated by Koenker and Bassett (1978), the τ-th quantile of y_i, conditional to $\boldsymbol{x}_i$, is:

$$Q_{y_i}(\tau|\boldsymbol{x}_i) = \boldsymbol{x}_i^{'}\boldsymbol{\beta}(\tau), \tag{5}$$

where, in line with Xiao et al. (2015), the $k \times 1$ vector $\boldsymbol{\beta}(\tau) = (\beta_1 + Q_u(\tau), \beta_2, \cdots, \beta_{k-1})^{'}$ is obtained minimizing the following loss function:

$$\hat{\boldsymbol{\beta}}(\tau) = \underset{\boldsymbol{\beta}\in\mathscr{R}^k}{\arg\min} \left[\sum_{i\in\left\{i:y_i\geq \boldsymbol{x}_i^{'}\boldsymbol{\beta}\right\}} \tau|y_i - \boldsymbol{x}_i^{'}\boldsymbol{\beta}| + \sum_{i\in\left\{i:y_i< \boldsymbol{x}_i^{'}\boldsymbol{\beta}\right\}} (1-\tau)|y_i - \boldsymbol{x}_i^{'}\boldsymbol{\beta}| \right]. \tag{6}$$

The asymptotic properties of the regression quantile estimator in (6) are discussed in Bassett and Koenker (1978).

The work of Koenker and Zhao (1996) is the first contribution where the VaR (or any other quantile of interest) is estimated within the QR framework. In particular,

the authors consider the LARCH(q) model of Taylor (1986), defined by:

$$r_i = (\beta_0 + \beta_1|r_{i-1}| + \cdots + \beta_q|r_{i-q}|)z_i, \quad \text{with } i = 1, \cdots, N, \tag{7}$$

where $z_i \overset{iid}{\sim} (0,1)$. The vector $\boldsymbol{\beta}(\tau) = (\beta_0(\tau), \beta_1(\tau), \cdots, \beta_q(\tau))'$ is obtained minimizing the function in (6), replacing y_i with r_i and $\boldsymbol{x}_i = (1, |r_{i-1}|, \cdots, |r_{i-q}|)'$. Koenker and Zhao (1996) illustrate the asymptotic properties of such estimator. Under this notation, the τ-th conditional quantile of r_i, that is the VaR at τ%, is:

$$\hat{Q}_{r_i}(\tau|\boldsymbol{x}_i) = \boldsymbol{x}_i'\hat{\boldsymbol{\beta}}(\tau). \tag{8}$$

The innovation of this work is to enlarge the set of covariates of Eq. (7). More in detail, we add a MIDAS term, allowing the inclusion of variable(s) observed at different frequencies with respect to that of the dependent variable. More in detail, let t be the period of observation for the MIDAS variable. This period may be a week, a month, a quarter, and so forth. The LARCH(q) of Eq. (7) changes to the proposed Q–LARCH–MIDAS specification, that is:

$$r_{i,t} = (\beta_0 + \beta_1|r_{i-1,t}| + \cdots + \beta_q|r_{i-q,t}| + \theta \sum_{j=1}^{K} \delta_k(\omega)|X_{t-j}|)z_{i,t}, \tag{9}$$

where $r_{i,t}$ is the log-returns of day i within the period t, the coefficient θ signals the impact of the weighted summation of the K realizations of the additional variable X_t, observed each period t. The variable X_t could be a macro-economic variable driving the log-returns of $r_{i,t}$ or a proxy of volatility at lower frequency (for instance: weekly or monthly aggregated realized volatility). The only condition that the Q–LARCH–MIDAS requires is the (weak) stationarity of X_t. Globally, there are N_t days for the period t and there are T different "lower frequency" periods. In total, there are N days, obtained from $N = \sum_{t=1}^{T} N_t$. In order to take benefit of the information coming from variable(s) observed at lower frequencies, the MIDAS component is a one-sided filter of the K lagged realizations of a given variable X_t, through the weighting function $\delta_k(\omega)$, calculated for $k = 1, \cdots, K$. As in the related literature, we use the Beta function, which is:

$$\delta_k(\omega) = \frac{(k/K)^{\omega_1 - 1}(1 - k/K)^{\omega_2 - 1}}{\sum_{j=1}^{K}(j/K)^{\omega_1 - 1}(1 - j/K)^{\omega_2 - 1}}. \tag{10}$$

Given that we are only interested in the cases where the most recent observations have a larger weight, we set $\omega_1 = 1$ and $\omega_2 \geq 1$. This will allow only for a monotonic decreasing system of weights.

The parameter space of the Q–LARCH–MIDAS model consists of the following vector $\Theta = \{\beta_0, \beta_1, \cdots, \beta_q, \theta, \omega_2\}$. The estimation of $\hat{\boldsymbol{\beta}}(\tau)$ is obtained by minimizing the loss function in (6), where as above y_i is replaced by $r_{i,t}$ and $\boldsymbol{x}_i = (1, |r_{i-1,t}|, \cdots, |r_{i-q,t}|, WS_{i-1,t})'$, with $WS_{i-1,t} = \sum_{j=1}^{K} \delta_k(\omega)|X_{t-j}|$.

3 Empirical Analysis

The main application of this work focuses on the estimate of the VaR measures for the S&P 500 Index. Most of the data have been collected from the "realised library" of the Oxford-Man Institute. The returns of interest are the open-to-close daily log-returns, for the period 3 July 2000 – 12 November 2019 (4861 daily observations). The additional MIDAS component in the Q–LARCH–MIDAS model is the realized volatility, after a weekly aggregation (with $K = 4$ and $K = 8$). Moreover, we also use the Q–LARCH–MIDAS with a monthly MIDAS term: the (first difference of the) U.S. Industrial Production (IP), collected from the Federal Reserve Economic Data (FRED) archive, with $K = 6$ and $K = 12$ as number of lagged realizations. The competing models of the proposed Q–LARCH–MIDAS specification are: Q–LARCH, GARCH (G) and GARCH with Student's t-distribution (G–t), RiskMetrics (RM), standard GARCH–MIDAS (G–M) Engle et al. (2013), with IP as MIDAS component and $K = 12$, Symmetric Absolute Value (SAV), Asymmetric Slope (AS) and Indirect GARCH (IG) specifications for the CAViaR (Engle and Manganelli, 2004) model.

We evaluate the performance of the proposed model through the Model Confidence Set (MCS) (Hansen et al., 2011), employed with the VaR loss function proposed by González-Rivera et al. (2004). The full sample period has been further divided into three sub-periods: the first two correspond to the same periods used in Laurent et al. (2012) and the third period represents the Great Recession (according to the NBER dates). Overall, the proposed model behaves very well. In fact, for $\tau = 0.05$, the Q–LARCH–MIDAS with weekly MIDAS component model always enters the MCS. Moreover, looking at the full sample period, only the models based with the MIDAS component belong to the set of superior models.

Table 1 S&P 500: Model Confidence Set for 5% VaR measures

	Q–L–M	Q–L–M	Q–L–M	Q–L–M	Q–L	G	G–t	RM	G–M	SAV	AS	IG
X_t	RV	RV	IP	IP					IP			
Freq.	W	W	M	M					M			
K	4	8	6	12					12			
Period 1	0.1405	0.1405	0.1438	0.1432	0.1436	0.1406	0.1404	0.1406	0.1373	0.1414	0.1349	0.1386
Period 2	0.0786	0.0786	0.0796	0.0796	0.0807	0.0780	0.0781	0.0785	0.0774	0.0785	0.0794	0.0781
Period 3	0.2193	0.2199	0.2073	0.2088	0.2158	0.2351	0.2345	0.2320	0.2283	0.2410	0.2356	0.2325
Full Period	0.1109	0.1110	0.1109	0.1109	0.1118	0.1119	0.1121	0.1118	0.1100	0.1131	0.1116	0.1116

Notes: The table reports the averages for the loss function proposed by González-Rivera et al. (2004), under four different periods. Shades of gray denote inclusion in the MCS at significance level $\alpha = 0.25$. Models' labels are in the text. X_t indicates the MIDAS component, "Freq." its frequency (Weekly or Monthly) and K the number of lagged realizations of the MIDAS component included in the model. Period 1: July 2000 to March 2003 (681 obs.); Period 2: April 2003 to July 2007 (1088 obs.); Period 3: December 2007 to June 2009 (397 obs.); Full Period: July 2000 to November 2019 (4861 obs.).

Company requirements in Italian tourism sector: an analysis for profiles

Requisiti aziendali nel settore turistico in Italia: una lettura per profili

Paolo Mariani, Andrea Marletta, Lucio Masserini, Mariangela Zenga

Abstract The recruitment process represents a way to evaluate the skills that a candidate needs to have in the workplace. This paper aims to evaluate the requirements for new hires in the tourism sector. In particular, we analysed the profiles of 1.526 workers recruited in 2017 by The Adecco Group in Italy. A multinomial logistic regression is carried out to obtain more in-depth knowledge regarding the most selected (or preferred) profiles by employers, among those evaluated.

Abstract *Il processo di reclutamento rappresenta un modo per valutare le skills necessarie ai candidati per entrare nel mercato del lavoro. Lo scopo di questo lavoro è valutare i requisiti necessari per le nuove assunzioni nel settore turistico. In particolare, sono stati analizzati i profili di* 1.526 *lavoratori assunti nel 2017 da The Adecco Group in Italia. Una regressione logistica multinomiale è stata effettuata per ottenere informazioni riguardo ai profili più selezionati (o preferiti) tra quelli valutati.*

1 Introduction

In the job market, the recruitment process represents a primary utility for companies: in fact, finding the right person for the right job at the right time is essential for the sake of company's performance. On the contrary, a wrong choice in the recruitment process could have bad consequences, both from a monetary point of view and in terms of loss of time.

The successful way to select the best candidate is to measure her/his attributes and competencies that could be divided into 3 categories: knowledges, abilities and attitudes. Knowledges are defined as a set of structured principles and theories useful for the correct implementation of the profession. Abilities involve procedures and processes that define the capabilities to accomplish the professional tasks. Attitudes are cognitive features affecting the professional development and execution of job activities.

In this paper the attributes and competencies for employers (travel consultants and clerks) in the tourism sector are analyzed. According to Isfol (2017) [3], skills more required for these professional figures are customer and personal service and foreign language. Customer and personal service are related to the knowledge of principles and processes for providing customer and personal services (i.e. customer needs assessment, meeting quality standards for services, and evaluation of customer satisfaction). Foreign language regards knowledge of the structure and content of a foreign language including the meaning and spelling of words, rules of composition and grammar and pronunciation.

2 Data and methods

In this paper, the data is sourced from the 2017 Adecco Group data-base, where the statistical unit is represented by a candidate receiving a job offer and the explanatory variables are the mandatory requirements needed to pass the recruitment process. The job positions are made comparable using the ESCO international classification. Information about job offers generates knowledge about the criteria used for the selection of the best candidate. In 2017, there were more than 120.000 job positions divided into the following 9 industries: Information Technology and digital, engineering, medical, finance, tourism, Human Resource, commercial, food services and production. In this paper, the work positions analysed are in the tourism sector, so the sample size is $n = 1.526$. The job profiles included are hotel concierge, airport baggage handler and travel consultant. The results are presented only for the subsample related to the travel consultant professional role. The number of the analysed job offers is $n = 626$.

Using these data, a multinomial logistic regression approach has been proposed to identify some relevant profiles. Given an unordered response variable y with $h = 1, 2, \ldots, J$ categories, the equation that expresses a multinomial logit model directly

in terms of the response probabilities, indicated with π_j, conditional to a vector of explanatory variables (x), can be written as it follows [1]:

$$\pi_j(x) = P(y = j|x) = \frac{exp(\alpha_j + \beta_j' x)}{1 + \sum_{h=1}^{J-1} exp(\alpha_h + \beta_h' x)}$$

For identification purpose, $\alpha_j = 0$ and $\beta_j = 0$, where J is the reference category. Furthermore, the numerator for various j sum to the denominator, so $\sum_j^J \pi_j(x) = 1$. Parameter estimation is performed via ML by using the Newton-Raphson method.

3 Results

A multinomial logistic regression [2] was carried out in order to obtain a more in-depth knowledge of the most selected (or preferred) profiles by employers, among those evaluated. In particular, four profiles of candidates have been obtained on the basis of some pre-requirements: the base outcome is a candidate without any specific characteristics served as the reference group against which all the other profiles were compared; candidates with a degree or a high school diploma; candidates with previous experience; and candidates with both a degree or a high school diploma and a previous experience. Furthermore, a set of covariates was used to explain the choice of the profile. Some variables refer to the characteristics of the employers as follows: two dummy variables for identifying the enterprise's sub-sector of economic activity: Fashion, Show and Events (not = 0; yes = 1); and Tourism, Tour Operator and Travel Agencies (not = 0; yes = 1); two binary variables for identifying the macro region of Italy where the enterprise is located: North (not = 0; yes = 1) and Centre (not = 0; yes = 1); two binary variables for identifying the size of the enterprise: Small (not = 0; yes = 1) and Medium (not = 0; yes = 1); a quantitative variable regarding the length of the employment contract (expressed in months). Moreover, two dummy variables that refer to features of the candidates have been included in the model: motivation (not = 0; yes = 1) and adaptability (not = 0; yes = 1).

Table 1 shows the maximum likelihood estimates of the multinomial logistic regression model that allows to identify the variables that affect the choice of candidates' profile by employers. The model's results can also be interpreted in terms of relative-risk ratios by raising the regression coefficients to an exponent. The relative risk ratio describes how much the probability of being in a certain category of the response variable relative to that of the referent group is expected to change for a unit change in the predictor variable, given that the other variables in the model are held constant. After estimation, the small p-value from the Likelihood Ratio (LR) test ($p < 0.001$) leads us to conclude that at least one of the regression coefficients in the model is not equal to zero.

For candidates with a degree or a high school diploma, the only variable that influence the choice is the size of the enterprise. In particular, medium-sized en-

terprises are those more interested in selecting graduates; for these enterprises the relative risk of choosing a candidate with a degree or a high school diploma over candidates without any specific characteristics (Profile 1) is 2.14 relative to that of other enterprises.

Candidates with a previous experience showed two influential variables: the size of the enterprise and the macro region where the enterprise is located. As for candidates with a degree or a high school diploma, medium-sized enterprises prefer this kind of candidates; the relative risk of 2.27 means that the probability of choosing candidates with a previous experience over candidates with the baseline profile is more than twice that of the enterprises of other size. For enterprises located in the north of Italy, the probability of selecting candidates with a previous experience over candidates with the baseline profile is 4.97 times higher than that of enterprises located in other macro regions.

Table 1 Maximum likelihood estimates of multinomial logistic regression model and estimates ranking

Base outcome	**Adaptability & Medium size**	**Motivation & North**	**Travel Agencies & Duration**
Intercept	-0.733	-2.707	-0.280
Fashion, Show and Events	-0.477	-0.623	-0.452
Tourism, Tour Operator and Travel Agencies	0.720	1.232	1.840
North	-0.688	1.603	-0.797
Center	0.184	0.670	-0.860
Small	-0.287	-0.327	-0.074
Medium	0.762	0.818	1.132
Duration of the employment contract	-0.001	-0.001	0.001
Motivation	0.038	0.439	-0.987
Adaptability	0.947	-0.807	0.960
Fashion, Show and Events	8	8	6
Tourism, Tour Operator and Travel Agencies	3	2	1
North	9	1	7
Center	4	4	8
Small	7	7	5
Medium	2	3	2
Duration of the employment contract	6	6	4
Motivation	5	5	9
Adaptability	1	9	3

Source: elaboration on AdeccoGroup data

Candidates who have both a degree or a high school diploma and a previous experience presented six variables affecting the choice of employers. Again, medium-sized enterprises prefer this kind of a candidates, with a relative risk of 3.10. However, the macro region also shows relevant differences; enterprises located in the north and centre of Italy have a lower probability of choosing these candidates, with a relative risk of 0.451 and 0.423, respectively. Moreover, enterprises operating in the sectors of tourism, tour operator and travel agencies are particularly interested in recruiting these candidates, with a probability of selection over candidates with

the base outcome that is 6.30 times higher than that of enterprises in other sectors of economic activity. Two further variables influence the choice, adaptability with a relative risk of 2.96 and the length of the employment contract, since for this profile selected candidates tend to have, on average, contracts with a longer duration.

In the bottom part of the table 1 rankings are presented comparing the estimates of the covariates in descending order for the three profiles. There is a big difference among the three rankings. About the sub-sector, coefficients of Tourism, Tour Operator and Travel Agencies is in the top three for all profiles representing the highest estimate for candidates who have both a degree and a previous experience. On the other hand, the coefficient for Fashion, Show and Events stands in the last position, this means that is more related to the base outcome profile. The estimate for the North macro-region is the lowest for candidates with a degree (no experience) and the highest for those with previous experience (no degree or high school diploma). For candidates with a degree and no experience the highest estimate is for adaptability. For all three profiles, the coefficient for medium companies is very high representing one of the top three positions in the rank.

4 Conclusions

In this paper an analysis of the matching of labour supply and demand was performed based on the job offer data of an important multinational company operating in the field of personnel selection. More specifically, this study aims at evaluating how knowledges, skills and attitudes of the candidates can influence the recruitment phase and choice. The analysis was carried out using a multinomial logistic regression model by taking the most selected (or preferred) profiles by employers as categories of the dependent variable. In particular, these profiles are differentiated by the hard skills, that is, knowledge of the English language, education level and previous experience. A set of the company's covariates such as size, the specific sub-sector of activity within the tourism sector, the geographic area of location were also considered to characterise the employers. Furthermore, candidates' skills such as motivation and adaptability were considered as well as the length of the contract proposed by the company to the candidate. Results show that candidates' profiles with hard skills are preferred by medium-sized companies, whereas companies located in the north of Italy seem to prefer candidates with a previous experience.

Determinants of Firms' Default Risk after the 2008 and 2011 Economic Crises: a Latent Growth Models Approach

Rischio di bancarotta dell'ultimo decennio per le imprese manifatturiere italiane: un modello di curva a crescita latente

Lucio Masserini, Matilde Bini and Alessandro Zeli

Abstract Between 2008 and 2009, European countries became mired in the Great Recession, derived from the US subprime crisis, with financial contraction and bank failures spreading out across the Atlantic and causing damage to financial markets and the real economy. Then, starting in 2011, the crisis affected the euro zone and the sovereign debts of European countries until 2014. For Italy, the crisis period led to a deep negative conjuncture until 2009 and then to a slight recovery until the first half of 2011 and an intense recession from 2011 to 2015. The aims of this work are to identify some determinants of the defaults of Italian firms during the years 2008–2012 and to understand the effects of the Great Recession on the default probability. To perform this analysis, a Latent Growth Curve Model is proposed, using an important Italian private database of Italian firms.

Abstract *In Italia, il periodo di crisi economica è stato caratterizzato da una profonda congiuntura negativa fino al 2009 e da una leggera ripresa fino alla prima metà del 2011 e poi da un'intensa recessione dal 2011 al 2014. Lo scopo di questo lavoro è di studiare gli effetti della grande crisi sul rischio di fallimento delle imprese manifatturiere nel periodo post crisi (2017) e di misurare l'impatto di alcuni fattori su tale rischio. Viene proposto un modello di Curva di crescita latente, sui dati contabili delle società di capitale italiane.*

Key words: Bankruptcy, Firms' default, Interest coverage ratio, Latent Growth Curve Model, Panel data

1 Introduction

In Italy, the crisis period from 2007 to 2014 can be divided into two sub-periods: the first, from 2008 to 2011, led to a deep negative conjuncture until 2009 with a subsequent slight recovery until the first half of 2011, while the second led to an intense recession, begun in 2011 and enduring until 2014. The aim of this paper is to analyse firms' defaults, using information on financial ratios from a large panel of Italian manufacturing firms. Since in the majority of financial literature major attention is devoted to financial conditions [1,2,3,6,7], this study intends to take into consideration more factors characterising a firm that, together with financial and economic conditions, can determine a firm's success or failure. Hence, the main motivation of this study is to assess whether classification variables such as a firm's size, industrial sector, and territorial location can better explain its default risk. An important feature of this study is the large number of enterprises included in the sample, covering a large range of sizes, economic activities, and geographic locations. The analysis is carried out using a statistical approach based on a Latent Growth Curve Model (LGCM) with an Italian private database containing the book-value data of the joint-stock company Italian firms. Unlike traditional longitudinal data analysis techniques, a LGCM allows inferences to be made about individual level effects as well as group effects [4]. Results we obtained allow us to answer the main research questions, such as whether the economic cycle influenced the default risk, how the default risk differs throughout different industries, and whether cumulative indicators have an effect on default probability.

2 Italian manufacturing database

We used a private database called *Analisi Informatizzata delle Aziende Italiane* (AIDA) that contains the book-value data of 16,383 joint-stock Italian firms over the period 2008–2017. First, we checked and controlled the data in order to avoid any inconsistencies in the items of the financial statement and strong outliers among all variables and indicators of interest. We included firms that underwent insolvency proceedings (e.g. failure, liquidation, and extraordinary administration). The target population is represented by Italian manufacturing firms (traced from 2008 to 2017). As a result, we ended up with a balanced panel of 7,689 companies that were used in the statistical analysis, repeated for five years.

3 Latent Growth Curve Model

The analysis was carried out using a Latent Growth Curve Model [5], which assumes the existence of latent trajectories for each firm, measured by the repeated values of the response variable (y_i) over time. In this analysis, the response variable is Interest Coverage, whose values are measured on a continuous scale and observed from 2008 to 2012. This approach was chosen for its flexibility in longitudinal data modelling: it allows for the estimation of different functional forms, the incorporation of both time-varying covariates (TVCs) and time-invariant covariates (TICs), as well as the assessment of the goodness of fit through indices (see, for more details, [9]) and the possibility of dealing with missing data [8]. In general, the LGCM can be expressed in terms of a trajectory equation and a structural model. In particular, given $\mathbf{y}_i$, a $T \times 1$ vector of repeated observed measures for firm *i* at time points $t = 1,2...T$, the trajectory equation, is defined as it follows:

$$\mathbf{y}_i = \mathbf{\Lambda}\boldsymbol{\eta}_i + \boldsymbol{\varepsilon}_i$$

$\boldsymbol{\eta}_i$ is the $m \times 1$ vector of the underlying latent factors which identifying the latent growth factors (e.g. initial status and trend factors); $\mathbf{\Lambda}$ is a $T \times m$ matrix of factor loadings for T time points, whose elements are fixed to specify the functional form for the individual trajectories; $\boldsymbol{\varepsilon}_i$ is a random vector of time-specific error terms. On the other hand, the structural model can be formulated as follows:

$$\boldsymbol{\eta}_i = \boldsymbol{\mu}_\eta + \mathbf{\Gamma}\mathbf{x}_i + \boldsymbol{\zeta}_i .$$

$\boldsymbol{\mu}_\eta$ is an $m \times 1$ vector of factor means; $\mathbf{\Gamma}$ is an $m \times k$ matrix of regression coefficients between the latent factors and the observed covariates; $\boldsymbol{\zeta}_i$ is an $m \times 1$ vector of error terms, which represents the random components of the model. Finally, a further response variable u_i (Bankruptcy 2017) is added as a distal outcome, whose values can be predicted by the latent growth factors, as follows:

$$u_i = \tau + \boldsymbol{\beta}\boldsymbol{\eta}_i + \boldsymbol{\upsilon}_i$$

Here, the vector of regression coefficients $\boldsymbol{\beta}$ represents the effects of the growth factors on the distal outcome, τ is the intercept and $\boldsymbol{\upsilon}_i$ are the error terms. The final model is shown in Fig. 1, which summarizes graphically the whole system of equations. The rectangular boxes in this figure represent the observed variables

(repeated outcome variables, as well as TICs and TVC), while the circles represent the latent variables (growth factors):

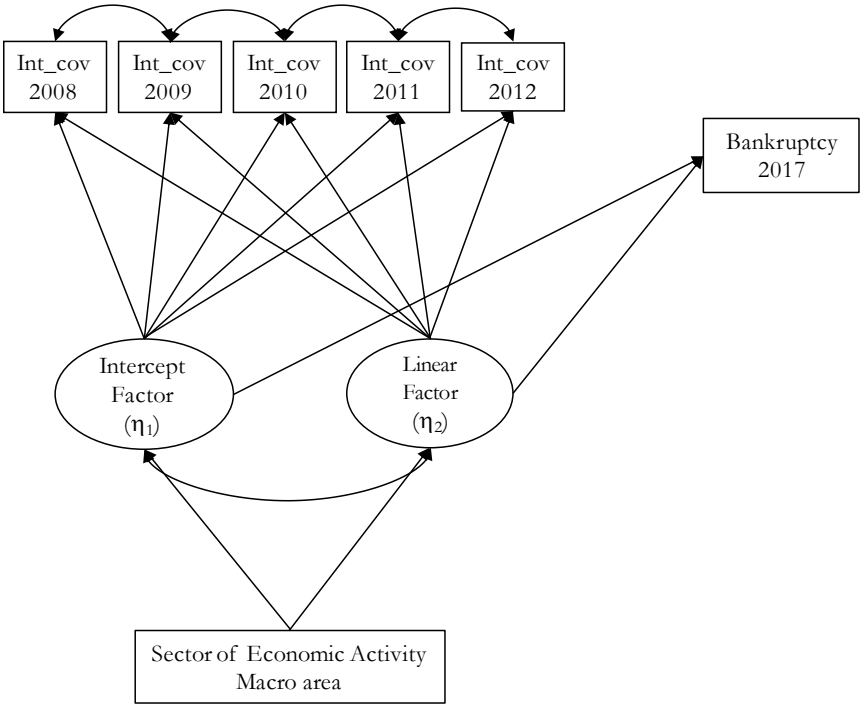

Figure 1: Path diagram of the LGCM

4 Results

Below, the results from the analysis performed by fitting a LGCM are shown. First, a set of alternative unconditional LGCMs with correlated measurement errors between adjacent time points were estimated (such as linear, quadratic, piecewise linear with two knots, and latent basis). These estimates allowed for the identification of a more suitable functional form for the individual latent trajectories. The model parameters were estimated by using the WLSMV (Weighted Least Square Mean and Variance adjusted) estimator with robust standard errors [10]. The model's goodness of fit was evaluated by RMSEA (Root Mean Square Error of Approximation), CFI (Comparative Fit Index), TLI (Tucker-Lewis Index) and SRMR (Standardized Root Mean Squared Residual) [9]. Based on the results, the linear form LGCM was preferred given the satisfactory values of the indices

(RMSEA = 0.041, CFI = 0.999, TLI = 0.997, SRMR = 0.023). The corresponding results show an adequate fit of the estimated model.

Table 1: LGCMs model parameter estimates for the response variable Interest coverage

Parameter	***Estimate***	***P-value***
Intercept Factor Mean (μ_1)	15.794	0.000
Intercept Factor Variance (ψ_{11})	1609.466	0.000
Linear Factor Mean (μ_2)	0.987	0.012
Linear Factor Variance (ψ_{22})	84.385	0.000
Correlation Intercept Factor vs. Linear Factor (ψ_{12})	0.084	0.429

Results in Table 1 show that the starting point of the response variable Interest Coverage is 15.794 with a significant and remarkable variability (1609.466). Moreover, Interest Coverage shows a linear growth trend (0.987) which also exhibits a significant variability. Differences in growth parameters can be analysed by sector of economic activity and a firm's geographical location in Table 2, where the asterisks show significant differences with respect to the average at the 0.05 significance level.

Table 2: Differences of growth curve parameters relative to baseline level for various sectors of economic activity and geographic location

Parameter	***Intercept***	***Slope***
Food and Tobacco	1.825	0.852
Textile and Leather	-6.775	1.886
Wood, Publishing, and Paper	6.171	-2.094
Refining	1.159	1.723
Chemistry and Rubber	-0.234	0.258
Metallurgy and Steel Industry	2.578*	-1.035
Electric Machines and Mechanical	7.628	0.486
Transport	4.762	-3.008*
Other Industries and Maintenance (Reference Category)	5.431	1.418
North	7.823*	0.197
Centre	6.515	0.174

Firms in the metallurgy and steel industry sector and those located in the North of Italy show a higher level of interest coverage at the beginning of the observed period. On the other hand, a significant and lower rate of growth is found in those firms that belong to the transport sector.

Table 3 shows the parameter estimates where Interest Coverage is used to predict a firm's situation in terms of risk of failure after five years, as measured by Bankruptcy 2017, introduced as a distal outcome. In particular, this approach allows for the evaluation of the Interest Coverage trend during the crisis period (2008–2012) and the impact of this trend on the risk of failure after five years.

Table 3: Effects of Interest coverage on Bankruptcy 2017

Parameter	***Estimate***	***P-value***
Intercept (τ)	1.360	0.000
Intercept Factor (β_1)	-0.004	0.002
Linear Factor (β_2)	-0.064	0.000

The Latent Growth Curve Model successfully detects a firm's outcome in terms of bankruptcy five years later. Indeed, the bankruptcy risk is well predicted by the linear function, and the model estimates show that in the considered period, industries in which Italian manufacturing is stronger in terms of interest coverage have a lower risk of bankruptcy.

Double Asymmetric GARCH–MIDAS model - new insights and results

Modello Double Asymmetric GARCH–MIDAS: nuovi approfondimenti e risultati

Alessandra Amendola, Vincenzo Candila, Giampiero M. Gallo

Abstract The recently proposed Double Asymmetric GARCH-MIDAS (DAGM) model aims at separating the positive and negative macro variable variations within the long-run term and adds an asymmetric effect in the short-run component. In this work, the intent is to further extend the model in two main directions. A realized measure is included as a daily lagged variable in the short-run component (the so-called "–X" term) and a multi-step-ahead forecasting procedure is implemented for the class of GARCH–MIDAS (GM) models with the additional "–X" term. The extended DAGM-X model, which nests the DAGM and GM, is extensively evaluated under alternative configurations concerning the S&P 500 Index.

Abstract *Il presente lavoro illustra una estensione del modello Double Asymmetric GARCH–MIDAS (DAGM), recentemente proposto. Nella modellizzazione, oltre agli effetti asimmetrici nelle componenti di lungo e di breve periodo, è stata introdotta una misura di volatilità realizzata giornaliera come variabile addizionale per la componente di breve periodo (la cosiddetta parte "–X"). Inoltre, è stata sviluppata una procedura per le previsioni multi-step-ahead, valida per tutti i modelli GARCH–MIDAS (GM), anche con un termine aggiuntivo "–X". La performance del DAGM–X, che generalizza il modello DAGM e il modello GM, è stata valutata in riferimento all'indice S&P 500.*

1 Introduction

The connection between the volatility of financial assets and the macroeconomic variables (MVs) has a long history. During the last decade, the GARCH–MIDAS model has been successfully used to include such a MVs into the so-called long-run volatility component, which varies with the same frequency as the MVs and around which the daily short-run component fluctuates as well. The Double Asymmetric GARCH–MIDAS (DAGM) model, recently proposed in Amendola et al. (2019), separates the positive and negative MV variations within the long-run term and adds an asymmetric effect in the short-run part. In this paper, we push one step further the DAGM model, including a realized measure as a daily lagged variable in the short-run component (the so-called "–X" term). Moreover, we introduce a multi-step-ahead forecasting procedure suitable for the class of GARCH–MIDAS (GM) models (Engle et al., 2013) with the "–X" term. The proposed DAGM–X model, which nests the standard DAGM and GM, is extensively evaluated under several alternative configurations, focusing on the S&P 500 Index. The daily S&P 500 5-minute realized volatility is included as a daily lagged variable in the short-run component while the rate of change of the monthly US Industrial Production, Housing Starts, and New Orders are used as the driver of market volatility. The idea is that a succession of negative values (over a somewhat long past, and suitably weighted) transmits a different type of increasing impulse to volatility than its positive counterpart. The empirical results give evidence that the DAGM–X model can outperform the standard DAGM, GM, and GM–X models, independently of the forecasting horizon considered. Furthermore, the proposed model is very often superior to the well known HAR model of Corsi (2009), mainly if longer forecasting horizons are taken into account.

2 DAGM–X model

Letting $r_{i,t}$ represent the log–return, that is, the first difference of the log–closing prices for day i of the period (week or month) t (with $i = 1, \cdots, N_t$, where N_t is the number of days for period t), our GM framework defines:

$$r_{i,t} = \sqrt{\tau_t \times g_{i,t}}\varepsilon_{i,t}. \tag{1}$$

In this expression, $\varepsilon_{i,t}$ is the innovation term, $g_{i,t}$ follows a unit–mean reverting GJR-GARCH(1,1) process (short–run component), and τ_t provides the slow–moving local level of volatility (long–run component).

The short–run component is then given by:

$$g_{i,t} = (1 - \alpha - \beta - \gamma/2) + \left(\alpha + \gamma \cdot \mathbb{1}_{\left(r_{i-1,t}<0\right)}\right) \frac{\left(r_{i-1,t}\right)^2}{\tau_t} + \beta g_{i-1,t}, \tag{2}$$

where $\mathbb{1}_{(.)}$ is an indicator function.

The long–run component is defined as:

$$\tau_t = exp\left(m + \theta^+ \sum_{k=1}^{K} \delta_k(\omega)^+ MV_{t-k}\mathbb{1}_{(MV_{t-k}\geq 0)} + \theta^- \sum_{k=1}^{K} \delta_k(\omega)^- MV_{t-k}\mathbb{1}_{(MV_{t-k}<0)}\right), \tag{3}$$

where m plays the role of an intercept, θ^+ and θ^- represent the asymmetric responses to the one–sided filter, and $\delta_k(\omega)^+$ and $\delta_k(\omega)^-$ are suitable functions weighing the past K realizations of the additional stationary predetermined variable labelled MV_t as the *MIDAS variable*. Throughout this work, the Beta function will be used as weighting function of all the GM models, that is:

$$\delta_k(\omega)^+ = \frac{(k/K)^{\omega_1^+ - 1}(1-k/K)^{\omega_2^+ - 1}}{\sum_{j=1}^{K}(j/K)^{\omega_1^+ - 1}(1-j/K)^{\omega_2^+ - 1}}, \tag{4}$$

$$\delta_k(\omega)^- = \frac{(k/K)^{\omega_1^- - 1}(1-k/K)^{\omega_2^- - 1}}{\sum_{j=1}^{K}(j/K)^{\omega_1^- - 1}(1-j/K)^{\omega_2^- - 1}}, \tag{5}$$

with the restriction $\omega_1^+ = \omega_1^- = 1$, which gives a higher weight to the most recent observations (monotonically decreasing weighting scheme). This is in line with what suggested in Ghysels and Qian (2019). Note that the Beta functions assure that $\sum_{k=1}^{K}\delta_k(\omega_2^+) = 1$ and $\sum_{k=1}^{K}\delta_k(\omega_2^-) = 1$.

The extension we suggest is to extend the short-run equation to some additional volatility determinants, observed at the same frequency of $r_{i,t}$. This allows us to move out of the classical GM framework with just MVs. In particular, the short-run component will change to:

$$g_{i,t} = (1-\alpha-\beta-\gamma/2) + \left(\alpha + \gamma\cdot\mathbb{1}_{\left(r_{i-1,t}<0\right)}\right)\frac{\left(r_{i-1,t}\right)^2}{\tau_t} + \beta g_{i-1,t} + \tilde{z}\cdot X_{i-1,t}, \tag{6}$$

where the variable $X_{i-1,t}$ is observed at the same frequency as $r_{i,t}$.[1] We define the model with the short-run component in (6) as DAGM–X, which nests the DAGM if $z = 0$. In order to estimate the DAGM–X (and, hence, also the GM–X), the following assumptions are made:

Assumption 1 *The innovation $\varepsilon_{i,t}$ in (1) is iid, with $E\left[\varepsilon_{i,t}\right] = 0$ and $E\left[\varepsilon_{i,t}^2\right] = 1$.*

Assumption 2 *The short-run parameters are subject to: $\alpha > 0$; $\beta \geq 0$; $\alpha + \beta + \gamma/2 < 1$;*

Assumption 3 *$\tilde{z} \geq 0$; $X_{i,t} \geq 0$, $\forall i$ and t; $X_{i,t}$ is stationary and ergodic.*

[1] Note that, because of this extension,

$$E(g_{i,t}) = 1 + \frac{\tilde{z}}{(1-\alpha-\beta-\gamma/2)}\bar{X} \equiv 1 + z\bar{X}.$$

Assumptions 1–2 are standard in the GARCH literature. Together with Assumption 3 (Han and Kristensen, 2014), the positiveness of $g_{i,t}$, $\forall i$ and t is guaranteed. The parameter space of the DAGM–X- model[2] is $\Theta = \left\{\alpha, \beta, \gamma, \tilde{z}, m, \theta^+, \omega_2^+, \theta^-, \omega_2^-\right\}$. The maximum likelihood (ML) estimates for Θ are obtained once a distribution is chosen for the innovation term in (1). If $\varepsilon_{i,t}$, conditional on the information set up to day $i-1$ of period t, denoted by $\Phi_{i-1,t}$, is assumed to be standard normally distributed, then the following log-likelihood can be maximized:

$$\mathscr{L}(\Theta) = -\frac{1}{2}\sum_{t=t_s}^{T}\sum_{i=1}^{N_t}\left[\log(2\pi) + \log(g_{i,t}\tau_t) + \frac{r_{i,t}^2}{g_{i,t}\tau_t}\right], \tag{7}$$

where t_s is taken sufficiently large in order to assure that different models, with different choices of K, will have the same information set. This is crucial when several models, with alternative K lags, are evaluated in terms of information criteria.

If it is straightforward to derive the one-step-ahead volatility, the multi-step-ahead predictions require some preliminary assumptions, mainly if the model at hand includes the "–X" part. Firstly, let $\sigma_{i,t} = \sqrt{\tau_t \times g_{i,t}}$ be the standard deviation in a GM framework, conditionally to $\Phi_{i-1,t}$. Moreover, let $\Phi_{N_T,T}$ denote the information set available the last day (N_T) of the last period (T). Let $\tilde{\sigma}_{f,T+1}$ be the conditional standard deviation forecast for the day f of the period $T+1$, conditional on the information set $\Phi_{N_T,T}$, that is: $\tilde{\sigma}_{f,T+1} = \left(\sqrt{g_{f,T+1} \times \tau_{T+1}} | \Phi_{N_T,T}\right)$. The main difference between $\tilde{\sigma}_{f,T+1}$ and $\sigma_{i,t}$ is that the former is based on a fixed information set, while the latter on an information set which updates daily. The one-step-ahead predictions depend on τ_t, which in turn is based on the MIDAS variable observed up to period $t-1$. Therefore, in the multi-step-ahead context, τ_{T+1} is a function of historical values of the MIDAS variable observed up to period T, which are included in $\Phi_{N_T,T}$ and is kept constant for all days in $T+1$. The multi-step-ahead predictions require an estimate for the short-run component $g_{f,T+1}$: extending, e.g. Conrad and Kleen (2019), we have:

$$E(g_{f,T+1}|\Phi_{N_T,T}) = 1 + z\cdot\bar{X} + (\alpha+\beta+\gamma/2)^{f-1}(g_{1,T+1} - 1 - z\cdot\bar{X}), \tag{8}$$

where $\bar{X}$ is the average of the X variable calculated over the period up to $\Phi_{N_T,T}$. Note that, as usual, the short-run prediction depends just on $g_{1,T+1}$ (a function of the information set $\Phi_{N_T,T}$) and reduces to the customary $1 + (\alpha+\beta+\gamma/2)^{f-1}(g_{1,T+1}-1)$ when the short-run unconditional expectation is equal to one ($z=0$). In either case, as f increases, the short-run prediction will approach its unconditional mean, and that will combine with τ_{T+1} to produce the overall forecast.

[2] Recall the DAGM–X nests the DAGM and the GM. Therefore, the following discussion can be naturally applied to all the other models, once that the parameter space has been reduced.

3 Empirical application

The empirical application focuses on the volatility of S&P 500 Index, while the MVs are the US Industrial Production (*IP*), Housing Starts (*HS*), and New Orders (*NewOr*). Data on S&P 500 Index and its realized volatility (calculated aggregating at 5-minutes the squared intradaily returns) have been collected from the realised library of the Oxford-Man Institute. Data on the MVs come from the Federal Reserve (St.Louis) Economic Data archive. We use the returns as daily close–to–close log–differences of the S&P 500 Index, on a sample period between 2 January 2002 and 31 December 2019 (4500 daily observations). All the MVs have been considered in terms of month-to-month growth rate. The S&P 500 realized volatility, labelled as $RVol_{i,t}$, entering the "–X" part of the short-run component includes the overnight volatility. Some summary statistics (minimum, maximum, mean, standard deviation, skewness and kurtosis) for all variables considered are in Table 1. The last column of Table 1 reports the estimated coefficient of the predictive regression as recently proposed by Conrad and Schienle (2018), to which we refer for the details on the procedure. Overall, these variables appear to be good predictors of the long-run component.

Table 1 Summary statistics

	Obs.	Min.	Max.	Mean	SD	Skew.	Kurt.	π_1
Daily data								
$r_{i,t}$	4500	-9.688	10.642	0.023	1.158	-0.231	9.523	
$RVol_{i,t}$	4500	0.128	8.958	0.835	0.605	3.392	20.363	
Monthly data								
ΔIP	215	-4.337	1.517	0.088	0.678	-1.984	9.569	-0.125^{***}
ΔHS	215	-18.681	24.647	0.326	8.431	0.176	-0.278	-0.01^{***}
$\Delta NewOr$	215	-9.680	10.363	0.250	2.250	-0.427	3.617	-0.042^{***}

Notes: The table presents the summary statistics for the close-to-close S&P 500 log-returns ($r_{i,t}$), S&P 500 realized volatility with overnight returns ($RVol_{i,t}$), US Industrial Production, Housing Starts and New Orders growth rates (ΔIP, ΔHS and $\Delta NewOr$, respectively). Sample period: 2 February 2002 - 31 December 2019. Percentage scale. The table reports the number of observations (Obs.), the minimum (Min.) and maximum (Max.), the mean, standard deviation (SD), Skewness (Skew.) and Kurtosis (Kurt.). The symbol Δ denotes the first difference. π_1 represents the estimated coefficient of the predictive regression as proposed by Conrad and Schienle (2018). *, ** and *** represent the significance at levels $10\%, 5\%, 1\%$, respectively, associated to HAC robust standard errors, for the null of $\pi_1 = 0$.

In what follows, we use six different specifications for the two models at hand, the DAGM(–X) and GM(–X), labelled as $M_1, \cdots, M_6$. Even–numbered models include the $RVol_{i,t}$ in the "–X" part. Moreover, we also use the HAR model of Corsi (2009). The volatility proxy used is the 5-minute realized volatility. The results of the comparison of all the models, carried out through the Model Confidence Set (MCS, Hansen et al. (2011)), are reported in Table 2 .

Table 2 MSE losses and MCS composition for the out-of-sample period

		MIDAS VAR.	*–X spec.*	1-day	5-days	10-day	1-month	2-months	3-months
DAGM(–X)	M_1	ΔIP		0.122	0.114	0.147	0.197	0.237	0.253
	M_2	ΔIP	$RVol_{i-1,t}$	0.106	0.104	0.133	0.165	0.187	0.204
	M_3	ΔHS		0.114	0.107	0.14	0.189	0.229	0.246
	M_4	ΔHS	$RVol_{i-1,t}$	0.097	0.093	0.122	0.152	0.166	0.177
	M_5	$\Delta NewOr$		0.142	0.128	0.163	0.221	0.276	0.316
	M_6	$\Delta NewOr$	$RVol_{i-1,t}$	0.12	0.116	0.147	0.191	0.24	0.25
GM(–X)	M_1	ΔIP		0.125	0.114	0.148	0.2	0.252	0.278
	M_2	ΔIP	$RVol_{i-1,t}$	0.104	0.099	0.127	0.159	0.184	0.194
	M_3	ΔHS		0.117	0.108	0.141	0.188	0.224	0.242
	M_4	ΔHS	$RVol_{i-1,t}$	0.103	0.098	0.126	0.162	0.188	0.189
	M_5	$\Delta NewOr$		0.135	0.122	0.156	0.212	0.268	0.304
	M_6	$\Delta NewOr$	$RVol_{i-1,t}$	0.111	0.104	0.131	0.161	0.182	0.194
	HAR			0.097	0.113	0.127	0.163	0.207	0.199

Notes: The table reports the average MSE losses for the full out-of-sample period, starting on 2 January 2014 and ending on 31 December 2019 (1506 daily obs.), according to the 1-day to 3-months volatility forecasts. Shades of gray denote inclusion in the MCS at significance level $\alpha = 0.25$.

We find that the extended models with the realized volatility as the "–X" term always belong to the MCS and are often able to outperform the HAR model, independently of the forecasting horizon considered.

European SMEs and Circular Economy Activities: Evaluating the Advantage on Firm Performance through the Estimation of Average Treatment Effects.

PMI europee e attività di economia circolare: una valutazione del vantaggio sulla performance delle imprese attraverso la stima degli effetti medi del trattamento.

Luca Secondi

Abstract This paper aims at analysing the effects of carrying out Circular Economy activities within European SMEs by means of the micro-data from the Flash Eurobarometer 441 survey and the estimation of endogenous Average Treatment Effects. Valuable findings about the economic advantages of carrying out Circular Economy sustainable practices within the corporate management systems were obtained.

Abstract *Questo studio ha lo scopo di analizzare gli effetti delle attività di economia circolare implementate all'interno delle PMI europee utilizzando i micro-dati dell'indagine Flash Eurobarometer n.441 e attraverso la stima degli effetti medi del trattamento. Risultati interessanti emergono circa i vantaggi economici derivanti dall'esecuzione di pratiche sostenibili di economia circolare all'interno dei sistemi di gestione aziendale*.

Key words: circular economy, firm performance, ATE, ATET, endogeneity

1 Introduction

The transition towards a circular model of economies has been officially recognized by the European Commission (EC) in 2015 (December, 2nd 2015) with the adoption

[1] Luca Secondi, University of Tuscia; email: secondi@unitus.it

of the Circular Economy Action Plan (CEAP), which included measures that can help to stimulate Europe's transition towards a Circular Economy (CE), enhance global competitiveness, promote sustainable economic growth, create new jobs and increase firm efficiency in using resources (Özbuğday et al, 2020).

The European Union (EU) CEAP establishes a concrete and ambitious programme of action and can represent an accelerator of the 2030 Agenda for Sustainable Development Goals foreseen by United Nations (Principato et al. 2019). In a circularity perspective, the value of products and materials is kept as long as possible so that waste and resources are minimized similarly to when a product reaches the end of its life and is reused to create further value. The proposed actions aim at enlarging product lifecycles by means of a greater level of product recycling and re-use bringing benefits to both the environment and the overall economy. However, the transition from the current linear economic model to a circular model requires the rethinking of market strategies towards a new integrated model of production, distribution, consumption as well as the introduction of new business models in order to gain economic benefits, contribute to innovation, growth and social inclusion (Ruggieri et al, 2016; Zamfir et al, 2017).

The EC has constantly monitored the level of EU-country transitions towards CE and according to the most recent published report (European Commission, 2019) the implementation of the CEAP has accelerated the evolution towards CE in Europe. As an example, it was found that in 2016, the sectors considered relevant to the CE employed more than 4 million workers, a 6% increase compared to 2012. The circularity approach has also opened new business opportunities and in 2016, circular activities such as repair, reuse or recycling generated almost 147 billion Euro value added while accounting for around 17.5 billion Euros value of investments (European Commission, 2019).

The topic of CE has also stimulated much interest both among academics and practitioners (Kirchherr et al, 2017) regarding the analyses at both micro and macro levels of firms' knowledge, awareness and implementation of CE practices and, ultimately, of the level of transition of economies towards CE.

By focusing on the number of scientific papers published in international journals within Scopus, the locution "circular economy" is present in approximately 5,500 papers (abstract, title and keywords) in the period 2016-2020, covering above all environmental science, engineering, energy, business management and accounting subject macro-areas. On the other hand, official statistics at European level has also implemented measures for monitoring CE with the introduction of 10 key indicators by Eurostat covering each phase of the product lifecycle as well as competitiveness related aspects.

Among the initiatives carried out at European level for monitoring the implementation of CE activities at single-firm level, the EC has commissioned a sample survey carried out in 2016 addressing the specific topic of CE within Small and Medium Enterprises (SMEs) in Europe - i.e. the Flash Eurobarometer (FE) 441 survey – with the main focus of exploring CE activities carried out within SMEs (European Commission, 2016).

This paper aims at analysing the effect of implementing CE practices within European SMEs on the company's economic performance. By considering the micro

data from the FE 441 survey, we firstly explore the level of implementation of the different activities that contributes to the CE. Secondly, we estimate the effects and the potential advantages (if any) of carrying out at least one of the CE related activities. To achieve the aim of the study we considered the firm's own decision of implementing a CE activity as a treatment effect which can affect its economic performance (in terms of total turnover and the related growth) and we estimated the Average Treatment Effect (ATE) and the Average Treatment Effect on the Treated (ATET), by controlling for the endogeneity of the treatment assignment (Wooldridge 2010; 2014). The treatment effects were estimated by considering the observational nature of the data and estimating endogenous treatment effects which enabled us to create an analysis that resembles what would occur had the treatment been randomly assigned (D'Agostino, 2007).

2 Materials and Method

2.1 The Flash Eurobarometer (FE) 441 survey

The microdata used in this study were collected within the FE 441 survey carried out by the TNS political and social network in the EU28 member states from 18th to 27th of April 2016 as a business to business survey which involved 10,406 SMEs employing 1 or more persons (the upper limit considered for defining a SME was 250 employees). The concerned NACE sectors were: Manufacturing (NACE category C), Retail (NACE category G), Services (NACE categories H/I/J/K/M/N) and Industry (NACE categories B/D/E/F).

The FE-441 survey investigated the following aspects: i) the proportion of SMEs undertaking activities related to the CE, and the kind of activities being taken; ii) the SME's awareness of the kinds of finance available for activities related to the CE as well as the most common sources of finance used; iii) the quality of information available to help companies access finance, iv) actual and perceived issues with regard to undertaking activities related to the CE and iv) the awareness of government programmes supporting activities related to the CE.

Specifically, the questionnaire examined if and to what extent the following activities has been undertaken within each company in the last three years: i) re-plan of the way water is used to minimise usage and maximise re-usage; ii) use of renewable energy; iii) re-plan energy usage to minimise consumption; iv) minimise waste by recycling or reusing waste or selling it to another company; v) re-design products and services to minimise the use of materials or use recycled materials).

2.2 The estimation of Endogenous Treatment Effects

The main identification challenge for estimation purposes is to know what would have happened with the firms implementing at least one activity related to CE if they had not implemented the action/s. In order to achieve this purpose it would be essential to have experimental data with a control group of SMEs similar to those implementing the activities (the treatment group), since firms implementing CE activities can differ analytically from firms not implementing any CE activities. Indeed, SMEs self-select into the decision of carrying out at least one of the activities related to CE and it may be more likely according to the firms' sector, dimension, localization and other firm structural characteristics. Moreover, some variables used to measure the impact on firm total turnover of carrying out the CE activity might also endogenously determine the firm's likelihood of implementing a CE activity.

Bearing the above considerations in mind, we therefore specified a linear model for modelling the outcome variable defined as the SMEs' level of total turnover growth in the last 3 years and a probit model for modelling the SMEs' decisions of implementing CE activities. We verified the existence of endogeneity between the two processes and we adopted a control-function approach which explicitly includes residuals from the treatment models for the potential outcomes.

More specifically, the selected Endogenous Treatment Effect estimation (Wooldridge, 2010; 2014) enabled us to extract experimental-style causal effects from observational data thus looking like as the treatment would have been randomly assigned (D'Agostino, 2007) and to estimate the Average Treatment Effect (ATE), the Average Treatment Effect on the Treated (ATET) and the Potential Outcome Means (POMs), by also considering treatment assignment as correlated with the potential outcome. The treatment-effect models we considered for estimating the effects of CE activities on firms' turnover follow this specification:

$$y_{i0} = E(y_{i0}|\mathbf{x_i}) + \epsilon_{i0} \tag{1}$$

$$y_{i1} = E(y_{i1}|\mathbf{x_i}) + \epsilon_{i1} \tag{2}$$

$$t_i = E(t_i|\mathbf{z_i}) + v_i \tag{3}$$

$$y_i = t_i y_{i1} + (1 - t_i) y_{i0} \tag{4}$$

$$E(\epsilon_{ij}|\mathbf{x_i}, \mathbf{z_i}) = E(\epsilon_{ij}|\mathbf{z_i}) = E(\epsilon_{ij}|\mathbf{x_i}) = 0 \quad for \;\; j \in \{0,1\} \tag{5}$$

$$E(\epsilon_{ij}|\mathrm{t}) \neq 0 \quad for \;\; j \in \{0,1\} \tag{6}$$

where for the ith firm: y_{i0} is the potential outcome when the treatment is not received, y_{i1} identifies the potential outcome when receiving the treatment (in our study of implementing at least one CE activity), t_i identifies the observed binary treatment (equal to 1 if at least one CE activity is carried out and 0 if none of the CE activities is implemented within the firm) and y_i is the observed outcome, therefore representing the percentage points by which the company's turnover has increased or decreased over the last three years. Each one of the potential outcomes is determined by its expected value conditional of a regressor vector $\mathbf{x}_i$ and an unobserved random component ϵ_{ij}, for j $\in$ {0,1}. The same specification was adopted for the treatment equation (3) which is given by its expectation conditional on a set of regressors $\mathbf{z}_i$ –

which, according to a methodological perspective are not required to differ from $\mathbf{x}_i$ – and an unobserved component v_i. The equation (6) explicitly takes into consideration endogeneity within the model specification.

We included as covariates in the models: NACE sector (Outcome Model, OM, and Treatment Model, TM), company establishment year (OM), country where the company is located (TM), the percentage of the company's turnover invested in Research and Development (TM), types of activities carried out (OM), size of the company as expressed in terms of number of employees (TM) as well the unemployment rate (year 2016) and the related compound annual average rate of change (years 2013-2015) at national level (OM) as contextual territorial variables.

3 Preliminary Results and Conclusion

As a general descriptive result, it emerged that approximately three quarters of companies (73%) carried out at least one CE related activity among the activities listed in the questionnaire prepared by the EC, with almost all companies located in Malta (approximately 95%) which has implemented at least one of these CE activities, followed by 89% in Ireland and 85% in Luxembourg and Spain, compared to 44% in Bulgaria and Estonia and 47% in Lithuania (European Commission, 2016).

By focusing on the specific activities implemented, it was found that the majority of companies (55%) mentioned minimising waste by recycling, reusing or selling it to another company. Follows the activity of re-planning energy usage to minimise consumption implemented by approximately 38% of the companies. Moreover, about a third of companies (34%) have redesigned products and services to minimise the use of materials or use recycled materials. Further, almost 1 out of 10 companies is planning to redesign products and services for these reasons while approximately 1 out of 5 SMEs has re-planned the way water is used to minimise usage and maximise re-usage. Lastly, among of all the activities investigated, companies are least likely to be using renewable energy (16%).

Table 1 reports the estimated ATEs and ATETs. The existence of endogeneity between the two processes was confirmed by the Wald (endogeneity) test which lead us to reject the null hypothesis that treatment and outcome unobservable are uncorrelated (Chi-square(2) =35.20, p-value=0.0000).

Table 1: Estimation results: Endogenous treatment effect estimation

Endogenous treatment effect estimation	***Coef.***	***Robust SE***	***z***	***P > |z|***
ATE - Average Treatment effect				
Treatment (1=implemented CE activities *vs* 0=not implemented)	14.897	3.855	3.86	0.000
PO-mean - Treatment (0=not implemented CE activities)	-7.663	3.740	-2.05	0.040
ATET – Average Treatment Effect on the Treated				
ATET-Treatment	13.974	4.958	2.82	0.005

Endogenous treatment effect estimation	*Coef.*	*Robust SE*	*z*	*P > |z|*
(1=implemented CE activities *vs* 0=not implemented)				
Potential Outcome Mean - Treatment (0=not implemented CE activities)	-10.544	4.943	-2.13	0.033

Notes: outcome dependent variable: turnover increase/decrease in the last three years expressed in percentage points; treatment binary variable: decision of implementing at least one CE activities.

As an overall result, it was found that the average effect of the treatment in the population – $ATE = E(y_1 - y_0)$ – would be an average increase of the total turnover by approximately 14.9 percentage points, thus enforcing the importance of implementing CE initiatives, activities and practices within company management systems. On the other hand, the average treatment effect among those that received the treatment – i.e. the ATET estimated as the mean of the difference y_1 and y_0 among the subjects that actually receive the treatment – revealed that the companies' turnover would lead to a decrease (observed considering the last three years) of approximately 10.5 percentage points if none of these SMEs carried out any CE activities. Additionally, for those companies which carried out at least one CE activity, the average increase in the company's total turnover is approximately 14 percentage points greater than if none of these companies carried out any CE activities.

These preliminary results focused on the estimates concerning the overall decisions of implementing at least one CE activity. Further estimations focusing on specific CE single-activities foreseen in the FE-441 survey, as well as separate models distinguishing for turnover thresholds in order to explore equal access of companies to circularity practices are ongoing, with the aim of effectively identifying those factors which can support the importance of a sustainable management system as priority in the firms' administration and growth.

Financial Spillover Measures to Assess the Stability of Basket-based Stablecoins

Misure di Spillover Finanziari per Valutare la Stabilità di Basket-based Stablecoins

Paolo Pagnottoni

Abstract The paper aims to assess, from an empirical viewpoint, the advantages of a stablecoin whose value is derived from a basket of underlying currencies, against a stablecoin which is pegged to the value of one major currency, such as the dollar. To this aim, we first find the optimal weights of the currencies that can comprise our basket. We then employ variance decomposition methods to understand which foreign currency mostly drives the others. We then look at how the stability of either stablecoin is affected by currency shocks. Our empirical findings show that our basket based stablecoin is less volatile than all single currencies. This results is fundamental for policy making, and especially for emerging markets with a high level of remittances: a librae (basket-based stablecoin) can preserve its value during turbolent times better than a libra (single currency based stablecoin).

Abstract *Questo studio ha l'obiettivo di individuare, da un punto di vista empirico, i vantaggi di uno stablecoin derivato da un paniere di valute, confrontato con uno stablecoin legato al valore di una valuta di punta, come il dollaro. A questo proposito, troviamo prima i pesi ottimali delle valute che compongono il nostro paniere. Impieghiamo poi metodi di decomposizione della varianza per capire quale delle valute traina maggiormente l'andamento delle altre. I nostri risultati empirici mostrano che il nostro stablecoin fondato su un paniere di valute è meno volatile di tutte le singole valute. Questi risultati sono fondamentali per il policy making, e specialmente per i mercati emergenti con un alto livello di rimesse: un "librae" (stablecoin basato su un paniere di valute) può preservare il suo valore durante periodi turbolenti meglio di un "libra" (stablecoin basato su una singola valuta).*

1 Introduction

Many researchers posed the question of whether a Synthetic Hegemonic Currency (SHC) would be best provided by the public sector. The rationale would be that a global currency, underpinned by a basket of reserve assets, could better support global outcomes. For example, an SHC could dampen the dominating influence of the US dollar on global trade, it could alleviate spillovers to exchange rates from shocks to the US economy, and trade across countries could become less dependent on the dollar.

The revival of discussions concerning an SHC, have somewhat been sparked by the discourse surrounding central bank digital currency (CBDC) and stablecoins. In particular, Facebook announced plans for its own privately issued stablecoin that could emulate some of the characteristics of an SHC. The proposition is to construct a stablecoin that can circulate globally with a value that is derived from an underlying basket of assets comprised of the major currencies. Whilst the exact composition of the underlying basket of assets is yet unspecified, the objective is to devise a digital currency whose exchange rate fluctuations are minimised against several currencies. These plans have been met with resistance from regulators and Facebook itself has repeatedly stated that the Libra stablecoin could be backed by a single currency (the dollar).

Against this background, we investigate the consequences of a global SHC ("Librae", in a literal sense), regardless of whether issued by a private company such as Facebook, or by a central bank. In particular, we first look at the optimal design of an SHC that is backed by a basket of underlying reference currencies, such as those included in the International Monetary fund Special Drawings Rights (SDRs). We then study the currencies which mostly determine price change spillovers among exchange rates, using the framework of (3). For the optimal construction of a basket of currencies, we follow (1) to compute a minimum variance currency basket using major currencies. We construct a reference basket that contains the Dollar (USD), the Euro (EUR), the Yen (JPY), the Renminbi (CNY) and the Pound Sterling (GBP). By construction, our basket based currency should be the least varying in comparison to those contained in the basket, and our results confirm this.

Our price change spillover decomposition shows that the dollar is the currency that has the largest impact on the others, especially in terms of exporting contagion. As a consequence, a negative shock on the dollar causes a shock on all currencies and, through high order contagion, on the dollar itself, leading to a new lower equilibrium. Differently, a shock in the value of the SHC, caused by a shock of a currency in the basket, is offset by the diversification effect and, therefore, the starting equlibrium is maintained. This implies that remittances converted in basket based stablecoin better maintain their value, with respect to those converted in dollars (or dollar based stable coins).

2 Methodology

We aim to build a basket of predetermined (reference) currencies with optimal weights, namely, weights which minimize the variability of a basket based stablecoin. This translates into an optimal control problem which minimizes the variance of the basket constructed with the above mentioned currencies. We follow (1) to build the reduced normalized values (RNVALs) associated to the currencies as well as the above mentioned basket.

We evaluate spillovers through the methodology by (2). As in their seminal paper, we start from estimating a Vector AutoRegressive (VAR) model which we convert into its corresponding vector moving average (VMA) representation, that is

$$x_t = \varepsilon_t + \Psi_1 \varepsilon_{t-1} + \Psi_2 \varepsilon_{t-2} + \cdots \tag{1}$$

where x_t being the $(n \times 1)$ vector of first differences in RNVALs at time t, ε_t a zero-mean white noise process having variance-covariance matrix Σ_ε, $\Psi_1, \Psi_2, ...$ the $(n \times n)$ are the matrices of VMA coefficients. The VMA coefficients are recursively computed as $\Psi_i = \Phi_1 \Psi_{i-1} + \Phi_2 \Psi_{i-2} + ... + \Phi_i \Psi_1$, having $\Psi_i = 0 \; \forall i < 0$ and $\Psi_1 = I_n$.

(2) build their methodology on the KPPS H-step ahead forecast error variance decomposition. Considering two generic variables x_i and x_j, they define the own variance shares as the proportion of the H-step ahead error variance in predicting x_i due to shocks in x_i itself, $\forall i = 1, ..., n$. On the other hand, the cross variance shares (spillovers) are defined as the H-step ahead error variance in forecasting x_i due to shocks in x_j, $\forall i = 1, \cdots, n$ with $j \neq i$. In other words, denoting as $\theta^g_{ij}(H)$ the KPPS H-step forecast error variance decompositions, with $h = 1, \cdots, H$, we have:

$$\theta^g_{ij}(H) = \frac{\sigma_{jj}^{-1} \sum_{h=0}^{H-1} (e_i' \Psi_h \Sigma e_j)^2}{\sum_{h=0}^{H-1} (e_i' \Psi_h \Sigma \Psi_h' e_i)} \tag{2}$$

with σ_{jj} being the standard deviation of the innovation for equation j and e_i the selection vector, i.e. a vector having one as i^{th} element and zeros elsewhere. Intuitively, the own variance shares and cross variance shares (spillovers) measure the contribution of each variable to the forecast error variance of itself and the other variables in the system, respectively, thus giving a measure of the importance of each variable in predicting the others.

Note that the row sum of the generalized variance decomposition is not equal to 1, meaning $\sum_{h=0}^{H-1} \theta^g_{ij}(H) \neq 1$. (2) circumvent this problem by normalizing each entry of the variance decomposition matrix by its own row sum, i.e.

$$\tilde{\theta}^g_{ij}(H) = \frac{\theta^g_{ij}(H)}{\sum_{j=1}^{n} \theta^g_{ij}(H)} \tag{3}$$

We make use of directional spillovers indexes (DSI) to measure the spillover from exchange i to all other exchanges J (cfr. Eq. 4) and the spillover from all exchanges J to exchange i (cfr. Eq. 5) as:

$$DSI_{J\leftarrow i}(H) = \frac{\sum_{\substack{j=1 \\ j\neq i}}^{n} \tilde{\theta}^{g}_{ji}(H)}{\sum_{j,i=1}^{n} \tilde{\theta}^{g}_{ij}(H)} \cdot 100 \tag{4}$$

$$DSI_{i\leftarrow J}(H) = \frac{\sum_{\substack{j=1 \\ j\neq i}}^{n} \tilde{\theta}^{g}_{ij}(H)}{\sum_{j,i=1}^{n} \tilde{\theta}^{g}_{ij}(H)} \cdot 100 \tag{5}$$

From the definitions of directional spillover indexes, it is natural to build a net contribution measure, impounded in the net spillover index (NSI) from market i to all other markets J, namely:

$$NSI_i(H) = DSI_{J\leftarrow i}(H) - DSI_{i\leftarrow J}(H) \tag{6}$$

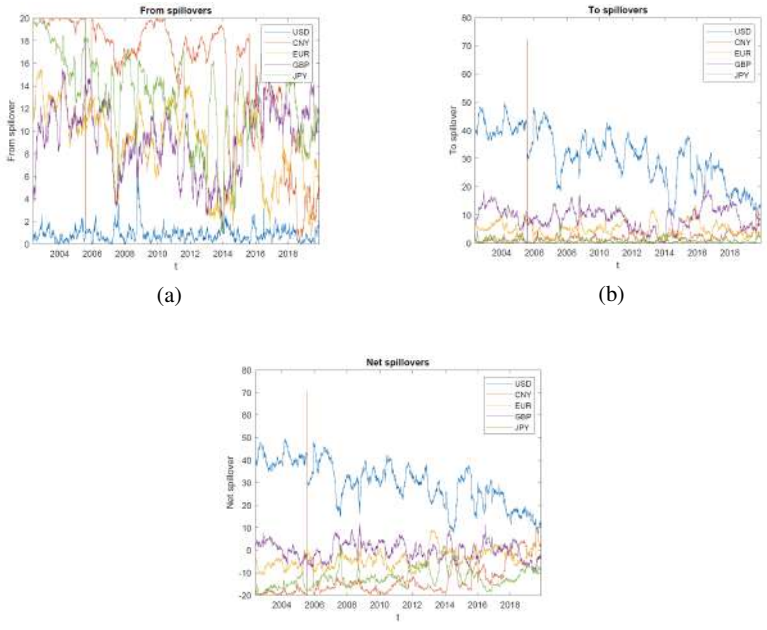
All the metrics discussed above are able to yield insights regarding the mechanisms of market exchange spillovers both from a system-wide and a net pairwise point of view. Furthermore, performing the analyses on rolling windows we are able to study the dynamics of spillover indexes over time.

3 Data and Empirical Findings

To test our proposal, we make use of historical data, according to a retrospective analysis. In particular, we use daily foreign exchange rate data over the period 1 January 2002 - 30 November 2019. To build our optimal basket of currencies, we collect data relative to the foreign exchange pairs between the currencies that are included in the IMF's Special Drawings Rights: the US dollar, the Chinese Renmimbi, the Euro, the British pound and the Japanese Yen.

We now consider spillovers between exchanges, to evaluate the price change connectedness of the currencies that compose the basket, and to understand which is the relative importance of each of the currencies in transmitting shocks. In this way, we are also able to determine which currencies potentially cause strong (or weak) price changes in our proposed stablecoin value. Dynamic directional spillovers can shed light on which of the currencies transmit price change spillovers to others and which of them receive price change spillovers from others. We plot from, to, net and pairwise spillovers in Figure 1.

We can highlight that that USD is the most influential currencies in terms of return spillovers. Indeed, the magnitude of spillovers received from others is weak



(a) (b)

(c)

Fig. 1: From, to and net spillovers

compared to that transmitted to others. Moreover, the net spillover dynamics summarizes the dominant position of the USD, being it always positive and taking relatively high values over the sample period. However, the magnitude of spillovers transmitted by USD follows a negative trend over time, meaning the currency is gradually losing its potentiality to contribute to the evolution of the others, perhaps due to the affirmation of emerging economies in the latter period, especially after the 2009 crisis. Despite that, the latter considerations are in line with the full sample results obtained above, which point to the dominance of USD as a spillover transmitting currency.

The dynamic analysis shows that CNY is not such a leading currency in transmitting price change shocks. Indeed, the full sample result is arguably driven by a noticeable spike which occurred on 21 July 2005. Indeed, during that day the Chinese Central Bank officially announced the abandonment of the eleven-year-old peg to the dollar and pegged the CNY to a basket of currencies whose composition was not disclosed. This caused a prompt revaluation to CNY 8.11 per USD, as well as to 10.07 CNY per Euro. However, the peg to the dollar was reinstituted as the financial crisis strengthened in July 2008. These results indicate that CNY does not particularly contribute to the price change evolution of the other currencies in the basket, although it can exert shocks through sudden policy decisions.

4 Conclusion

In the paper we present a methodology to build a basket based stable coin whose weights can maximise stability over a long time period. The proposed stable coin (Librae) appears to be less volatile than single currencies and, therefore, with respect to single currency stable coins (Libra). It can thus constitute a valuable proposal especially for workers who live abroad and make remittances to their own country, a market segment with a high potential of being attracted by payments in stablecoins.

We have also proposed a variance decomposition technique based on a VAR model, aimed at showing which currencies mostly impact the Foreign Exchange market and whether a single currency or a basket based stablecoin is more resilient to currency shocks. Our results show that the dollar is the currency which mostly impact the market, and that a basket based coin is better than a dollar based one, from a stability and value maintenance viewpoint.

With a basket based stablecoin it is possible to offset the risk of currencies shocks. This is of relevance for different policy purposes and, in particular, for emerging markets and countries having high remittances. Indeed, by holding stablecoins rather than single currencies the risks associated to currency shocks are mitigated and stablecoins holder can count on a currency whose value is less volatile than traditional fiat currencies and, thereby, more reliable. The latter fact has also positive consequences on cross-border payments side, provided that the stability of the stablecoin mitigates the foreign exchange risk, thus contributing to the fact that buyers and sellers give or receive an amount of money whose value is less sensitive to variations over time.

Forecasting Banknote Flows in BdI Branches: Speed-up with Machine Learning

Forecast dei Flussi di Banconote nelle Filiali della Banca d'Italia con metodi di Machine Learning

Brandi Marco, Fusaro Monica, Laureti Tiziana and Rocco Giorgia

Abstract Every day banknotes are withdrawn from and deposited to Banca d'Italia branches by banks. Up to 455 time series need to be predicted simultaneously. In order to find a model with the best trade-off between forecasting performance and time consumption, a comparison between different machine learning approaches is presented.

Abstract *Le banche prelevano e depositano quotidianamente banconote presso le filiali della Banca d'Italia. É necessario prevedere contemporaneamente fino a 455 serie storiche. Viene presentato un confronto tra diversi modelli di machine learning in termini di previsione e di tempo di esecuzione, con lo scopo di trovare un modello con il miglior compromesso tra i due aspetti.*

1 Introduction

In Italy, the provision of banknotes relies on a complex supply chain (cash cycle) [16]. Commercial banks and the postal system provide cash to the public through their branches and ATMs. Every day, these stakeholders request banknotes from the branches of Banca d'Italia, which must guarantee their availability to fully satisfy demand; at the same time, they deposit unfit banknotes and excess stocks that have to be processed by the branches to retire unfit banknotes from circulation. Therefore, branches must be supplied with new banknotes in time to satisfy cash handlers' requirements and at the same time they should be streamlined in case of excessive stocks.
In this framework, Banca d'Italia needs to plan the transfers from the central hub to the branches and back beforehand, to guarantee security standards. This requires a forecast of the deposited and withdrawn banknotes for each branch and denomination. Furthermore, the forecast needs to be updated every week.
Daily withdrawals (W) and deposits (D) data for each branch and denomination are aggregated, due to the weekly nature of banknote transfers. Weekly time series refer to 35 branches (distributed in all Italian regions), 7 denominations for deposits (€5 - €500), and 6 for withdrawals (€5 - €200).[1] Then, a total of 455 time series should be analyzed. Data from January 2009 to June 2019 for a total of 546 observations are used for each time series. Considering the data-intensive nature of the problem, the use of classical forecasting approaches implicates a high degree of computational complexity, as well as the need to verify many assumptions for the model. Machine learning approaches for forecasting time series are explored to overcome these issues since they relax assumptions, such as the distribution form, and link the dependent variable to the covariates using an unknown distribution form [5]. Moreover, machine learning is a data-driven approach oriented to predict and forecast, which is able to pick up non-linear relationships. It also facilitates the implementation of ensemble methods, which generally outperform single methods [15, 8]. The main disadvantage of machine learning methods resides in the fact that their output is often hard to be interpreted. Given the focus in forecasting of the study, this drawback is not a concern. Time series problems are more difficult to handle with machine learning algorithms, due to the time dependency between the response variables. The forecasting procedure has been adapted in this respect.

2 Methodology

As discussed above, machine learning algorithms are not easily implemented to treat time series due to the time dependency of the data, but there are several examples of models that can be used for time series forecasting [2, 9, 10]. In this work, a

[1] The Eurosystem' national central banks stopped the issuance of €500, with the exception of Germany and Austria which stop issuing the €500 at the end of April 2019.

forecast procedure is provided starting from the work of Laurinec [14], who uses regression trees in order to forecast electricity consumption with double seasonality modeling. Each of the 455 time series is treated individually, whereas the two flows of banknotes W and D are modeled equally. Let Y_t be an observation at time t (with $t = 1,\ldots,546$) for a single time series referred to one of the two flows for a denomination in a branch.
First, Y_t has been decomposed in trend, seasonal and remainder components, using nonparametric regression LOESS (STL) introduced in [7] as follows:

$$Y_t = T_t + S_t + R_t \ , \tag{1}$$

Then, the forecast is obtained by estimating separately the two components:

$$\hat{Y}_{t+h} = \hat{T}_{t+h} + \hat{\tilde{Y}}_{t+h} \ , \tag{2}$$

1. The trend component $\hat{T}_{t+h}$ is estimated using simple ARIMA models with automatic parameter selection as proposed by [13];
2. The detrended component $\hat{\tilde{Y}}_{t+h}$ is obatained applying machine learning algorithms to the detrended time series $\tilde{Y}_t = S_t + R_t$.

In order to handle time series with machine learning, an extraction of time-based features is necessary. The following explanatory variables are therefore considered:

- Seasonal variable S_t: estimated within the decomposition of Y_t, it is related to the week of the year and it is constant between years;
- Lag variables to $t-4$: $\tilde{Y}_{t-1}, \tilde{Y}_{t-2}, \tilde{Y}_{t-3}, \tilde{Y}_{t-4}$;
- Fourier coefficients: $a_i \cos(\omega_i t)$, $b_i \sin(\omega_i t)$ for $i = 1,\ldots,K$ as suggested in [18] in order to model seasonality, where ω_i is the Fourier basis;
- Dummy variable indicating Easter week (variable across years) E_t.

The relationship between the response variable and the explanatory variables can be synthesized by the following formula:

$$\tilde{Y}_t = f\left(S_t, \tilde{Y}_{t-1}, \tilde{Y}_{t-2}, \ldots, a_1, b_1, \ldots, E_t\right) \ , \tag{3}$$

where the link function f can be estimated using machine learning algorithms.
The final forecast is obtained using a MIMO (*Multi Input Multi Output*) strategy, which can potentially improve the performance of the forecast [1]. Furthermore, this strategy is able to preserve the stochastic dependency among the predicted values characterizing the time series. However, preserving the stochastic dependencies constrains all the horizons to be forecast with the same model structure, reducing the flexibility of the forecast approach. With this approach the computational time is lower than other existing strategies.

2.1 Machine learning algorithms

Machine learning methods used in this work mainly include tree-based algorithms as decision trees (*CART*) [6] and conditional inference trees (*CTREE*) [11].
In order to improve the forecast, ensemble methods are considered, since they combine several decision trees to produce better predictive performance. The underlying idea is that a group of weak learners gather to produce a strong learner, hence increasing the accuracy of the model although losing interpretability. In this study, bagging and random forest algorithms are considered. The bagging algorithm (bootstrap aggregating: *BCART* and *BCTREE*) [3] takes the average of the predictions obtained by several decision trees (or conditional inference trees) applied to different bootstrap samples of the original one. Random forests (RF) are a combination of decision trees where each tree depends on the values of a random vector sampled independently and with the same distribution for all trees in the forest [4]. The splits in each tree allow evaluating the variable importance in predicting the values.
Additionally, the most commonly used artificial neural networks (ANN) [17] is performed. The multilayer perceptrons consists of at least three layers of nodes: an input layer, a hidden layer and an output layer. Except for the input nodes, each node is a neuron that uses a nonlinear activation function and the backpropagation is used for training the algorithm.
The seasonal ARIMA (SARIMA) model with automatic parameter selection [13] is considered as a benchmark model to compare the results of machine learning with a classical approach.

2.2 Evaluating forecasting performance

In order to evaluate the forecasting performance of the different algorithms, each time series is preliminarily divided into train and several test sets. Specifically, to evaluate the forecast performance at different time horizons, the test set is considered adding one week each time, so that the dimensions of the different test sets are equal to $h = 1,\ldots,52$ up to an entire year of observations. Therefore, the forecast performances are evaluated using the MASE (*Mean Absolute Scaled Error*), which is scale-independent, proposed by [12] to compare different methods across different series. Let $e_t = Y_t - \hat{Y}_t$ be the forecast error, a scaled error is defined as follows:

$$q_t = \frac{e_t}{\frac{1}{n-1}\sum_{i=2}^{n}|Y_i - Y_{i-1}|}. \tag{4}$$

Mean absolute scaled error is then defined as $MASE = \mathbb{E}(|q_t|)$. Furthermore, the time consumption is evaluated considering the time of execution of each single algorithm on all the time series.[2]

[2] All the algorithms were executed on a PC with processor INTEL(R) Core(TM) i5-4300U 1.90GHz and 8,00 GB RAM. R version 3.6.2

3 Results

The results in terms of MASE and time execution are analyzed among the different models. (Fig. 1). In terms of forecast performance, machine learning ensemble methods outperform single methods. The distribution of MASE for random forest and bagging methods is more concentrated than for SARIMA with RF presenting the lowest variability. RF has a MASE lower than the SARIMA one in above 60% of time series forecast and only 5% of cases have a relevant greater MASE than SARIMA.

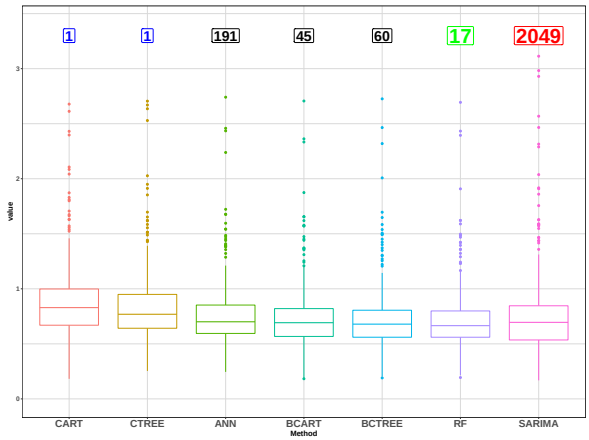

Fig. 1 Distribution of MASE for different methods. Execution time in minutes is reported in the upper part of the figure.

Time of execution is also considered (top of Fig. 1). Although the single decision tree models have the lowest execution time (1 minute), RF looks very promising with 17 minutes, especially compared to SARIMA, which takes up to 34 hours to run for all the time series.
The random forest algorithm is the model with the best trade-off between accuracy and time of execution.

4 Conclusions

This study considers the problem of forecasting a high number of time series. The forecast for each single time series is investigated and machine learning approaches are exploited. Even considering auto-selection of the parameters, classical approaches, with many assumptions that need to be verified, are not the most

suitable solution for forecasting such a high number of time series. Moreover, the predictive performance of machine learning methods generally outperforms, or at least matches, that of classical methods, especially in the case of random forests algorithms.
Machine learning methods are very time-saving with respect to the classical approach. Lower time of execution is the main advantage, considering the applied and operative nature of the problem.
Machine learning algorithms also allow to include more variables and the models could be improved moving from Easter dummy variable to a special dummy variable in order to include local holidays or events at each of the Banca d'Italia branches. A formal selection of variable lags could also be included in the training of machine learning algorithms.

Fully reconciled GDP forecasts from Income and Expenditure sides

Previsioni riconciliate del PIL dal lato del reddito e della spesa

Luisa Bisaglia, Tommaso Di Fonzo and Daniele Girolimetto

Abstract We propose a complete reconciliation procedure, resulting in a 'one number forecast' of the *GDP* figure, coherent with both Income and Expenditure sides' forecasted series, and evaluate its performance on the Australian quarterly *GDP* series, as compared to the original proposal by Athanasopoulos *et al.* (2019).
Abstract *In questo lavoro viene proposta una procedura di riconciliazione delle previsioni del PIL e delle sue componenti tanto dal lato del Reddito quanto da quello della Spesa, volta a produrre previsioni coerenti rispetto ad entrambi i lati. Tale procedura, applicata alle serie trimestrali del PIL australiano, viene posta a confronto con la proposta originale di Athanasopoulos et al. (2019).*

Key words: forecast reconciliation, cross-sectional (contemporaneous) hierarchies, GDP, Income, Expenditure

1 Introduction and summary

In a recent paper, Athanasopoulos *et al.* (2019, p. 690) propose "the application of state-of-the-art forecast reconciliation methods to macroeconomic forecasting" in order to perform aligned decision making and to improve forecast accuracy. In their empirical study they consider 95 Australian Quarterly National Accounts time series, describing the Gross Domestic Product (*GDP*) at current prices from Income and Expenditure sides, interpreted as two distinct hierarchical structures. In the former case (Income), *GDP* is on the top of 15 lower level aggregates (figure 1), while in the latter (Expenditure), *GDP* is the top level aggregate of a hierarchy of 79 time series (see figures 21.5-21.7 in Athanasopoulos *et al.*, 2019, pp. 703-705).

In this paper we re-consider the results of Athanasopoulos *et al.* (2019), where the forecasts of the Australian quarterly *GDP* aggregates are separately reconciled from Income ($\widetilde{GDP}^{I}$) and Expenditure ($\widetilde{GDP}^{E}$) sides. This means that $\widetilde{GDP}^{I}$ and

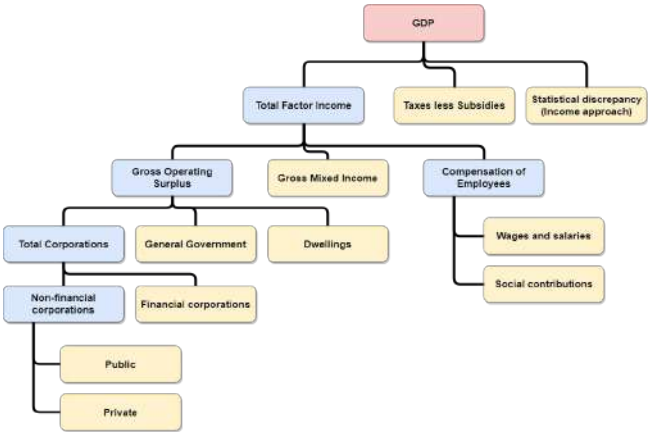

Fig. 1 Hierarchical structure of the income approach for Australian GDP. The pink cell contains the most aggregate series. The blue cell contain intermediate-level series and the yellow cells correspond to the most disaggregate bottom-level series. Source: Athanasopoulos *et al.*, 2019, p. 702.

$\widetilde{GDP}^{E}$ are each coherent within its own pertaining side with the other forecasted values, but in general $\widetilde{GDP}^{I} \neq \widetilde{GDP}^{E}$ at any forecast horizon. This circumstance could confuse and annoy the user, mostly when the discrepancy is not negligible (see Figure 2), and calls for a complete reconciliation strategy, able to produce a 'one number forecast' of the *GDP* figure, which is the main target of the paper.

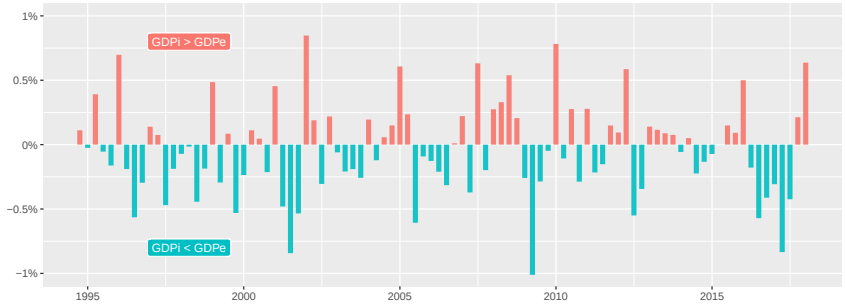

Fig. 2 Discrepancies in the reconciled 1-step-ahead *GDP* forecasts from Income and Expenditure sides. ARIMA base forecasts reconciled according to MinT-shr procedure (see section 3). Source data: Athanasopoulos *et al.* (2019).

We show that fully reconciled forecasts of *GDP*, coherent with all the reconciled forecasts from both Expenditure and Income sides, can be obtained through the classical least squares adjustment procedure proposed by Stone *et al.* (1942). It should be noted that the proposed solution has been considered by van Erven and Cugliari (2015) and Wickramasuriya *et al.* (2019) as an alternative formulation, equivalent to the regression approach by Hyndman *et al.* (2011). As far as we know, however, it has never been applied so far to distinct hierarchies sharing only the top level series. The procedure can be seen as a forecast combination (Bates and Granger, 1969) -

working on different series rather than on the output of multiple models - which makes additional use of external constraints valid for the series and their forecasts.

2 From single side to complete aggregation constraints

Denoting with x_t the actual *GDP* at time t, the relationships linking the series of, respectively, the Income and Expenditure sides hierarchies can be expressed as

$$\mathbf{y}_t^I = \mathbf{S}^I \mathbf{b}_t^I, \qquad \mathbf{y}_t^E = \mathbf{S}^E \mathbf{b}_t^E, \quad t = 1, \ldots, T, \tag{1}$$

where $\mathbf{y}_t^I = \begin{bmatrix} x_t & \mathbf{a}_t^{I\prime} & \mathbf{b}_t^{I\prime} \end{bmatrix}'$, $\mathbf{y}_t^E = \begin{bmatrix} x_t & \mathbf{a}_t^{E\prime} & \mathbf{b}_t^{E\prime} \end{bmatrix}'$, $\mathbf{b}_t^I$ and $\mathbf{b}_t^E$ are (10×1) and (53×1), respectively, vectors of bottom level (disaggregated) series, $\mathbf{a}_t^I$ and $\mathbf{a}_t^E$ are (5×1) and (26×1), respectively, vectors of higher levels (aggregated) series, and

$$\mathbf{S}^I = \begin{bmatrix} \mathbf{1}_{10}' \\ \mathbf{C}^I \\ \mathbf{I}_{10} \end{bmatrix}, \qquad \mathbf{S}^E = \begin{bmatrix} \mathbf{1}_{53}' \\ \mathbf{C}^E \\ \mathbf{I}_{53} \end{bmatrix}$$

are contemporaneous (cross-sectional) summing matrix mapping the bottom level series into the higher-levels variables in each hierarchy, where $\mathbf{1}_k$ denotes a $(k\times 1)$ vector of ones, $\mathbf{I}_k$ denotes the identity matrix of order k, and $\mathbf{C}^I$ and $\mathbf{C}^E$ are the (5×10) and (26×53), respectively, matrices of 0's and 1's describing the aggregation relationships between the bottom level series and the higher level series (apart *GDP*) for Income ($\mathbf{C}^I$) and Expenditure ($\mathbf{C}^E$) sides. The relationships (1) can be equivalently written as

$$\mathbf{U}^{I\prime}\mathbf{y}_t^I = \mathbf{0}, \qquad \mathbf{U}^{E\prime}\mathbf{y}_t^E = \mathbf{0}, \quad t = 1, \ldots, T, \tag{2}$$

where $\mathbf{U}^I = \begin{bmatrix} \mathbf{I}_6 \\ -\mathbf{1}_{10} \; -\mathbf{C}^{I\prime} \end{bmatrix}$, and $\mathbf{U}^E = \begin{bmatrix} \mathbf{I}_{27} \\ -\mathbf{1}_{53} \; -\mathbf{C}^{E\prime} \end{bmatrix}$ are (16×6) and (80×27) matrices, respectively. The only variable subject to linear constraints on both the Income and Expenditure sides in expressions (1) and (2) being x_t (i.e., *GDP*), we can express the aggregation relationships linking the 95 'unique' variables as

$$\mathbf{U}'\mathbf{y}_t = \mathbf{0}, \quad t = 1, \ldots, T, \tag{3}$$

where $\mathbf{y}_t = \begin{bmatrix} x_t & \mathbf{a}_t^{I\prime} & \mathbf{b}_t^{I\prime} & \mathbf{a}_t^{E\prime} & \mathbf{b}_t^{E\prime} \end{bmatrix}'$ is a (95×1) vector , $\mathbf{0}$ is a (33×1) null vector, and $\mathbf{U}'$ is the following (33×95) matrix:

$$\mathbf{U}' = \begin{bmatrix} 1 & \mathbf{0}_5' & -\mathbf{1}_{10}' & \mathbf{0}_{26}' & \mathbf{0}_{53}' \\ 1 & \mathbf{0}_5' & \mathbf{0}_{10}' & \mathbf{0}_{26}' & -\mathbf{1}_{53}' \\ \mathbf{0}_5 & \mathbf{I}_5 & -\mathbf{C}^I & \mathbf{0}_{5\times 26} & \mathbf{0}_{5\times 53} \\ \mathbf{0}_{26} & \mathbf{0}_{26\times 5} & \mathbf{0}_{26\times 10} & \mathbf{I}_{26} & -\mathbf{C}^E \end{bmatrix}. \tag{4}$$

3 Optimal point forecast reconciliation

Forecast reconciliation is a post-forecasting process aimed at improving the quality of the *base* forecasts for a system of hierarchical/grouped, and more generally linearly constrained, time series (Hyndman *et al.*, 2011, Panagiotelis *et al.*, 2019) by exploiting the constraints that the series in the system must fulfill, whereas in general the base forecasts don't. In this framework, as base forecasts we mean the $(n \times 1)$ vector $\hat{\mathbf{y}}_{T+h} \equiv \hat{\mathbf{y}}_h$ of unbiased point forecasts, with forecast horizon $h > 0$, for the $n > 1$ variables of the system.

Following Stone *et al.* (1942), we consider the classical measurement model

$$\hat{\mathbf{y}}_h = \mathbf{y}_h + \boldsymbol{\varepsilon}_h, \quad E(\boldsymbol{\varepsilon}_h) = \mathbf{0}, \quad E\left(\boldsymbol{\varepsilon}_h \boldsymbol{\varepsilon}_h'\right) = \mathbf{W}_h, \tag{5}$$

where $\hat{\mathbf{y}}_h$ is the available measurement, $\mathbf{y}_h$ is the target forecast vector, and $\boldsymbol{\varepsilon}_h$ is a zero-mean measurement error, with covariance $\mathbf{W}_h$, which is a $(n \times n)$ p.d. matrix, for the moment assumed known. Given a $(n \times K)$ matrix of constant values $\mathbf{U}$, summarizing the K linear constraints valid for the n series of the system ($n > K$), in general it is $\mathbf{U}'\hat{\mathbf{y}}_h \neq \mathbf{0}$, and we look for reconciled forecasts $\tilde{\mathbf{y}}_h$ such that $\mathbf{U}'\tilde{\mathbf{y}}_h = \mathbf{0}$.

The reconciled forecasts $\tilde{\mathbf{y}}_h$ can be found as the solution to the linearly constrained quadratic minimization problem:

$$\tilde{\mathbf{y}}_h = \underset{\mathbf{y_h}}{\arg\min} \left(\hat{\mathbf{y}}_h - \mathbf{y}_h\right)' \mathbf{W}_h^{-1} \left(\hat{\mathbf{y}}_h - \mathbf{y}_h\right), \quad \text{s.t. } \mathbf{U}'\mathbf{y}_h = \mathbf{0},$$

which is given by

$$\tilde{\mathbf{y}}_h = \left[\mathbf{I}_n - \mathbf{W}_h\mathbf{U}\left(\mathbf{U}'\mathbf{W}_h\mathbf{U}\right)^{-1}\mathbf{U}'\right]\hat{\mathbf{y}}_h. \tag{6}$$

The key item in expression (6) is matrix $\mathbf{W}_h$, which is generally unknown and must be either assumed known or estimated. In agreement with Athanasopoulos *et al.* (2019), denoting with $\widehat{\mathbf{W}}_1$ the $(n \times n)$ covariance matrix of the in-sample one-step-ahead base forecasts errors of the n series in the system, we consider 3 cases:

- OLS: $\mathbf{W}_h = \sigma^2\mathbf{I}_n$
- WLS: $\mathbf{W}_h = \widehat{\mathbf{W}}_D = \text{diag}\{\hat{w}_{11}, \ldots, \hat{w}_{nn}\}$
- MinT-shr: $\mathbf{W}_h = \widehat{\mathbf{W}}_{shr} = \lambda\widehat{\mathbf{W}}_D + (1-\lambda)\widehat{\mathbf{W}}_1$

where $\widehat{\mathbf{W}}_{shr}$ is the shrinked version of $\widehat{\mathbf{W}}_1$, with diagonal target and shrinkage intensity parameter λ proposed by Schäfer and Strimmer (2005) (more details can be found in Wickramasuriya *et al.*, 2019).

4 The accuracy of the reconciled forecasts of the Australian GDP

According to the notation of the previous section, for the complete Australian *GDP* accounts from both Income and Expenditure sides, it is $n = 95$, $K = 33$, and matrix $\mathbf{U}'$ is given by (4). In addition, the available time series span over the period 1984:Q1 - 2018:Q4.

Base forecasts for the $n = 95$ separate time series have been obtained by Athanasopoulos *et al.* (2019) through simple univariate ARIMA models[1], selected using the `auto.arima` function of the R-package `forecast`. We did not change this first, crucial step in the forecast reconciliation workflow, since the focus is on the potential of forecast reconciliation.[2]

Our reconciliation proposal is applied within the same forecasting experiment designed by Athanasopoulos *et al.* (2019). They consider forecasts from $h = 1$ quarter ahead up to $h = 4$ quarters ahead using an *expanding* window, where the first training sample is set from 1984:Q4 to 1994:Q3 and forecasts are produced for 1994:Q4 to 1995:Q3. The base forecasts are reconciled using OLS, WLS and MinT-shr procedures, and the accuracy is measured by the Mean Squared Error (MSE).

Figure 3 shows the *skill scores* using MSE, that is the percentage changes in MSE registered by each reconciliation procedure, relative to base forecasts, computed such that positive values signal an improvement in forecasting accuracy over the base forecasts. The left and the central columns of the figure refer to the results for the Income and Expenditure sides variables separately considered, while the right column shows the results of the procedure proposed in this paper.

The results confirm also for the enlarged system the findings of Athanasopoulos *et al.* (2019, p. 709):

- reconciliation methods improve forecast accuracy relative to base forecasts;
- negative skill scores are registered only for OLS-reconciled forecasts of bottom level series ($h = 2,3,4$);
- MinT-shr is the best reconciliation procedure in most cases.

In addition, looking at the second row of figure 3, we see that for any forecast horizon the improvements in the unique *GDP* reconciled forecasts are always larger than those registered for $\widetilde{GDP}^E$. The same happens with $\widetilde{GDP}^I$, $h = 3,4$, while for $h = 1,2$ the skill scores are very close.

GLASSO Estimation of Commodity Risks
Stima GLASSO dei Rischi delle Commodities

Beatrice Foroni and Saverio Mazza and Giacomo Morelli and Lea Petrella

Abstract In this paper we apply the Graphical LASSO (GLASSO) procedure to estimate the network of twenty-four commodities divided in energy, agricultural and metal sector. We follow a risk management perspective. We use GARCH and Markov-Switching GARCH classes of models with different specifications for the error terms, and we select those that best estimate Value-at-Risk for each commodity. We achieve GLASSO estimation exploring the precision matrix of the multivariate Gaussian distribution obtained from a Gaussian Copula, with marginals given by the residuals of the models, selected via backtesting procedure. The analysis of interdependences in the resulting network is carried out by using the eigenvector centrality metric.

Abstract *In questo articolo applichiamo la procedura GLASSO per stimare il network di ventiquatto commodities divise nei settori dell'energia, agricoltura e metalli. Seguiamo un approccio di valutazione del rischio. Usiamo modelli GARCH e Markov-Switching GARCH con differenti specificazioni per il termine di errore, scegliendo il modello che meglio stima il Value-at-Risk. Effettuiamo la stima GLASSO analizzando la matrice di precisione di una distribuzione Normale ottenuta a partire da una Copula Gaussiana, le cui marginali sono date dai residui*

dei modelli selezionati attraverso la procedura di backtesting. L'analisi delle interdipendenze nel network viene effettuata usando la metrica di centralità dell'autovettore.

Key words: Value at Risk, GARCH, Energy Commodities, Gaussian Copula

1 Introduction

Over the last two decades, financial markets have recorded an increase of investments in commodities, a feature known as *financialization of commodities*. In particular, investments in commodity futures have tripled making their prices more vulnerable to fluctuations originated in, e.g., volatility. During stress periods, such price swings together with the strong interconnections of commodity markets create alerts for contagion effects. In this paper, we investigate interdependences among and within twenty-four time series of commodity returns representative of the energy, agriculture and metals sectors. We use GARCH and Markov-Switching GARCH (MSGARCH) models with different error term distributions to forecast the Value-at-Risk (VaR) of each commodity. For a given time horizon t and a confidence level p, the VaR is the loss in market value that is exceeded with probability 1-p thus, evaluating the quality of its estimates is of utmost importance. To do this in the context of risk management, backtesting is the most recognized test procedure. We use three different backtesting methodologies that allow us to quantify the quality of the forecasts from a risk perspective. These are the Unconditional Coverage (UC) test of [15], the Conditional Coverage (CC) test of [6] and the Dynamic Quantile (DQ) test of [9]. The residuals of the models, selected through VaR backtesting procedures, are then used as marginals in a Gaussian copula. The Gaussianity achieved allows to exploit Graphical LASSO (GLASSO) estimation of the Gaussian Graphical model in order to identify the underneath co-dependence structure in the network of commodities, where vertices represent the commodities and their dependence is visualized by edges. We carry out the analysis of the network using the eigenvector centrality metric that provides indications on which are the most geographically central and important nodes in the graph. A recent study of within and between interdependences among commodities is in [4]. We differentiate from their analysis in that we operate in a risk management perspective and obtain i) model selection of GARCH and MSGARCH according to backtesting procedures of VaR forecasts and ii) a sparse Gaussian Graphical representation of the commodities achieved via GLASSO estimation. Co-movements in commodity markets are addressed in [7] to examine the relation between Gold and Silver in the metal sector. The seminal paper of [17] detects inter-sectorial co-movements between oil price and metals finding short and long-run equilibrium relationships whereas dependence between oil and agriculture are studied in e.g.,[16].Gold (GC1)[1], Silver (SI1), Palladium (PA1), Copper (HG1), and Zinc (LX1) are representative of the metals sector; WTI Crude

[1] Bloomberg tickers

Oil (CL1), Heating Oil (HO1), Gasoline (XB1), Low Sulfur Gasoline (QS1), Natural Gas (NG1), Natural Gas UK (FN1), and Ethanol (DL1) are representative of the energy sector; Corn (C1), Oats (O1), Rough Rice (RR1), Soybeans (S1), Wheat (W1), Cocoa (CC1), Cotton (CT1), Coffee (KC1), Sugar (SB1), Soybean Oil (BO1), Soybean Meal (SM1), and Orange Juice (JO1) are representative of the agricultural sector. The results show a prevalence of the two-regime models over the single regime ones and Soybean Oil (BO1) for the agriculture sector, Natural Gas (NG1) for energy and Copper (HG1) and Palladium (PA1) for the metal sector seem to be the most central node in the estimated graph. The rest of the paper is organized as follows. In Section 2 we describe the approach and the models used whereas in Section 3 we discuss the main results regarding the model selection, the dependence structure in the Graphical model, the network metrics and conclude.

2 Model Specification

We define y_t the log-return of a financial asset at time t. We follow [14] for the general specification of the MSGARCH model:

$$y_t|(s_t = k, \mathscr{I}_{t-1}) \sim \mathscr{D}(0, h_{k,t}, \xi_k) \tag{1}$$

$$h_{k,t} \equiv \alpha_{k,0} + \alpha_{k,1}\varepsilon_{t-1}^2 + \beta_k h_{k,t-1} \tag{2}$$

where $\mathscr{D}(0, h_{k,t}, \xi_k)$ is a continuous distribution with zero mean, time-varying variance equal to $h_{k,t}$ and additional shape parameters gathered in the vector ξ_k and $\mathscr{F}_{t-1}$ the information set up to time $t-1$. We assume that the latent variable s_t, defined on a discrete space $\{1,\ldots,K\}$, evolves according to an unobserved first order ergodic homogeneous Markov chain with transition probability $\mathbf{P} \equiv \left\{p_{ij}\right\}_{i,j=1}^{K}$, where $p_{ij} = P[s_t = j|s_{t-1} = i]$. When $k = 1$ we obtain the GARCH(1,1) specification. To ensure positivity of $h_{k,t}$ it is required that $\alpha_{k,0} > 0$, $\alpha_{k,1} > 0$, and $\beta_k \geq 0$. Covariance-stationarity in each regime is obtained by requiring that $\alpha_{k,1} + \beta_k < 1$. For each commodity, we choose the model that best predicts its VaR accurately and replicates the well known stylized facts using backtesting procedures. We use the residuals of the models selected via backtesting procedure as marginal of a Gaussian copula function. This way, the Graphical LASSO (GLASSO) procedure introduced in [11] that relies on the gaussianity assumption can be applied to estimate the sparse inverse covariance matrix $\Omega = K^{-1}$. GLASSO builds on a linear regression model to shrink to zero some coefficient, that results in a maximum likelihood problem using a L_1-norm penalty term. It solves the following problem:

$$\max_{\Omega} \log\det\Omega - tr(\Sigma\Omega) - \rho\left\|\Omega\right\|_1 \tag{3}$$

where tr indicates the trace of the matrix and $\|\Omega\|_1$ the L_1-norm that can be calculated as the sum of the absolute values of the elements of Ω. The parameter ρ controls the size of the penalty and it determines the number of zeros in the sparse precision matrix Ω: a higher (lower) value is responsible for a more (less) sparse matrix. Like most of the shrinking methodologies, to get a reliable selection it is fundamental the right choice of the penalization parameter ρ. We follow [12], in selecting $\rho = \hat{\rho}$ such that $\hat{\rho}$ minimizes the cross-validation estimator of the risk. We use the K-fold cross-validation with $K = 10$, which allows the tuning parameter in the GLASSO to remain persistent. In the following Section we emphasize the fundamental results obtained with the techniques described above.

3 Main Results and Conclusion

We study the returns of three different commodity sectors: agriculture, energy and metals. We estimate the models described in Section 2 for $K = 1$ (i.e. GARCH(1,1) models) and for $K = 2$ (i.e. MSGARCH(1,1) models) where we assume several distributions for the error term in (1) to account for well known stylized facts. In particular we use the standard Normal ("norm"), the Student-t ("std") and the Generalized Normal ("ged") distributions, as well as their skewed version (see e.g [3] and [10]) labeled "snorm", "sstd", and "sged", respectively. In Table 1 we show all the models considered for the application. It is worth noting that for the MS-GARCH models we fix $K = 2$ apriori where the two states idendify a low and a high volatility regime. The estimation procedure has been conducted using the maximum likelihood estimation as described in [3]. For each time series, we perform model selection by testing the forecast performance of two specific estimated quantiles, the 95-th and the 99-th, thus offering a risk management perspective of the analysis. Among the models available after the backtesting, we select those that succeeds in at least two out of three tests. We compute network metrics that quantify the position of the nodes in the Gaussian Graphical model obtained. In particular, we focus on the *eigenvector centrality*, which provides indications on which are the most geographically central and important nodes [13]. In a risk management framework, eigenvector centrality is a measure used to capture the capacity of a node (a single commodity) to cause systemic risk, that is, a contagion of risks on other nodes [5]. Table 1 shows the outcome of the backtesting procedure. On the one hand, we observe that there is a considerable prevalence of the Markov-Switching specification in the selected models: 18 selected models present a Markov-Switching specification. This confirms what is pointed out in [2] that is, the two-regime specification better captures the jumps in the dynamic of the volatility in financial returns. On the other hand, we find that there is no prevalence for the asymmetric distributions over the symmetric ones. In Figure 1 we show the graph representation of the adjacency matrix obtained from the estimation of the sparse covariance matrix through the GLASSO algorithm. The dimension of the nodes is proportional to the eigenvector centrality score. According to such metric, we observe the most important nodes in

Commodity sector

Table 1 Best models selected

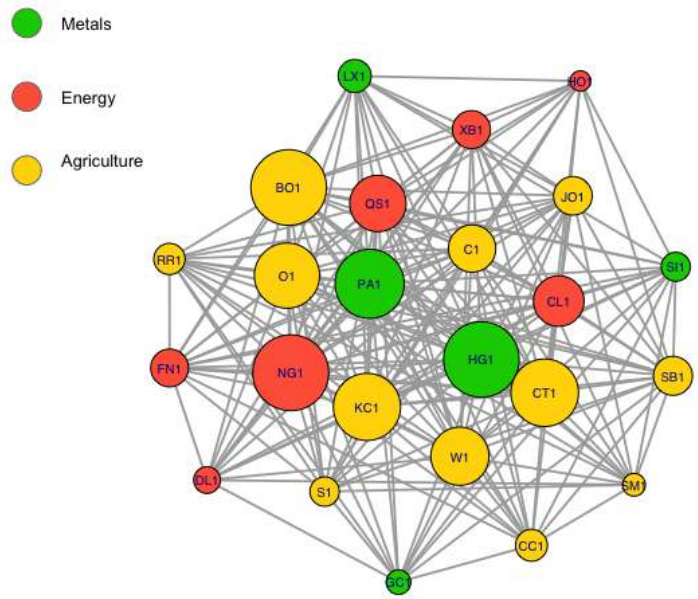

Fig. 1 Graphical model of the commodity futures obtained with GLASSO. The size of the nodes is proportional to their centrality.

the graph: Soybean Oil (BO1) for the agriculture sector, Natural Gas (NG1) for the energy sector and Copper (HG1) and Palladium (PA1) for the metal sector.

Regarding Soybean Oil (B01), the fact that it presents the maximum connection rate with the energy sector can also be found in and [8]; indeed it is known that Biodiesel production in the USA is based predominantly on Soybean Oil, precisely for the 82% [1]. Among the least central commodities we find the Gold (GC1) with a position in the dependence structure that highlights its nature of refuge commodity: showing a marginal role this commodity can be a good investment in anticipation

of high volatility periods. Concluding, the application of VaR backtesting procedure for the set of commodity returns studied has allowed to extend the literature on the model selection with GARCH and MSGARCH dynamics, in a risk management framework. The structure of interdependences in the commodity network has been detected in a Gaussian Graphical model. The choice of exploiting network metrics in a risk oriented framework could bring relevant informations both in terms of effects of risk contagion and for improvements of policy formulation in developing and developed countries.

Measuring the Effect of Unconventional Policies on Stock Market Volatility

Gli Effetti delle Politiche Monetarie Non Convenzionali sulla Volatilità del Mercato Azionario

Giampiero M. Gallo, Demetrio Lacava and Edoardo Otranto

Abstract Our research analyzes the impact of the ECB's unconventional monetary policy on stock market volatility in four Eurozone countries (France, Germany, Italy and Spain). We estimate Multiplicative Error Models to quantify the part of volatility depending directly on unconventional policies: we distinguish between the announcement effect (through a dummy variable) and the implementation effect (measured by a proxy for securities held for monetary policy purpose). While we observe an increase in volatility on announcement days, we find a negative implementation effect, which provides a remarkable dampening effect in the long term.

Abstract *Il presente studio rappresenta un'analisi quantitativa dell'effetto delle politiche monetarie non convenzionali, stabilite dalla BCE, sulla volatilità del mercato azionario nei principali paesi dell'Eurozona. Lo studio è basato sulla stima di Multiplicative Error Models, i quali permettono di distinguere la parte di volatilità derivante direttamente dalle politiche monetarie non convenzionali. Il principale risultato è rappresentato da una riduzione della volatilità dovuta all'implementazione delle politiche non convenzionali (e misurata attravero una proxy degli asset presenti nel bilancio della BCE per scopi di politiche monetarie non convenzionali), nonostante un immediato aumento della volatilità stessa, causato dagli annunci di politica monetaria stabilita dalla BCE.*

Key words: Unconventional monetary policy, Financial market, Realized Volatility, Multiplicative Error Model

1 Introduction

During the great recession, interest rates were brought close or beyond the zero lower bound, so that many central banks had to resort to unconventional monetary policy measures in order to stimulate the real economy. These policies consist of an expansion in the central bank's balance sheet - generally through asset purchase programs - which in turn affects the real economy by modifying inflation rate expectation during periods in which the so-called liquidity trap makes conventional policy no longer effective.
Coming after the Federal Reserve in the US and the Bank of England, the European Central Bank (ECB) implemented several unconventional monetary measures between 2009 and 2018. Even though the main concern is about their effects on the real economy, these policies have also unintended effects on financial markets that have been largely studied by recent literature. Less expectedly, to the best of our knowledge, not much attention was devoted to the impact of the quantitative easing on financial volatility as key research objective (for example Shogbuyi and Steeley, 2017), modelling volatility mainly through the GARCH family models.
In what follows, we analyze the impact of unconventional policies on stock market volatility within the Multiplicative Error Model framework (Engle and Gallo, 2006), by proxying for unconventional policies through the ratio between the securities held for unconventional policies purposes and ECB's total asset (D'amico, English, Lopez-Salido and Nelson, 2012). In carrying out our analysis we employ an annualized realized kernel volatility measure built on high frequency data, which should remove endogeneity arising when monetary policy decisions coincide with a stock price reduction. Finally, through a multi-step forecasting procedure it emerges how unconventional policy deploys its effects on volatility for a period between 25 and 60 business days, after which volatility converges to its long-run level.

2 The models

Multiplicative Error Models (MEM, Engle and Gallo, 2006) have proved effective in representing volatility dynamics as the product of a time-varying component, μ_t (following a GARCH–like process), and a positive random innovation, ε_t.[1] This has several advantages: it ensures positiveness without resorting to logs, and it exploits more accurate measurement of volatility. Within the MEM setup, Brownlees, Cipollini and Gallo (2012) as well as Otranto (2015) propose a new model specification, by decomposing the mean equation as the sum of two components, both evolving according to GARCH models. The approach provides a general framework within which the consideration of quantitative easing as an unobservable factor al-

[1] In what follows, we call AMEM the MEM with asymmetric effects, and AMEMX the AMEM including exogenous regressors (represented by x_t and Δ_t; see later) in the μ_t equation.

lows for an estimate of its impact on the evolution of volatility. In what follows we explore how unconventional policies can affect volatility both in an additive and a multiplicative way. In our specification, the first component of the mean equation evolves as a GARCH model (capturing the pure volatility dynamics) while the second one follows an autoregressive process with exogenous variables, to capture both the announcement and the implementation effects of unconventional measures.
One model we propose (following Brownlees, Cipollini and Gallo, 2012, we call it Composite AMEM–ACM) consists of four equations:[2]

$$\begin{aligned} &RV_t = \mu_t \varepsilon_t, \;\; \varepsilon_t | \Psi_{t-1} \sim Gamma(\vartheta, \tfrac{1}{\vartheta}) \\ &\mu_t = \varsigma_t + \xi_t \\ &\varsigma_t = \omega + \alpha RV_{t-1} + \beta \varsigma_{t-1} + \gamma D_{t-1} RV_{t-1} \\ &\xi_t = \delta E\left(x_t | \Psi_{t-1}\right) + \varphi \Delta_t + \psi \xi_{t-1} \end{aligned} \tag{1}$$

In this model, ς_t represents the proper volatility of the market, due to its intrinsic dynamics, which evolves as described by the third equation in (1); ξ_t represents the effect due to the unconventional policies and follows an AR(1) process with the addition of the impacts of the conditional expectation of an exogenous variables x_t made at time $t-1$ and of the mean shift impact in volatility on a day of a monetary policy announcement by the Central Bank (Δ_t is a dummy variable, taking value 1 in day characterized by the communication of policies news by ECB, 0 otherwise). The variable, x_t, represents the ratio between the amount employed in unconventional polices and total asset (UMP/TA), its expectation may naïvely be assumed to be x_{t-1}. Finally, as argued by Brownlees, Cipollini and Gallo (2012) (on the basis of Engle and Lee, 1999), the coefficient ψ in ξ_t process, is required to be $0 < \psi < \beta < 1$ so as to ensure the identification of the model by having the long run component more persistent than the short one. Such a model makes it possible to quantify and plot the effect of the unconventional ECB actions on the volatility RV_t, even in relative terms as $\frac{\xi_t}{\mu_t}$.
It is important to notice that, since the unconventional policy component is an unobservable signal, it remains to be seen whether its impact on the general level of volatility should be considered in an additive way, as in (1), rather than as a multiplicative component, in the spirit of Brownlees, Cipollini and Gallo (2011). In the latter case, we must have μ_t equal to ς_t multiplied by a component whose unconditional mean is equal to one as an identifying condition. In what follows, we discuss two different specifications of the Multiplicative ACM which ensure the compliance with this constraint. In the first specification we allow ξ_t to impact on RV_t through a logistic function. The model, called Logistic-ACM (L-ACM), differs from model (1) just in the second equation, which becomes $\mu_t = \varsigma_t \cdot 2(\exp(\xi_t)/1 + \exp(\xi_t))$.
Alternatively, we can specify $\mu_t = \varsigma_t \cdot \xi_t$ but we need to modify the above specification for ξ_t by adding a constant term in its equation. Within this specification, named Linear-ACM (Li-ACM), we have

[2] RV_t is the realized volatility at time t relative to a certain asset (index); D_t a dummy assuming value 1 when the return of the asset (index) at time t is negative, 0 otherwise (asymmetric effect).

$$\xi_t = \left(\frac{1 - \delta \bar{x} - \varphi \bar{\Delta}}{1 - \psi} \right) + \delta x_{t-1} + \varphi \Delta_t + \psi \xi_{t-1},$$

where $\bar{x}$ and $\bar{\Delta}$ represent mean values.

3 Estimation results

In this section, we discuss the estimation results according to the estimated models (tables are not reported for the sake of space, but they are available upon request). The first result is in line with other papers (e.g. Shogbuyi and Steeley, 2017): the sign of the coefficient φ of the dummy variable signals that there is a mean positive shift in volatility on days of monetary policy communication: such an increase in volatility is between 2.185 points for the most important market (Germany) and 3.694 points for Spain, which expectedly (together with Italy) is a sensible market to this kind of policy. The coefficient on our proxy is significant at 1% level and enters in the model with the expected negative sign. The higher impact is observed for the Southern countries: on average, the short run and the long run effects in Italy and Spain are higher than France and Germany by about 40% and 16%, respectively.

The impact of unconventional policies on stock market volatility is evident also by looking at the ratio between the corresponding component and the overall level of volatility: the estimated range of reduction of volatility caused by ECB's unconventional policies is between -3.19 and -3.86 (for Germany and Spain, respectively). This long run effect can be seen also in figure 1, which plots the evolution of the volatility components ς, the blue line, and ξ, across three red dotted-lines: the lowest represents the characteristic path of the component depending directly on unconventional policies; the highest, instead, represents volatility spikes due to the day of announcement effect; finally, the intermediate line, represents the level of volatility on days after a monetary policy announcement, when volatility comes back to its previous level. The effect is more evident starting from October 2014 - when the ECB implicitly communicated to the market it would purchase also private sector bond - because of the change in the slope of ξ equation (red line), which lasts for the entire period of the program. Results remain almost unchanged when we consider the multiplicative specifications. Once again our proxy enters in the model with the expected sign and with the highest level of significance. In both cases, coefficients are somewhat lower, also in view of the fact that in this case unconventional policies affect volatility in a multiplicative way. Note that in the additive version of ACM model generally ξ_t is negative - so that a higher proxy's coefficient (in absolute value) will reduce stock market volatility, whereas within the multiplicative versions ξ_t is always positive, but attain the reduction in volatility with coefficients associated to the proxies being less than 1.

Comparison between models is based on the information criteria (AIC and BIC) and loss functions for evaluating the forecasting power of the models (MSE and MAE). Focusing on information criteria, the ACM model is the best model in 3 out

of 4 cases. However, when we consider MSE and MAE, the L-ACM is the preferred one for Germany and Spain, while the additive ACM is the best model for France and Italy.
Finally, we rely on a multi-step out-of-sample forecasting procedure to assess how long unconventional policies reduce volatility. For this purpose, we consider the period from June 1, 2014 to August 24, 2017 as the estimation period, making forecasts for the following year. Results are summarized in Figure 2, where we can notice that volatility converges to a constant level. Of course the duration of the effects differs model by model and country by country: it lasts between 25 and 60 days, estimated via AMEMX, for the FTSEMib and the DAX30, respectively.

4 Conclusion

In this paper we examine how unconventional monetary policies by ECB affect realized volatility. The innovative feature of this study lies in the model we use, the Composite AMEM, which allows us to distinguish between a pure volatility mechanism and the part of volatility depending directly on quantitative easing policies. Results show how an increase in securities held by ECB for monetary policy purposes relative to ECB total asset reduces volatility in all markets for a period between 25 and 60 business days, with disrupted countries generally benefitting more. However, our proxies do not allow us to distinguish the specific effect of each policy, so that we cannot identify which of these extraordinary measures is more effective, nor the presence of spillovers among countries.

Multidimensional versus unidimensional poverty measurement

Misura multidimensionale versus unidimensionale della povertá

Michele Costa

Abstract This paper proposes a comparison between uni- and multidimesional approaches to the measurement of poverty. Traditional uni-, fuzzy uni- and fuzzy multidimensional indicators are compared by means of a rank correlation analysis. The robustness of the comparison is ensured by a simulation study. Our results stress that unidimensional indicators provide partial information on the poverty condition.
Abstract *Viene proposto un confronto tra gli approcci uni- e multidimensionale alla misura della povertá. Indicatori tradizionale uni, fuzzy uni e fuzzy multidimensionale sono confrontati grazie ad una analisi di correlazione sui ranghi. La robustezza del confronto é assicurata da uno studio di simulazione. I risultati sottolineano che l'approccio unidimensionale fornisce informazioni parziali sulla povertá.*

Key words: Multdimensional poverty, rank correlation analysis, fuzzy indicators

1 Introduction

If there is a general consensus on the multidimensional view of poverty, its empirical implications are still largely unexplored. An effective comparison between different approaches to poverty measurement is to be done by comparing the sets of poor units defined by each approach. If the poor sets are not particularly different, even distant methods would point out to the same poor units, and in this case the simplest approach is to be preferred. On the contrary, if we observed different poor sets, the distance in theory would be replicated and confirmed in the analysis of real data. In order to provide insights on the comparison between unidimensional and multidimensional poverty indicators, we develop a rank correlation analysis, focused on the correct definition of the set of poor units. The robustness of the results is ensured by a simulation study, developed on the framework of fuzzy set methods.

2 Unidimensional and multidimensional poverty indicators

Let be A the set of the n units $\{a_1, a_2, ..., a_n\}$ and B the subset of the poor units, our purpose is to compare different definitions of B achieved by means of unidimensional and multidimensional poverty indicators (see e.g. Deutsch and Silber (2004) and Duclos et al. (2006)). The set B represents the key point of the comparison between the unidimensional and the multidimensional approaches: if the two methods suggest the same set, the multidimensional extension is not strictly necessary, with the unidimensional indicator being fully informative, while, if the two approaches indicate two different sets, it is important to evaluate their different information.

To address this point, we carry out a correlation analysis on the ranks u_i of the list of the units, from to poorest to the richest, obtained from the unidimensional approach and on the ranks v_i of the list resulted from the multidimensional approach.

The analysis is carried out by referring to a set of correlation indexes (see e.g. Balakrishnan and Rao (1998a,b)) applied to the ranks (u_i, v_i): the Bravais-Pearson coefficient r, the Kendall's τ, the Spearman index S and the Gini rank correlation, or cograduation, index G. Rank correlation analysis allows to effectively compare the two lists, and also to investigate the similarity of specific subgroups of units, which is particularly useful in our case, as we aim to the comparison between the subgroups of the poor units B and also between subsets of B.

The key element in order to define B is the indicator function $\mu(X)$, which determines the degree of membership of the i-th unit to the set B with respect to a certain attribute X. The indicator function transforms the achievement of a unit to the deprivation of that unit. A low or null achievement implies a maximum deprivation, that is $\mu(X) = 1$, while an high achievement leads to an absence of deprivation, thas is $\mu(X) = 0$. With respect to the unidimensional poverty measurement, we refer first to the traditional head count ratio H, where $\mu(X)$ can assume only two values, 1 for the poor and 0 for the non poor units, X is the income, z a poverty line and n_i the sample weight of the i-th unit:

$$\mu(X) = \begin{cases} \mu_1 \text{ with } \mu_1 = 1 \text{ if } X < z \\ \mu_2 \text{ with } \mu_2 = 0 \text{ if } X \geq z. \end{cases} \tag{1}$$

$$H = \sum_{i=1}^{n} \mu(X)_i n_i / \sum_{i=1}^{n} n_i \tag{2}$$

Still on the framework of the unidimensional approach, we resort to fuzzy set methods, which allow to overcome the rigidity imposed by two groups. Many Authors analyzed poverty by means of fuzzy sets, among the others Betti et al. (2004), Dagum and Costa (2004), Lemmi and Betti (2006). In the variety of the meaningful contributions, a specific mention is due to the totally fuzzy approach by Cerioli and Zani (1990) and to the relative fuzzy approach by Cheli and Lemmi (1995). Within fuzzy sets, $\mu(X)$ is no longer only equal to 0 or 1, but ranges between 0 and 1, thus allowing intermediate or partial membership to B. In this way the indicator function takes on a more complex form than in (1):

$$\mu(X) = \begin{cases} \mu_1 \text{ with } \mu_1 = 1 \text{ if } X \in [X_{min}, X_1] \\ \mu_2 \text{ if } X \in [X_1, X_2] \\ \ldots \\ \mu_{k-1} \text{ if } X \in [X_{k-2}, X_{k-1}] \\ \mu_k \text{ with } \mu_k = 0 \text{ if } X \in [X_{k-1}, X_{max}]. \end{cases} \tag{3}$$

Fuzzy sets methods allow to develop a multidimensional framework for the poverty measurement. Given n units, m inequality factors and m indicator functions $\mu(X_j)$, we obtain m undimensional poverty indexes as

$$I(X_j) = \sum_{i=1}^{n} \mu(X_j)_i n_i / \sum_{i=1}^{n} n_i \tag{4}$$

and n multidimensional individual indexes as

$$I(a_i) = \sum_{j=1}^{m} \mu(X_j)_i w_j / \sum_{j=1}^{m} w_j.$$

The weights w_j measure the intensity of deprivation related to the j-th inequality factor (Esposito and Chiappero Martinetti, 2019): a factor not possessed by any unit has no effect on the social exclusion, while, if all the units but a few possess the factor, it represents a relevant source of inequality and social exclusion. A weighting system consistent with that is (Cerioli and Zani, 1990)

$$w_j = log(n / \sum_{i=1}^{n} \mu(X_j)_i n_i) \tag{5}$$

The synthesis of the m unidimensional indexes $I(X_j)$ and of the n multidimensional indexes $I(a_i)$ in a multidimensional poverty index can be achieved as

$$I = \frac{\sum_{j=1}^{m} I(X_j) w_j}{\sum_{j=1}^{m} w_j} = \frac{\sum_{i=1}^{n} I(a_i) n_i}{\sum_{i=1}^{n} n_i} = \frac{\sum_{j=1}^{m} w_j \sum_{i=1}^{n} \mu(X_j)_i n_i}{\sum_{j=1}^{m} w_j \sum_{i=1}^{n} n_i} \tag{6}$$

In order to ensure an high degree of robustness (see also Alkire and Santos (2014) and Ravallion (2011)) to the comparison between uni- and multidimensional approaches, we develop a simulation study where the scores of $\mu(X)$ are not a priori chosen, but endogenously determined by means of a Monte Carlo experiment. We randomly extract $\mu(X)$ from an uniform distribution, following a scheme such as

$$\mu(X_j) = \begin{cases} \mu_{j1} \text{ with } \mu_{j1} = 1 \\ \mu_{j2} \text{ with } \mu_{j2} \in [\mu_{j3} + h, (1-h)] \\ \ldots \\ \mu_{jk-1} \text{ with } \mu_{jk-1} \in [h, (1-h)/(k-2)] \\ \mu_{jk} \text{ with } \mu_{jk} = 0 \end{cases} \tag{7}$$

where k_j is the exogenous number of classes proposed for X_j and h is an exogenous minimum distance between two different values of $\mu(X)$.

The main purpose of our Monte Carlo experiment, achieved by comparing exogenous schemes as in (3) to simulated schemes as in (7), is to investigate the stability of the fuzzy indicators and to provide a more general basis for the rank correlation analysis aimed at evaluating the differences between different sets B of poor units.

3 Data and results

As a case study we resort to the income distribution of the Italian households for the 2016. The SHIW data, provided by the Bank of Italy, allow to derive the m poverty indicators based on both individual and household information; in the following we use, for the undimensional case, the household equivalent income X_1, and, for the multidimensional indicator, we add the educational level of the head of the household X_2, his/her age X_3 and the geographical area of residence X_4.

The list u_i related to the unidimensional framework is derived following three directions. First on the basis of the headcount ratio H, with z being the 60% of the median $\bar{x}_{me}$ of the equivalent income. Second, by referring to $I(X_1)$, obtained with $k = 4$, and the indicator function reported on the first two columns of Table 1. Third, we vary the scores of $\mu(X_1)$ by running a Monte Carlo experiment on the basis of the scheme outlined in (7). Observations presenting the same poverty index are sorted by increasing size of the equivalent income X_1. Overall we obtain one list u_i from H, one from $I(X_1)$ and the exogenous $\mu(X_1)$ of Table 1 and 10000 lists u_i from the 10000 $I(X_1)$ calculated from the simulated $\mu(X_1)$: all the lists u_i are identical, since the ranking is invariant with respect to the size of the score of $\mu(X_1)$.

The multdimensional list v_i related to the multidimensional poverty measurement is obtained first by using the $m = 4$ indicators and the indicator functions described in Table 1. Second, also for the multidimensional case we develop a Monte Carlo study on the basis of the scheme (7) with the aim of mitigating the subjectivity of the choice of $\mu(X_j)$. Observations presenting the same value of I are sorted by increasing size of the equivalent income X_1. Overall we obtain one list v_i from the multidimensional index I obtained by using the exogenous indicator functions reported on Table 1 and 10000 lists v_i from I calculated on the simulated $\mu(X_j)$.

Table 1 Indicator functions $\mu(X_j)$ proposed for the household equivalent income X_1, the educational level of the head of the household X_2, his/her age X_3, geographical area of residence X_4

$\mu(X_1)$	X_1	$\mu(X_2)$	X_2	$\mu(X_3)$	X_3	$\mu(X_4)$	X_4
1.0	$x_{1i} < 0.4\bar{x}_{1me}$	1.0	$x_{2i} =$ none	1.0	$x_{3i} > 65$	0.4	$x_{4i} =$ south
0.9	$0.4\bar{x}_{1me} \leq x_{1i} < 0.8$ $0.6\bar{x}_{1me}$		$x_{2i} =$ element.	0.3	$x_{3i} < 30$	0	$x_{4i} =$ center
0.5	$0.6\bar{x}_{1me} \leq x_{1i} < 0$ $0.8\bar{x}_{1me}$		$x_{2i} =$ other	0	$30 \leq x_{3i} \leq 65$	0	$x_{4i} =$ nord
0	$0.8\bar{x}_{1me} \leq x_{1i}$						

A first direct comparison between u_i and v_i shows that the highest ranks of the multidimensional indicator I generally correspond to the highest ranks of the unidimensional list, while the lowest ranks of I do not correspond to the lowest ranks of the unidimensional case.

Rank correlation indexes allow to carry out a more detailed and informative analysis. Table 1 reports, for r, S, G and τ, the rank correlations between the unidimensional u_i and the multidimensional v_i lists by referring to the six cases developed in the paper: the head count ratio by the multidimensional index (HI) and by the simulated multidimensional index HI^*, the unidimensional fuzzy by the multidimensional index $I(X_1)I$ and by the simulated multidimensional index $I(X_1)I^*$, the simulated unidimensional fuzzy by the multidimensional index $I^*(X_1)I$ and by the simulated multidimensional index $I^*(X_1)I^*$. Since the lists u_i are identical, the related correlations have the same values, that is $HI = I(X_1)I = I^*(X_1)I$ and $HI^* = I(X_1)I^* = I^*(X_1)I^*$.

The first column of Table 2 reports selected values of the cumulative distribution of the equivalent income X_1: the last row of Table 2 shows the indexes for the whole population ($F(X_1) = 100$), while the first row refers to the poorest 5% of total population ($F(X_1) = 5$). For the simulated values is reported the mean of the 10000 correlation indexes.

Moving from the bottom to the top of Table 2 it is clearly observable a strong decrease in rank correlation, thus suggesting that multidimensional and unidimensional approaches define two different subsets of poor units.

The results for the Bravais-Pearson index are similar to the indications provided by the Spearman index, while Kendall's and Gini's measures report a lower correlation between u_i and v_i. All indexes, however, clearly signal a decreasing rank correlation for decreasing values of $F(X_1)$, with a minimum value around $F(X_1) = 0.25$.

Table 2 Rank correlation between unidimensional and multidimensional poverty indicators, Bravais-Pearson coefficient, Spearman index, Gini index, Kendall *tau*, Italian households 2016

	Bravais-Pearson		Spearman		Gini		Kendall	
$F(X_1)$	HI	HI^*	HI	HI^*	HI	HI^*	HI	HI^*
5	0.16	0.18	0.34	0.36	0.10	0.12	0.22	0.23
10	0.23	0.27	0.41	0.44	0.15	0.18	0.20	0.24
25	0.13	0.26	0.29	0.39	0.08	0.17	0.13	0.20
50	0.38	0.46	0.41	0.48	0.25	0.32	0.29	0.33
100	0.61	0.62	0.58	0.59	0.46	0.47	0.44	0.46

4 Conclusions

The key point of the comparison between the unidimensional and the multidimensional approaches refers to the set B of poor units: if the two methods suggest the

same set B, the multidimensional extension can be considered as an elegant and theoretically useful improvement, but not strictly necessary, with the unidimensional indicator being fully informative.

When, on the other hand, the two approaches indicate two different sets of poor units, it is important to evaluate the different information contained in the two sets.

The reference to the set B of poor units is useful also in order to evaluate the effects of different specifications of the $\mu(X)$: to the extent that different $\mu(X)$ modify, or not, the set B, we derive an indication on the robustness of the multidimensional indicators.

To provide a satisfactory answer we develop a rank correlation analysis, which allows to demonstrate that the unidimensional and the multidimensional approaches define two different sets of poor households. Consequently any socio-economic policy to reduce poverty developed on the basis of income information is likely to no achieve its proposed goals, being addressed to socioeconomic units which, at least in part, are, in effect, non-poor.

Information provided by a multidimensional approach allows to correctly individuate the set of the poor and is therefore essential to formulate actions able to reduce poverty.

Multiple outcome analysis of European Agriculture in 2000-2016: a latent class multivariate trajectory approach

Analisi multivariata dei risultati dell'Agricultura Europea nel 2000-2016: un approccio con traiettorie multivariate a classi latenti

Alessandro Magrini

Abstract The consideration of the environmental and social dimensions, besides the economic one, is of great importance to highlight both development and sustainability objectives in the evaluation of the agricultural sector. However, multiple outcomes analysis is challenging due to not only methodological issues, but also quality and availability of time series data. In this paper, we propose a latent class multivariate trajectory model, which is applied to 31 European countries by considering a set of economic, environmental and social indicators in the period 2000-2016. The results support the effectiveness of our approach by clearly identifying four groups of countries with emblematic characteristics of the agricultural systems: mature and sustainable, mature but with weak social sustainability, developing with and without clear sustainable objectives.

Abstract *La considerazione delle dimensioni ambientali e sociali, oltre a quella economica, è di grande importanza per evidenziare obiettivi di sviluppo e sostenibilità nella valutazione del settore agricolo. Tuttavia, l'analisi multivariata dei risultati è difficile a causa non solo di problemi metodologici, ma anche di qualità e disponibilità di serie temporali. In questo articolo, si propone un modello con traiettorie multivariate a classi latenti, che viene applicato a 31 paesi europei considerando un insieme di indicatori economici, ambientali e sociali nel periodo 2000-2016. I risultati supportano l'efficacia del nostro approccio identificando chiaramente quattro gruppi di paesi con caratteristiche emblematiche del settore agricolo: maturo e sostenibile, maturo ma con debole sostenibilità sociale, in via di sviluppo con e senza chiari obiettivi sostenibili.*

1 Introduction

In the last two decades, economists have studied the performance of the agricultural sector mainly focusing on productivity or on the value of the output produced (see [2] for a review). Even if this approach is generally adopted in the literature, several authors have pointed out that productivity does not properly measure sustainability (e.g., [1]), motivating a line of research trying to account for the externalities and the social value of Agriculture in the computation of productivity (see, for example, [3]). Recently, several challenging objectives besides productivity compatible with the sustainable livelihood framework [5] have become central in the Horizon 2020 agenda, including the provision of safety and healthy food, the improvement of socio-economic conditions in rural areas, the conservation of natural resources, environmental quality and biodiversity.

In this paper, we address the multiple outcomes analysis of the agricultural sector. At this purpose, we propose a latent class multivariate trajectory model, which is applied to 31 European countries by considering a set of economic, environmental and social indicators in the period 2000-2016.

This paper is structured as follows. In Section 2, the data are described and the statistical model is detailed. In Section 3, the results are reported and discussed. Section 4 contains concluding remarks and purposes for future work.

2 Data and statistical model

We considered a set of indicators covering the economic, environmental and social dimensions of the agricultural sector compatibly with the availability of publicly released data. For the economic dimension, we considered Agricultural Total Factor Productivity (TFP) and Gross Value Added (GVA), describing, respectively, the efficiency in production and the ability to generate value of the sector. For the environmental dimension, we considered greenhouse gas emissions due to Agriculture and nitrogen nutrient balance in soil, describing the negative pressure of the sector on the environment. For the social dimension, we considered the rural at risk-of-poverty and unemployment rates, describing the ability of Agriculture to deal with inequality and abandonment in rural areas.

We downloaded data on the indicators for 31 European countries (the 27 European Union member countries plus Iceland, Switzerland, Norway and United Kingdom) in the period 2000-2016 from Eurostat database, excepting TFP, downloaded from USDA database, and greenhouse gas emissions, downloaded from Faostat. To make the indicators comparable, we transformed them into index numbers with fixed base (year 2000).

Our statistical model borrows from group-based trajectory modeling [4], a special case of latent class growth curves where the units in the same group have the same trajectory. To perform a multiple outcome analysis, we extended such technique by replacing the univariate Normal linear regression within each group with

a multivariate Normal one. Let $i = 1,\ldots,n$ denote the unit, $j = 1,\ldots,n_g$ the group and $t = 1,\ldots,n_t$ the period, thus $\mathbf{y}_{it}^{(j)}$ represents the multivariate observation of the p indicators on unit i at time t given group j. For a polynomial degree $d \geq 1$, our model assumes:

$$\mathbf{y}_{it}^{(j)} = (1, t, t^2, \ldots, t^d)' \beta^{(j)} + \varepsilon_{it}^{(j)} \tag{1}$$

where:

- $\varepsilon_{it}^{(j)} \sim \text{MVN}(0, \Sigma^{(j)})$ is the p-variate random error for $\mathbf{y}_{it}^{(j)}$, with $\Sigma^{(j)}$ the $p \times p$ covariance matrix of the random errors in group j;
- $\beta^{(j)}$ is the matrix $(d+1) \times p$ of the regression coefficients in group j.

The likelihood of the model is:

$$L(\beta^{(j)}, \Sigma^{(j)}, \pi) = \prod_{i=1}^{n} \left[\sum_{j=1}^{n_g} \pi_j \prod_{t=1}^{n_t} p(\mathbf{y}_{it}^{(j)} \mid \beta^{(j)}, \Sigma^{(j)}) \right] \tag{2}$$

where $p(\mathbf{y}_{it}^{(j)} \mid \beta^{(j)}, \Sigma^{(j)})$ is the multivariate Normal density of $\mathbf{y}_{it}^{(j)}$ according to the regression in equation 1, and $\pi = (\pi_1, \ldots, \pi_{n_g})$ is vector of the prior probabilities of the n_g groups.

Model parameters $\beta^{(j)}$, $\Sigma^{(j)}$ and π are estimated by maximizing the likelihood in equation 2 using an our own implementation of the Expectation-Maximization (EM) algorithm, and the countries are assigned to the groups according to the maximum posterior probability implied by the estimated parameter values.

Fig. 1 Trajectories for countries in Group 1: mature and sustainable agricultural sector.

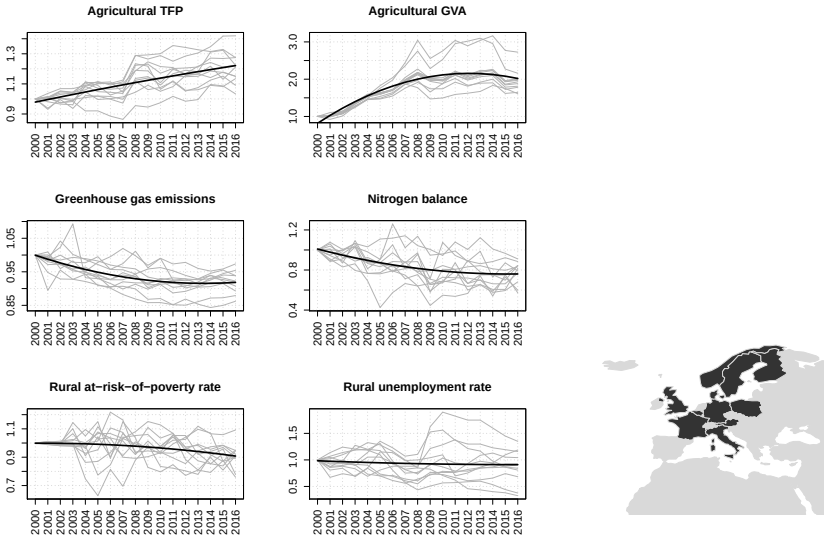

Fig. 2 Trajectories for countries in Group 2: mature agricultural sector but with weak social sustainability.

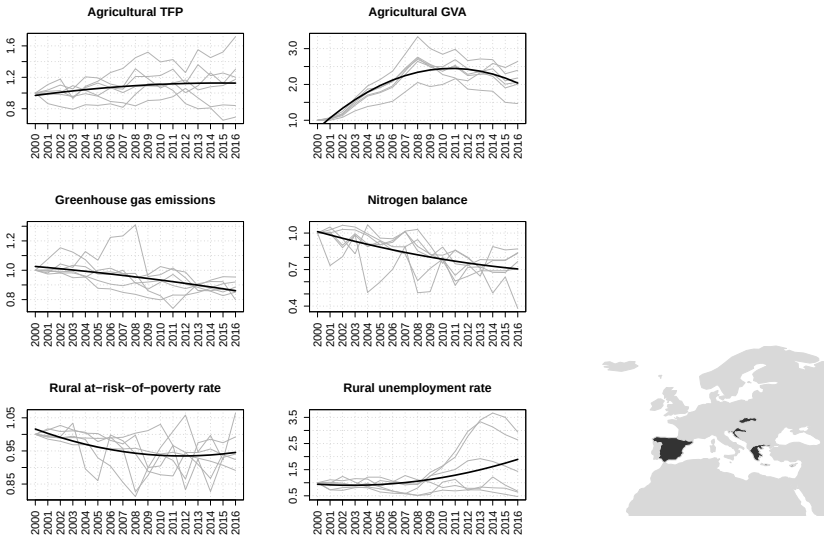

Fig. 3 Trajectories for countries in Group 3: developing agricultural sector with clear sustainability objectives.

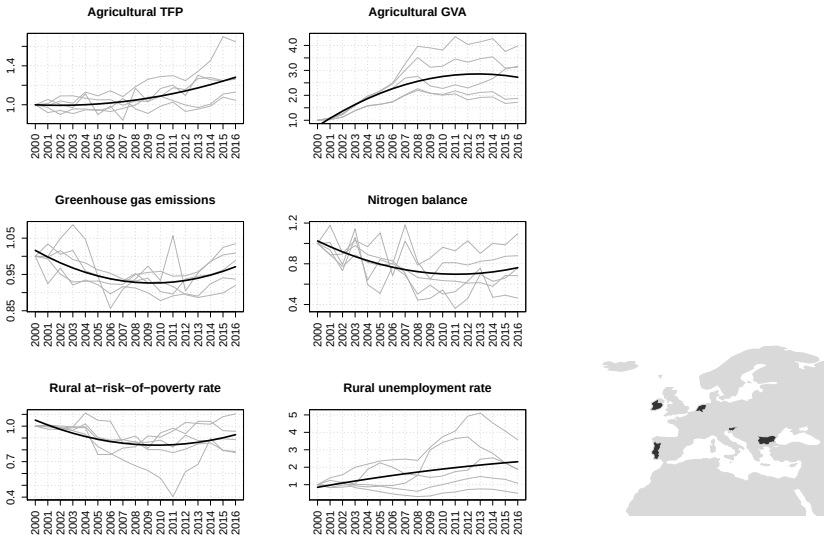
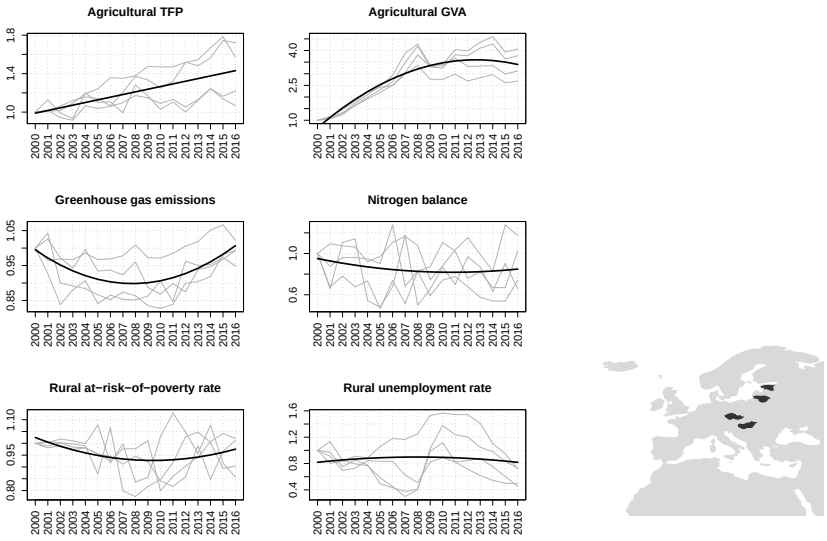


3 Results and discussion

We fitted several latent class models, combining a number of polynomial degrees between 2 and 3 with a number of groups between 3 and 12. We selected the model

Fig. 4 Trajectories for countries in Group 4: developing agricultural sector without clear sustainability objectives.



with 2 degrees and 6 groups, as it showed the lowest value of the Bayesian Information Criterion (BIC). Results are described below and displayed in Figures 1-4.

Group 1 (Austria, Belgium, Denmark, Finland, France, Germany, Italy, Norway, Poland, Sweden, United Kingdom) is characterized by increasing TFP, increase then slowdown in GVA decreasing emissions and nitrogen balance, slightly decreasing rural poverty and unemployment (Figure 1). This group includes countries characterized by a mature and sustainable agricultural sector.

Group 2 (Croatia, Cyprus, Greece, Malta, Slovakia, Spain) is characterized by slightly increasing TFP, increasing GVA, decreasing emissions, nitrogen balance and rural poverty, increasing rural unemployment (Figure 2). This group includes countries characterized by a mature agricultural sector, but with weak social sustainability.

Group 3 (Bulgaria, Ireland, Netherlands, Portugal, Slovenia) is characterized by increasing TFP, increase then slowdown in GVA, increase then slowdown in emissions and nitrogen balance reduction, slightly decreasing of rural poverty and increasing in rural unemployment (Figure 3). This group includes countries characterized by a developing agricultural sector with clear sustainable objectives.

Group 4 (Czechia, Estonia, Hungary, Lithuania) is characterized by increasing TFP, increase then slowdown in GVA, U-shaped pattern (with null final balance) in emissions, stable nitrogen balance, rural poverty and unemployment. (Figure 4). This group includes countries characterized by a developing agricultural sector without clear sustainable objectives.

Group 5 (Iceland, Romania, Switzerland) and Group 6 (Latvia, Luxembourg) do not allow to deduce any clear tendency (results not shown).

We see that variability between trajectories is large for some groups, due to some outlier trends. Note that if variability is suspected to bias some group-based trajectories, it is possible to increase the number of groups to keep the R-squared values above a certain threshold, eventually at the cost of obtaining singleton groups.

4 Concluding remarks

In this paper, we proposed and applied latent a class multivariate trajectory model to perform a multiple outcome evaluation of the agricultural sector. Our model clearly identified four groups of countries with emblematic characteristics of the agricultural systems: mature and sustainable, mature but with weak social sustainability, developing with and without clear sustainable objectives.

Our approach is able to classify a set of countries with respect an arbitrary number of indicators, thus representing a valid alternative to the environmentally-adjusted productivity measures recently proposed in the literature [3].

The main limitation of our approach relies in quality and availability of data. Publicly released time series, especially for environmental and social indicators, are typically short or present structural breaks due to changes in classifications and nomenclatures, together with measurement errors and missing values.

Nowcasting GDP using mixed-frequency based composite confidence indicators

Previsioni a breve termine del PIL con indicatori compositi di confidence basati su frequenze miste

Maria Carannante, Raffaele Mattera, Michelangelo Misuraca, Germana Scepi and Maria Spano

Abstract Composite confidence indicators are widely used to nowcast GDP. In this paper, we aim to construct a new composite confidence indicator which weighting scheme reflects the impact of consumer and business confidence on economic conditions. While GDP is quarterly measured, confidence indicators are monthly recorded. Our approach allows us to deal with data sampled at different frequencies. In particular, we propose a weighting scheme estimation based on U-MIDAS regression techniques.

Abstract *Gli indicatori compositi di confidence sull'andamento dell'economia sono largamente utilizzati per la previsione a breve termine del PIL. In questo lavoro noi proponiamo l'utilizzo di un nuovo sistema di pesi per la costruzione di un indicatore composito di confidence. Il PIL è una variabile economica rilevata quadrimestralmente, mentre gli indicatori di confidence sono rilevati mensilmente. Per superare questo problema, il nostro approccio sviluppa uno schema di pesi dell'indicatore composito basato su tecniche di regressione U-MIDAS.*

1 Introduction

Traditional forecasting requires the explicit formulation of a model, including precise specification of the variables to be included. As pointed out by [4], confidence indicators (e.g. business and consumers) are important variables for predicting subsequent economic conditions. Indeed, if consumers and manufacturers feel confident about the current and the future economic conditions, they might increase their consumption and production respectively. However, we should mention that the issue of predicting the present (i.e. nowcasting) is a very complicated task since macroeconomic data are released with different frequencies. Information about the Gross Domestic Product (GDP) is quarterly available, some others (e.g. Industrial Production, Confidence Indicators and so on) monthly or even daily. For nowcasting a low-frequency variable, as the GDP, by using high frequency "leading indicators", not standard econometric methods have been developed (for a review, see [1]). One of the most recent approach is based on the use of composite confidence indicators as "leadings" ([3, 4]).

In this paper, we aim to construct a new composite confidence indicator for GDP nowcasting. In this framework, the European Commision has developed the European Economic Sentiment Indicator (ESI) [3]. The ESI is a survey-based composite indicator based on four sub-indicators related to business surveys (for the industrial, service, construction and retail sector) and one on consumers survey. The weights associated with each sub-indicator are based on the "relevance criterion" [3]: briefly, they reflect the relevance of the corresponding sector in the total economy as share of GDP. If the interest is nowcasting GDP, the weights for building the composite index could be obtained through a direct approach, by estimating the impact of each sub-indicator on the GDP. In this case, data are sampled at different frequencies (quarterly and monthly) so mixed frequency regression methods have to be used (for a review see [1]). In this paper, we propose to use a weighting scheme based on an Unrestricted-MIDAS regression [2] (U-MIDAS) and show its properties in our case study.

The paper is structured as follows. In the next Section, our proposal is presented in detail. In Section 3 we apply such methodology to Italian GDP nowcasting.

2 Methodology

When the aim is to build a composite indicator, we have to take into account different aspects. Firstly, it is necessary to clearly define the phenomenon under investigation by considering all its sub-components. For each component, it is important assessing its relative importance in explaining the phenomenon and defining its weight.

In this paper, our interest is focused on the public confidence (sentiment) on overall economic conditions in terms of GDP. Public sentiment indicators are obtained from confidence surveys conducted by National Statistical Institutes. In order

to build an overall composite confidence indicator, weighting accurately each of the sub-components is a very important issue. For comparing our results with the ESI ones, we consider four indicators of public confidence for different business sectors (manufacturing, construction, services and retail) and one confidence indicator for the consumers.

In this context, different weighting schemes have been proposed [3]. Most of the composite indicators are based on equally weighted sub-components. In this scheme all sub-components have the same importance in constructing the composite index. This scheme can be used also when not enough information is available about the contribution of each sub-component. Other approaches are based on the definition of weighting schemes based on expert opinions. The ESI scheme, instead, assigns weights according to the share of GDP produced by the sector over the total [3].

We propose to compute the weights by means of regression models. This family of methods are well established in the literature of forecast combinations [5] but not in the composite indicators one.

Suppose we want to nowcast GDP through a new monthly Composite Confidence Index based on an alternative weighting scheme (*AW*). We denote: GDP as the quarterly Gross Domestic Product, CCI the monthly Consumer Confidence Index, MS the monthly Manufacturing sector Confidence Index, CS the monthly Construction sector Confidence Index, SS the monthly Services sector Confidence Index and RS the monthly Retail sector Confidence Index. We propose to compute the weights of the Composite Confidence Index *AW* by performing the following U-MIDAS regression:

$$\begin{aligned}\Delta GDP_t = \beta_0 + \sum_{i=0}^{2} \beta_{i+1}^{(1)} \Delta CCI_{t-i/3}^{(3)} + \sum_{i=0}^{2} \beta_{i+1}^{(2)} \Delta MS_{t-i/3}^{(3)} + \sum_{i=0}^{2} \beta_{i+1}^{(3)} \Delta CS_{t-i/3}^{(3)} + \\ + \sum_{i=0}^{2} \beta_{i+1}^{(4)} \Delta SS_{t-i/3}^{(3)} + \sum_{i=0}^{2} \beta_{i+1}^{(5)} \Delta RS_{t-i/3}^{(3)} + \varepsilon_t\end{aligned} \tag{1}$$

under the constraints: $\sum_{j=1}^{5} \sum_{i=0}^{2} \hat{\beta}_{i+1}^{(j)} = 1$ and $\hat{\beta}_{i+1}^{(j)} \geqslant 0$

where Δ represents the first difference operator and $\beta_{i+1}^{(j)}$ ($i = 0, \ldots, 2$, $j = 1, \ldots, 5$) the parameters estimated *via* OLS. Therefore all the indicators involved in the analysis have to be stationary.

When the frequency mismatch is not so huge, Foroni *et al.* [2] showed that U-MIDAS is preferable to a classical MIDAS approach. In order to obtain a single weight $\hat{\beta}^{(j)}$ for each sub-component, I_j, we aggregate the inter-quarterly weights $\hat{\beta}_{i+1}^{(j)}$. For instance, in the case of CCI:

$$\hat{\beta}^{(1)} = \sum_{i=0}^{2} \hat{\beta}_{i+1}^{(1)}$$

At the end of the estimation process, the *AW* composite confidence indicator is computed as:

$$AW = \sum_{j=1}^{5} \hat{\beta}^{(j)} I_j \tag{2}$$

The use of a U-MIDAS approach gives the possibility to compute the relevance of each sub-component by considering both the inter-quarterly impact on GDP and their evolution over time. Therefore, we tested also a time-varying approach, in which the weights and the resulting composite indicator can change during the time.

3 Application to Italian GDP nowcasting

We downloaded the Italian GDP (Fig. 1) and the Confidence indicators data from the ISTAT website[1]. Since it is necessary that all the sub-components are available in the same interval, we considered data from 1st March 2005 to 1st June 2019.

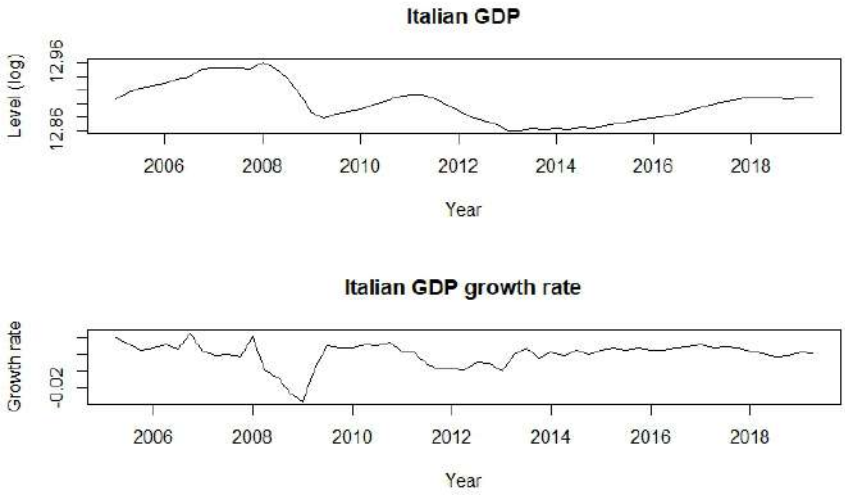

Fig. 1 Italian quarterly GDP: log-levels and growth rate (first difference)

[1] http://dati-congiuntura.istat.it/

The alternative weighting (AW) scheme returns very similar weights compared to ESI (Table 1).

Table 1 Composite Sentiment Indicator: weights

	AW	EW	ESI
Manifacturing sector Confidence	41.5%	20%	40%
Construction sector Confidence	25.9%	20%	5%
Services sector Confidence	1.8%	20%	30%
Retail sector Confidence	6.8%	20%	5%
Consumer Confidence	23.7%	20%	20%

Nevertheless, we noted that the weights associated with the construction and services sectors are overthrown. The AW scheme assigns an higher weight to the construction sector than the services one. This could mean that changes in confidence levels of construction firms have a much higher impact on GDP growth rate than changes in services confidence. This perspective is not taken into account by the ESI. Fig. 2 shows the composite indicators obtained with the three different weighting schemes.

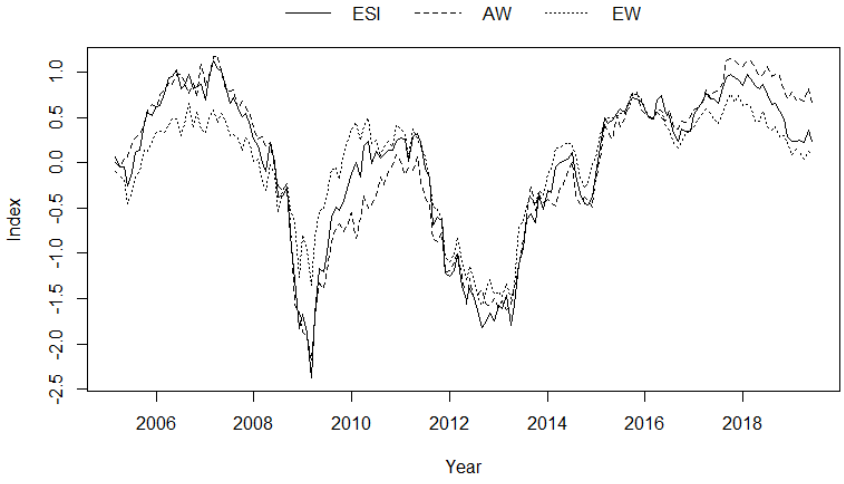

Fig. 2 Composite Confidence Indicators

We tested for stationarity but all the time series are not stationary. In order to assess the nowcasting power of the three composite confidence indicators, we performed the following U-MIDAS regression:

$$\Delta GDP_t = \alpha + \sum_{i=0}^{2} \beta_{i+1} \Delta CI^{(3)}_{t-i/3} + \sum_{i=0}^{2} \gamma_{i+1} \Delta X^{(3)}_{t-i/3} + \varepsilon_t \tag{3}$$

where α is a constant term, *CI* is the composite indicator, that is ESI, *EW*, *AW* or $AW^{\dagger}$ (*AW* with time-varying weights) as applicable, X_t is a matrix containing the other leading indicators, that is the Industrial Production Index and the Unemployment Rate, and β and γ are the respective weights.

Table 2 shows the nowcasting accuracy according to three different criteria: Mean Square Forecast Error (MSFE), Mean Absolute Forecast Error (MAFE) and Root-Mean Square Forecast Error (RMSFE).

Table 2 Prediction accuracy (MIDAS): results with rolling approach

	MSFE	MAFE	RMSFE	MSFE	MAFE	RMSFE
	(1)	(2)	(3)	(4)	(5)	(6)
AW	$1.26e^{-05}$	0.003086	0.003561	$6.23e^{-06}$	0.002007	0.002497
$AW^{\dagger}$	$1.26e^{-05}$	0.003029	0.003563	$6.15e^{-06}$	0.002077	0.002479
EW	$1.56e^{-05}$	0.003191	0.003954	$6.84e^{-06}$	0.002295	0.002616
ESI	$1.35e^{-05}$	0.003016	0.003681	$7.42e^{-06}$	0.002385	0.002724
X_t	NO	NO	NO	YES	YES	YES

According to the accuracy measures, the composite sentiment indicator with AW scheme has better power in nowcasting GDP than the other ones. However, we noted that ESI weighting scheme seems to be more accurate than the equally weighted one. If we consider additional leading indicators (column 4-6) the results are quite similar. The AW scheme still outperforms all the other approaches. In this case, the use of equal weights gives more accurate nowcasts for GDP than the ESI ones. In particular, we highlight that in both scenarios the $AW^{\dagger}$ approach is the best one.

Our results suggest that a data-driven approach for the weighting estimation returns better nowcastings for the Italian GDP than the other well-established alternatives.

On the tangible and intangible assets of Initial Coin Offerings

Panoramica degli asset tangibili e intangibili delle Initial Coin Offerings.

Paola Cerchiello and Anca Mirela Toma

Abstract The Initial Coin Offering (ICO) is one of the operations based on DLT or blockchain technology that allows fundraising activities for an entrepreneurial project, by issuing utility tokens instead of a security or an equity token. Based on a combination of different datasets with over 3000 observations and 30 features (such as social channels, amount raised, the duration, the rating, the community chat of the official telegram channel), the relative sentiment and the whitepaper characteristics) we provide an empirical approach how the wallet of tangible and intangible assets can be built in order to achieve the project's goals. By means of several statistical and text mining techniques we are able to exploit all the parameters in order to interpret the weights of features as ICO success or failure drivers.

Abstract *L'Initial Coin Offering (ICOs) è una delle possibili operazioni basate sulla tecnologia DLT o blockchain che consente a progetti imprenditoriali di raccogliere fondi, emettendo token di utilità anziché un token di sicurezza o di equità. Basato su una combinazione di diversi set di dati con oltre 3000 osservazioni e 13 variabili (come importo raccolto, durata, valutazione, chat della comunità del canale ufficiale di Telegram, relativo sentiment e caratteristiche del white paper) forniamo un approccio empirico su come costruire il portafoglio di beni materiali e immateriali per raggiungere gli obiettivi del progetto. Tramite diverse tecniche statistiche siamo in grado di sfruttare tutti i parametri al fine di interpretare i pesi delle variabili come driver di successo o fallimento delle ICO*

1 Introduction

The first Initial Coin Offering (ICO) was held in 2013. Since then, this new way of raising capital keeps investors and regulators around the world occupied as the number of held ICOs skyrocketed. An ICO (also called a token sale event) constitutes an alternative funding method for young and technically involved ventures. They offer a self created cryptocurrency to investors at the exchange of fiat money or established cryptocurrency. The sold currency, called a 'token' can meet different requirements. It can be constructed as a mean of payment, to enable access to services or else. It is however purely digital and the real world value depends on the success of the issuing venture. As the ICO environment grew big in a very small time frame, regulators around the world are still making a substantial effort to increase investor protection whilst fostering innovation in the Financial Technology (FinTech) environment. At the moment the regulation in terms of ICOs is characterized by the lack thereof. This leaves potential for scams and fraudulent activities[**?**]. Due to the continuing hype around the topic, gains for issuers of fraudulent ICOs can be astronomically high. In April 2018, a scam beyond the imaginary made heeadlines. The Vietnamese company Modern Tech JSC, had vanished into thin air with the generated ICO funds of USD 658 million. Over 32,000 investors were affected by the scam. Even though this was the biggest, scams in the environment are quite common. This work aims at addressing the specific characteristics of ICOs using relevant variables that play a key role in determining the success of the ICO.

As it stands there is no database with the information we are looking for, thus we have been building and constantly maintaining a dataset that is currently composed of 195 ICOs that occurred between October 2017 and November 2018. The database comprises companies from European countries namely France, Germany, Switzerland, Estonia, Latvia and non European countries such as Russia, United Kingdom, United States, Japan, Singapore, and Australia. The most common sectors in which ICOs operate are: high-tech services, financial services, smart contract, gambling platforms, marketplaces and exchanges.

2 Methodology

In this paper we leverage two kinds of information: structured and unstructured ones. Regarding the former, we take advantage of classical statistical classification models to distinguish the stauts of an ICO that made up of 2 classes, intended as follows:

- Success = 1: the ICO collects the predefined hard cap within the time horizon of the campaign;
- Failure/Scam = 0: the ICO does not collect the predefined hard cap within the time horizon of the campaign.

Logistic regression aims at classifying the dependent variable into two groups, characterized by a different status (1=scam vs 0=success or 1=success vs 0=failure) according to the following model:

$$ln(\frac{p_i}{1-p_i}) = \alpha + \sum_j \beta_j x_{ij}, \tag{1}$$

where p_i is the probability of the event of interest, for ICO i, $x_i = (x_{i1}, \ldots, x_{ij}, \ldots, x_{iJ})$ is a vector of ICOs-specific explanatory variables, the intercept parameter α, as well as the regression coefficients β_j , for $j = 1, ..., J$, are to be estimated from the available data. It follows that the probability of success (or scam) can be obtained as:

$$p_i = \frac{1}{1 + exp{-(\alpha + \sum_j \beta_j x_{ij})}}. \tag{2}$$

Considering the textual analysis of Telegram chats, we take advantage of quantitative analysis of human languages to discover common features of written text. In particular the analysis of relatively short text messages like those appearing on micro-blogging platform presents a number of challenges. Some of these are, the informal conversation (e.g. slang words, repeated letters, emoticons) and the level of implied knowledge necessary to understand the topics of discussion. Moreover, it is important to consider the high level of noise contained in the chats, witnessed by the fact that only a fraction of them with respect to the total number available is employed in our sentiment analysis.
We have applied a Bag of Word (BoW) approach, according to which a text is represented as an unordered collection of words, considering only their counts in each comment of the chat. The word and document vectorization has been carried out by collecting all the word frequencies in a Term Document Matrix (TDM). Afterwards, such matrix has been weighted by employing the popular TF-IDF (Term Frequency Inverse Document Frequency) algorithm. Classical text cleaning procedures have been put in place like stop-words, punctuation, unnecessary symbols and space removal, specific topic words addition. For descriptive purposes we have used word-clouds for each and every Telegram chat according to the general content and to specific subcategories like sentiments and expressed moods. The most critical part of the analysis relies on the sentiment classification. In general, two different approaches can be used:

- Score dictionary based: the sentiment score is based on the number of matches between predefined list of positive and negative words and terms contained in each text source (a tweet, a sentence, a whole paragraph);
- Score classifier based: a proper statistical classifier is trained on a large enough dataset of pre-labelled examples and then used to predict the sentiment class of a new example.

However, the second option is rarely feasible because in order to fit a good classifier, a huge amount of pre-classified examples is needed and this represents a particularly complicated task when dealing with short and extremely non conventional text like micro-blogging chats. Insofar, we decided to focus on a dictionary based approach, adapting appropriate lists of positive and negative words relevant to ICOs topics in English language.
The lexicons used are based on unigrams, i.e., single words, they contain many English words and the words are labeled with scores for positive/negative sentiment and also possibly emotions like joy, anger, sadness, and so forth. The NRC lexicon categorizes words in a binary fashion ("yes"/"no") into categories of positive, negative, anger, anticipation, disgust, fear, joy, sadness, surprise, and trust. The BING lexicon categorizes words into a binary manner into positive and negative categories. The AFINN lexicon assigns words with a score that runs between -5 and 5, with negative scores indicating negative sentiment and positive scores indicating positive sentiment. By applying the above described lexicons, we produce for each and every ICO a sentiment score as well as counts for positive and negative words. All these indexes are used as additional predictors within the logistic models.

3 Data

In this paper, we leverage on structured and unstructured information and empirically examine 195 ICOs starting from January 2017 till November 2018.
The first step in collecting data about each project is to gather information from the most used ICO related platforms as icobench, TokenData, coinschedule or similar. During such phase, we look for general characteristics such as the name, the token symbol, start and end dates of the crowdfunding, the country of origin, financial data such as the total number of issued token, the initial price of the token, the platform used, data on the team proposing the ICO, data on the advisory board, data on the availability of the website, availability of white paper, whitepaper characteristics and social channels.
Some of these data, such as short and long description, and milestones are textual descriptions. Others are categorical variables, such as the country, the platform, the category (which can assume many values), and variables related to the team members (name, role, group). The remaining variables are numeric, with different degrees of discretization.
As it concerns the unstructured data, insightful information can be derived from the white papers in terms of quality of the technical report and specific content. A white paper is a summary report that provides detailed information about the project, its originality and the benefits it can give to investors and users, about the technological features, team behind the project, project's background and future plans. The dimensions captured through the white paper features consists in checking the availability of the document for the ICO in question and additional

information about its scope (pages, sections, appendix). Furthermore, data on the disclosure of information regarding the issuers was collected (names and/or photographs of issuing and advisoring team members).
Social channels are more personal than every database, rating platform or websites, so they are a way to reach a wide range of users, to update them constantly about the evolution of the project and in the end to create a trusty environment that can finalize in a successful crowdfunding activity. In order to conduct the textual analysis, we enrich our database with the social channels data, such as the presence of a channel, the numbers of users as a proxy of the community engagement and as mentioned in the introduction the textual chat, retrieved backward till the creation of the chat, used to produce a sentiment based score of every ICO.

4 Results

The best model specified by AIC stepwise selection of features is reported in Table 1. The null deviance of the model is 210.680 on 194 degrees of freedom, the log-likelihood of the final model has a value of -28.821.

Table 1 Results of the logistic regression

	Dependent variable:
	class2
Telegram_du	-1.846^{**}
	(0.922)
Nr_Telegram	0.001^{**}
	(0.0002)
nr_team	0.282^{***}
	(0.103)
tw	3.884^{**}
	(1.743)
nr_adv	0.531^{***}
	(0.184)
Sent_NRC_sc	2.257^{***}
	(0.852)
name_team	1.670^{*}
	(0.876)
picture	-1.682^{*}
	(1.010)
Constant	-4.632^{**}
	(2.001)
Observations	195
Log Likelihood	-28.821
Akaike Inf. Crit.	75.641
Note:	*p<0.1; **p<0.05; ***p<0.01

It can be seen that the existence of a Telegram communication channel has a significant impact with a negative sign on the log odds of a successful ICO. The standard error for this term is 0.922. This means, that if all other variables are held constant, the existence of a Telegram channel has a negative effect of -1.846 on the log odds of a successful ICO. The number of people enrolled in the Telegram chat also has a significant effect on the dependent variable, however the effect is much smaller and has a positive sign. This means that with the amount of people participating in the communication channel, odds of a successful ICO rise. The number of members of the issuing team of an ICO has a highly significant effect with a positive sign on the log odds of a successful ICO. The existence of a twitter account dedicated to the ICO also has a highly significant impact with a positive sign. The dimension of this effect, all other variables held constant, is more than twice as high as the aforementioned effect of the existence of a Telegram channel. The number of advisors has a highly significant effect exhibiting a positive sign. The sentiment extracted from Telegram chats also has a high positive sign significant effect.

Seasonality variation of electricity demand: decompositions and tests

La variazione della stagionalità nella domanda di elettricità: scomposizioni e test

Luigi Grossi and Mauro Mussini

Abstract The change over time in seasonal concentration of electricity demand is broken down into two components. One component measures the contribution of the changes in the seasonal pattern of demand. The second component measures the contribution of the change in the magnitude of seasonality.
Abstract *La variazione nella concentrazione stagionale della domanda di energia elettrica è scomposta in due componenti. La prima componente misura il contributo dei cambiamenti nell'andamento stagionale. La seconda componente misura il contributo della variazione nell'intensità della stagionalità.*

Key words: decomposition**,** Gini index**,** seasonal concentration, electricity demand

1 Introduction

Liberalized electricity markets in the main economies of the world are organized by means of daily auctions where operators present their offers and bids. The most important session of the Italian electricity market (IPEX) is the day-ahead market (Mercato del Giorno Prima, MGP). In this market session, the equilibrium price and quantity for each hour (load period) of the next day is obtained by the intersection of the aggregated curves of demand and supply. Because of the intermittent nature of renewable sources, such as wind and solar, the regulator of the market (GME, Gestore

[1] Luigi Grossi, Dipartimento di Scienze Economiche, Università degli Studi di Verona; email: luigi.grossi@univr.it

Mauro Mussini, Dipartimento di Economia, Metodi Quantitativi e Strategie di Impresa, Università degli Studi di Milano Bicocca; email: mauro.mussini1@unimib.it

del Mercato Elettrico) provides the market with one-day-ahead predictions of the hourly electricity demand in order to ensure that the total power supply meets the global demand. It is then clear that the correct analysis and prediction of the dynamics of the demand is crucial in order to avoid shortages of supply and consequent black-outs [4]. Hourly time series of electricity demand are characterized by empirical regularities called "stylized facts" such as long-run cycles, presence of spikes and multiscale seasonality [6]. Seasonality can be thought as regular fluctuations with similar timing and magnitude from day to day, week to week and month to month.

Seasonality implies that electricity demand tends to be concentrated in certain periods of the day/year (peak periods), generating an unequal distribution of demand among the periods [5]. From this perspective, the degree of seasonality can be measured in terms of seasonal concentration by using a conventional concentration index, such as the Gini index or the Theil index.

Concentration indexes are descriptive statistical tools which were originally introduced in the literature on income inequality, but their field of application crossed that of the measurement of income inequality. Such indexes were used to quantify the level of seasonality in several studies examining the evolution of seasonality in tourist flows [1], [2]. The change over the days/years in seasonal concentration can be measured by observing the change in the concentration index. However, a basic element of seasonality cannot be monitored by examining solely the change in the concentration index. An essential feature of seasonality is that the intra-day/year fluctuations occur with the same timing from day to day and from year to year. However, the value of a concentration index does not vary if fluctuations have the same magnitude but a different timing. Since a conventional concentration index is invariant to changes in the seasonal pattern, a measure of seasonal stability is needed in addition to a measure of the change in seasonal magnitude when analysing the evolution of seasonality. In this paper, we show that these measures can be obtained by decomposing the change in seasonal concentration. In particular, seasonal concentration in a given day/year is measured by using the Gini index [3], a very popular measure of concentration. After measuring seasonal concentration in two different days/years, the change in seasonal concentration is split into two components. One component is a measure of seasonal stability, which tracks changes in the seasonal pattern. The second component measures the change in seasonal magnitude, assuming that the seasonal pattern is stable.

2 Decomposing the change in seasonal concentration

Let Y be a variable representing the forecasted demand of electricity in an area. Let $y_{1,t}, \cdots, y_{n,t}$ be the time series of electricity demand at time t, where t could be a generic day or a generic year; n is the number of periods in a day or in a year (e.g., $n = 24$, for hourly data, $n = 12$ for monthly observations) and $y_{i,t}$ is the electricity demand of period i in day/year t. To make the notation lighter, from now on, we will focus on the concentration of the hourly demand in a day, but the procedure might be

easily extended to the concentration of the monthly demand in a year. The Gini index measuring the concentration of electricity demand in t is

$$G_t = \frac{2cov[y_{i,t}, r(y_{i,t})]}{n\bar{y}_t}, \quad (1)$$

where $\bar{y}_t$ is the average electricity demand per period and $r(y_{i,t})$ is the rank of period i according to the increasing order of electricity demand.

Now suppose that the daily distribution of electricity demand is observed in day $t+k$. The change in the concentration of demand from day t to day $t+k$ is measured by the difference between the Gini index in $t+k$ and the Gini index in t:

$$\Delta G = G_{t+k} - G_t = \frac{2cov[y_{i,t+k}, r(y_{i,t+k})]}{n\bar{y}_{t+k}} - \frac{2co\ [y_{i,t}, r(y_{i,t})]}{n\bar{y}_t}. \quad (2)$$

However, ΔG does not necessarily capture all aspects of the change in seasonality. For instance, consider the numerical illustrations in figure 1 showing two hourly distributions of demand in days t and $t+k$. The twenty-four absolute figures in $t+k$ are equal to those in t but the ranking of hours by electricity demand has changed. The maximum value is observed at hour 14 at day *t*, while maximum demand at day *t*+*k* is at hour 12; hour 14 at day *t*+*k* has become the second highest demand value. Moreover, moving from day *t* to day *t*+*k*, hour 13 has changed its position from 23rd to 22nd. In such a situation, the Gini index in $t+k$ is equal to the Gini index in t. ΔG equals zero, suggesting that seasonality has remained unchanged since t, but the distribution of demand among hours has changed. To capture the changes in seasonality depicted in figure 1, a measure of seasonal stability and a "pure" measure of the change in seasonal magnitude are needed. These measures are obtained by decomposing ΔG.

Let $C_{t+k|t}$ stand for the concentration coefficient of electricity demand in $t+k$ obtained by sorting periods according to their ranking in t instead of that in $t+k$:

$$C_{t+k|t} = \frac{2cov[y_{i,t+k}, r(y_{i,t})]}{n\bar{y}_{t+k}}. \quad (3)$$

By adding and subtracting $C_{t+k|t}$ to the right-hand side of equation (2), the difference in the Gini index is broken down into two components:

$$\Delta G = \left\{\frac{2cov[y_{i,t+k}, r(y_{i,t+k})]}{n\bar{y}_{t+k}} - \frac{2cov[y_{i,t+k}, r(y_{i,t})]}{n\bar{y}_{t+k}}\right\} + \left\{\frac{2cov[y_{i,t+k}, r(y_{i,t})]}{n\bar{y}_{t+k}} - \frac{2cov[y_{i,t}, r(y_{i,t})]}{n\bar{y}_t}\right\}$$

$$\Delta G = R + M. \quad (4)$$

R in equation (4) is the re-ranking component measuring the change in concentration due to the position exchanges between periods in the ranking of periods from t to $t+k$. The re-ranking component is analogous to the re-ranking measure used for capturing the re-ranking of income receivers when decomposing the change in income inequality [5]. R equals zero if the ranking of periods in $t+k$ is the same as that in t. The component R reaches its highest value, that is $2G_{t+k}$, when the ranking

of periods in $t+k$ is completely reversed with respect to the ranking of periods in t. Since the re-ranking component captures any deviation in the seasonal pattern, R is seen as a measure of seasonal stability. The larger the re-ranking component, the more unstable the seasonal pattern.

The term M in equation (4) is the magnitude component measuring how much electricity demands in day $t+k$ are more (or less) concentrated on the periods with the highest ranks in day t. Since M is calculated by holding periods sorted according to their ranking in t, the seasonal pattern is supposed to be the same in t and $t+k$. The magnitude component is positive (negative) when the magnitude of seasonality has increased (decreased) over time. M is equal to zero if the electricity demand among periods has not changed or if the demand of all periods has changed in same proportion, leaving unchanged the relative disparities between values of demand.

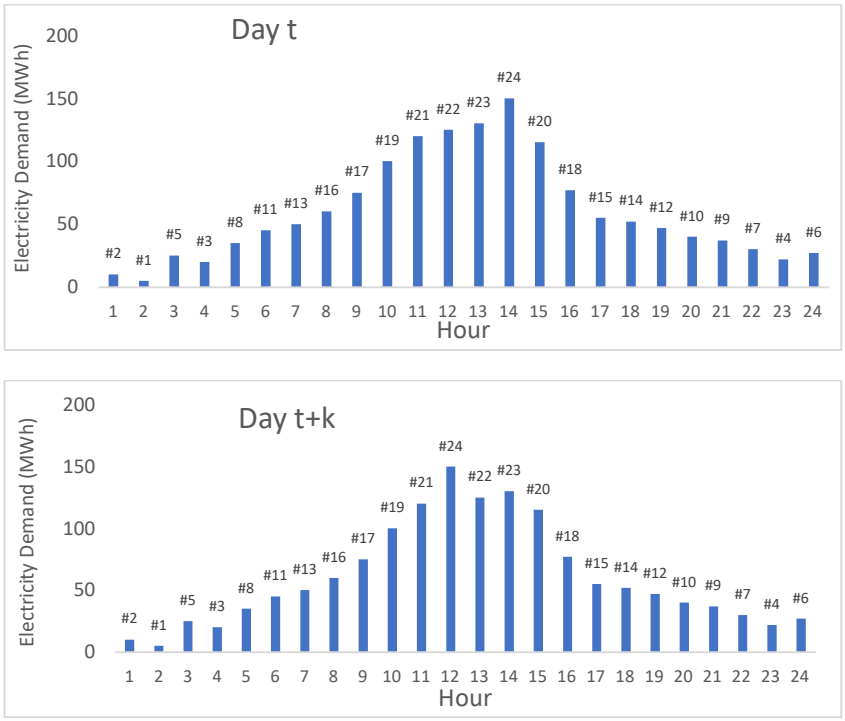

Figure 1: Hourly distributions of electricity demand in days t and $t+k$.

3 Application

The decomposition is used to analyse the evolution of seasonality in the average hourly electricity demand observed in the Italian electricity market called IPEX (see, https://www.mercatoelettrico.org). Although it is well known that the daily cycle of

hourly demand changes within days of the week and within days observed in different months [5], [6], the significance of this changes has never been tested. Moreover, it is very important to see if the change of the daily pattern can be significantly ascribed to one of the two components obtained in the previous section, or both. For instance, due to social behaviour and to the increase of light hours in the summer season the daily cycle of electricity consumption is smoother than in winter days and the peak of demand of electricity moves forward during the day. The first change should influence the magnitude component, while the second should affect the ranking component.

The change in the average daily seasonality over different months of the same year and of different years is examined using data observed in 2016 and 2018.

Table 1: decomposition of the change in seasonality in average daily cycles of different months.

	Indices		Variation	Components		Permutation test		
	G_t	G_{t+k}	ΔG	R	M	p(ΔG|H0)	p(R|H0)	p(M|H0)
January 2016 August 2016	0.10334	0.07505	-0.02829	0.0041	-0.0324	0.001	0.001	0.001
January 2018 August 2018	0.10556	0.07431	-0.03125	0.0051	-0.0363	0.001	0.001	0.001
August 2016 August 2018	0.07505	0.07431	-0.00074	0.0004	-0.0011	0.373	0.001	0.155

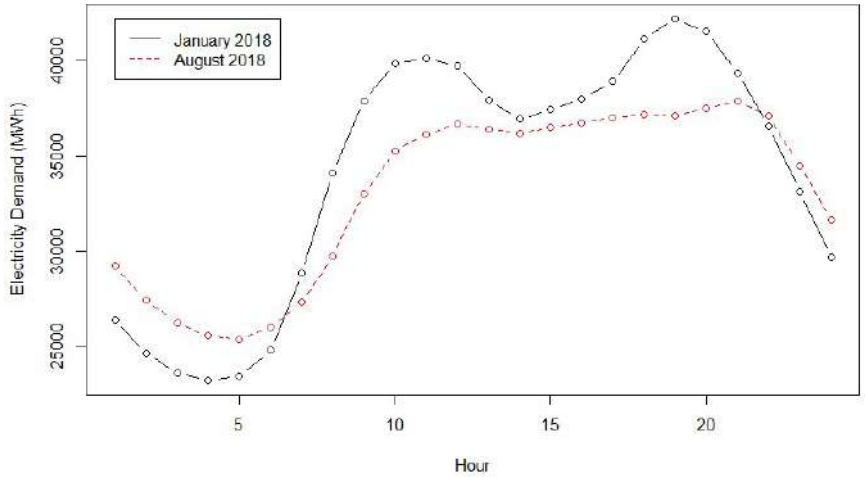

Figure 2: Average daily profile of electricity demand in January and August 2018. Data were downloaded from the website of the GME (Gestore Mercato Elettrico), www.mercatoelettrico.org.

Table 1 shows the output of the decomposition of the change in seasonal concentration comparing average daily cycles observed in different months. Last three columns report the *p*-values of the permutation test. First and second line of the table contains the results of the comparisons between a typical winter day profile (January) and a typical summer day profile (August) in 2016 and in 2018. The seasonal concentration

is lower in August because the demand of electricity in summer is more constant in the middle of the day. From the decomposition observed in the table, it is interesting to note that the reduction of seasonal concentration in summer days (ΔG) is due to a reduction of seasonal magnitude (component M is negative), while the contribution of the seasonal pattern is positive. The two average daily cycles in 2018 can be clearly observed in Figure 2. Although the seasonal concentration magnitude is reduced, the flatter pattern around midday goes in the opposite direction because of the change of many positions in the final ranking of hourly demand. Last row compares the seasonality of the average daily cycle in the same months (August) in 2016 and 2018. Although the global change of concentration is not significant, the seasonal pattern change, measured by R, is statistically significant.

4 Conclusion

In this paper a common approach used in the tourist literature to measure the seasonal concentration in tourist flows has been extended to the study of seasonality of the electricity demand. When measuring the change in seasonal concentration over time, observing the variation in the seasonal concentration index may lead to misleading conclusions since a small change in the index can be the outcome of the offsetting contributions of changes in the seasonal pattern and magnitude. The decomposition of the change in seasonal concentration sheds light on the different aspects of a change in the seasonal cycle of electricity demand, revealing the roles of changes in the seasonal pattern and magnitude. This decomposition provides regulators and other market operators with additional information on the change in the intra-day cycle of electricity consumptions. This is relevant in view of the massive penetration of renewable sources, especially photovoltaic plants, which follows the seasonal cycle of solar radiation.

SMEs circular economy practices in the European Union: Implications for sustainability

Economia circolare nelle PMI Europee: implicazioni per la sostenibilità

Nunzio Tritto, Josè G. Dias and Francesca Bassi

Abstract This paper studies the willingness of small and medium-sized companies in the European Union to undertake circular economy practices. The dataset comes from a survey involving more than 10,000 SMEs in the EU. This hierarchical structure – companies within countries – was analyzed using a multilevel factor model that takes the heterogeneity between countries into account. Both at company and country levels, there are factors that explain the attitude towards CE. Factor scores at both levels suggest a division between Western and Eastern countries (with some exceptions) regarding willingness to undertake CE activities by SMEs, which identify regional consequences of the EU policies towards CE.

Abstract *Questo lavoro studia la intenzioni da parte delle piccole e medie imprese europee di adottare le pratiche di economia circolare. I dati sono stati raccolti presso più di 10.000 PMI, localizzate nei 28 paesi dell'Unione Europea. La struttura gerarchica delle informazioni è stata tenuta in considerazione stimando modelli fattoriali miltilivello. Si è rilevato che vi sono sia fattori a livello di impresa che a livello di paese che spiegano la propensione nei confronti dell'economia circolare. In particolare, si sono evidenziate marcate differenze tra i paesi dell'Europa Occidentale e quelli dell'Europa Orientale. Questi risultati identificano il verificarsi di conseguenze diverse a livello regionale delle politiche Europee che cercano di favorire l'adozione dell'economia circolare*

Key words: Circular economy, sustainability, European Union, small and medium-sized companies, multilevel models.

1 Introduction

The introduction of the concept of Circular Economy (CE) can be traced at the end of the 20th century when seminal papers were published and it attracted the attention

of many scholars (Lieder and Rashid, 2016). The concept of CE has evolved in the world of business in an attempt to find a compromise between economic growth and environmental protection. This concept is in contrast with the most used idea of linear economy, i.e. take-make-use-dispose. The EU business world has to face the environmental issue for ethical reasons but also because the European Union developed environmental policies for the product life cycle (European Commission, 2003; Dalhammar, 2015). Small and medium-sized enterprises are defined by the European Commission as companies with less than 250 employees and with an annual turnover that does not exceed 50 million euros, or a total annual balance that does not exceed 43 million euros (European Commission, 2003). For the European Union, SMEs are fundamental for CE because they are more active in sectors such as recycling, repair, and innovation; on the other hand, they have some difficulties in applying for funding and in sticking to CE principles if their activity is not directly involved (European Commission, 2015).

This paper aims to analyze the willingness of European SMEs to undertake specific activities related to Circular Economy (CE) and to identify the potential drivers of this behavior. Data are collected from a sample of SMEs operating in the 28 EU Member States. Country-level characteristics are also included and their impact on the overall willingness to undertake CE activities is evaluated. The collected data is hierarchical: SMEs are nested into countries; this required the specification and the estimation of multilevel models to evaluate the impact of factors, at company and country level, on the latent structure.

2 Data and methods

Data come from the Flash Eurobarometer 441 conducted in April 2016 and it contains 10,618 CATI interviews. The 28 countries included in the survey are (alphabetical order): Austria, Belgium, Bulgaria, Cyprus, Croatia, Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, Netherlands, Poland, Portugal, Romania, Slovakia, Slovenia, Spain, Sweden, and United Kingdom. The data set contains five ordinal indicators on the implementation of CE practices in the past three years: 1. Re-plan of the way water is used to minimize use and maximize re-use; 2. Use of renewable energies; 3. Re-plan energy usage to minimize consumption; 4. Minimize waste by recycling or reusing waste or selling it to another company; and 5. Redesign products and services to minimize the use of materials or use recycled materials. The survey collects various company characteristics: the number of employees, total turnover in 2015, the age, the sector of economic activity, the type of goods and services sold, and the percentage of company's turnover in 2015 invested in Research and Development. Country-level covariates are available on the Eurostat website; however, there exists a problem of multicollinearity among indicators related to the same dimension (social, economic, environmental, institutional). For this reason, we selected only one variable per dimension: illiteracy rate, per capita GDP, generation of waste excluding major mineral wastes per GDP unit, corruption perception index.

Figure 1 summarizes the conceptual model of confirmatory factor analysis with a multilevel factor model (Hox et al., 2010). Two latent variables represent the willingness to undertake CE activities: one at company level (f^W), and one at country level (f^B). The H items Y_h correspond to the dependent variables of interest; the K variables X_k are the company-level covariates; and the set of M variables Z_m are the country-level covariates. This conceptual model represents a combination of a factorial model that links the latent constructs with the H items Y_h, and a linear model that regresses the two latent variables on the corresponding covariates at company and country level in a multilevel setting, respectively. Therefore, the final model assumes unidimensionality, i.e., a single individual latent variable that explains all observed items. Estimation is obtained with Maximum Likelihood (ML) method with Gaussian integration.

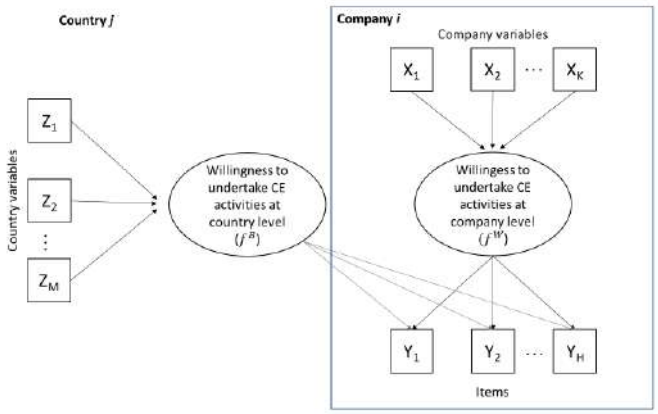

Figure 1: Conceptual model

3 Results

Confirmatory factor analysis (CFA) with one latent variable and five items has a good fit to the data: the RMSEA has a value lower than 0.05 (0.039); indexes CFI and TLI are greater than 0.95 (0.977 and 0.953, respectively). All factor loadings are greater than 0.7. The variances of the latent variables at the company and country level are both statistically significant, accounting for the presence of variability within and between countries. The following step of the analyses is the study of the impact of covariates at company and country level on the willingness to undertake CE practices, represented by the latent variable. We estimate two nested models (Table 1): the first one without country covariates (Model I) and the second one with these covariates (Model II). In general, it is possible to note that the differences between the two models in terms of the values of estimated coefficients, standard errors and p-values are negligible, as expected. The introduction of country-level variables in the model

does not affect other estimates. The estimated variance does not vary significantly as a result of the introduction of the upper level variables in the model. Values in Table 1 suggest that company size affects positively the willingness to undertake CE activities. The relationship between company's turnover in 2015 and undertaking of CE activities is linear and positive as well. Undertaking CE activities does not depend on the age of the company. The implementation of CE practices is more prevalent in companies that belong to more tangible sectors. Table 1 indicates a positive relationship between the percentage of turnover invested in R&D and the willingness to undertake CE practices.

R & D (%) (ref: < 5%)						
From 5% to 9.9%	0.595	0.076	0.000	0.596	0.076	0.000
From 10% to 14.9%	0.708	0.057	0.000	0.709	0.057	0.000
From 15% to 19.9%	0.834	0.166	0.000	0.834	0.165	0.000
20% or more	0.666	0.129	0.000	0.668	0.129	0.000
Variance	1.962	0.215	0.000	1.967	0.216	0.000

Table 2 lists estimated coefficients for the two models without (Model I) and with covariates at country-level (Model II). Illiteracy rate has a significant and positive but low slope (0.024). Per capita GDP (log-transformed) is not statistically significant. The increase in the variable measuring generation of waste per GDP has a negative, but very low, impact on the latent variable. Finally, the Corruption Perception Index has a not statistically significant impact on undertaking CE activities. In the model without the upper level covariates, the between variance is equal to 0.435 and the ICC is 0.181; as expected, in the model with country-level covariates, the between

variability and the ICC are both lower (respectively 0.214 and 0.098). This means that the heterogeneity between countries is 9.8% of the total variance.

Table 2: Country-level effects

	Model I			Model II		
	Estimate	S.E.	p-value	Estimate	S.E.	p-value
Illiteracy rate				0.024	0.007	0.001
GDP per capita (ln transformed)				0.230	0.318	0.470
Generation waste per GDP				-0.002	0.001	0.003
Corruption perception index				0.005	0.013	0.689
Variance	0.435	0.141	0.002	0.214	0.105	0.042
ICC	0.181			0.098		

4 Conclusions

This study focused on the willingness of small and medium-sized companies in the European Union to undertake CE practices. The first focus of the analysis was to synthesize the information of a set of variables related to CE practices creating a latent variable –willingness to undertake CE practices – through a Confirmatory Factor Analysis using ordinal data. Then we studied the effect of company-level and country-level covariates on this latent variable. The introduction of the macro-variables considerably reduces the intra-class correlation coefficient, which means that these variables give us important information about the differences between countries.

It is important to underline the limitations and possible developments of the analyses. The entire model has been thought in order to summarize the information about the five items of interest in one latent variable that measures the overall willingness and to study the impact of a small number of covariates at two levels, in order to have a parsimonious model. At company level, we chose to study objective covariates related to the characteristics of single companies, but it was possible also to introduce variables about the perception of the companies towards the CE concept. The choice of the country-level covariates was one possibility based on alternatives supported in the literature. As explained before, there are other indicators that may explain the latent variable, demanding a deeper research about it.

Another limitation involves the type of data analyzed. Usually surveys have the problem of social desirability bias, that is the trend of respondents to answer a question in order to give a better image of themselves, even if the survey is anonymous. This can negatively affect the validity of the survey and no instruments are available to avoid this snag. However, the introduction of the country-level covariates helps reduce this issue because the heterogeneity at the country-level is a good indicator about differences among respondents in cross-cultural research (Hoogendoorn et al., 2015).

Tax Incentives' Effect on the Provision of Occupational Welfare in Italian Enterprises

L'impatto delle agevolazioni fiscali sul welfare aziendale delle imprese italiane

Alessandra Righi

Abstract The goal of this paper is twofold; firstly, to describe the forms of occupational welfare in Italian enterprises and, secondly, to study the effect of recent tax incentives on the spread of these initiatives. Cluster analysis allows to verify to what extent the Small Manufacturing Enterprises (SMEs) in Italy have benefited from the new tax incentives and whether this has led to a greater diffusion of occupational welfare within these firms still having a low level of provision.

Abstract *Il lavoro intende descrivere le forme di welfare aziendale nelle imprese italiane e studiare l'effetto delle recenti misure di incentivazione fiscale sulla diffusione di queste iniziative. Un'analisi dei gruppi aiuta a capire se le PMI italiane hanno potuto beneficiare dei nuovi incentivi fiscali, consentendo una maggiore diffusione del welfare aziendale all'interno di queste imprese che offrono tali servizi ancora in misura limitata.*

Key words: cluster analysis, corporate welfare, Small Manufacturing Enterprises

1 Introduction

Occupational Welfare (OW) is the term used to describe the workplace schemes aimed at improving the well-being of the employees with the commitment of the parties involved in the labour relationship to improve the profitability or productivity of the company. This concept has been important through the history of industrial societies and its function has been to develop the human capital, through training and healthcare packages, pensions and other benefits, able to increase also the employee loyalty [3]. Nowadays, these provisions are used by companies for

* Alessandra Righi, Istat; email: righi@istat.it

arranging business interests, increasing their competitiveness, strengthening the collaboration with the workers and to compensate, at least in part, for the effects of the wage moderation regime practiced during the latest decades [8]. OW provision covers more than 20% of total employees in many European countries and, although in an unfavourable context (considering the large number of SMEs), this share increased in Italy since the 1990s [5].

Economic policies and collective bargaining proved to be important factors for the growth of the OW provision in Italy [8]. Recent legislation (e.g., Income Tax Code, the so-called TUIR) made more convenient for companies the supply of supplementary services compared to contractual salaries increases. Furthermore, the 2016 Italian Budget law abolished taxation on productivity bonuses when these are provided as welfare benefits, sustaining in this way the OW provision [6]. Besides, corporate bargaining has become increasingly important over the years and the OW initiatives become a source of legitimacy and power for the unions, which play a key role in the negotiation, the regulation and the administration of the OW schemes. [5].

A descriptive analysis of the forms of OW in Italian enterprises operating in the manufacturing industry and market services, through the most recent Italian official statistical sources, allows to study the characteristics of the provision and the effect of the tax incentives (in particular, of those introduced by the 2016 Italian Budget law) on the initiatives. Cluster analysis is aimed at identifying the characteristics of the enterprises who benefited from new tax incentives in order to find out if the new regulatory framework could favour the spread the OW provisions within small and medium enterprises, which still report low shares of these initiatives.

2 Data source and methods

Our data sources are the Harmonized Business Surveys[2], namely, monthly qualitative surveys conducted by the Italian Statistical Institute whose results are representatives of all the Italian enterprises. They are usually geared to measuring opinions of the operators regarding the trends of the most relevant economic variables, but an Ad hoc module surveyed the occupational welfare measures in February 2016 and 2017[3]. Similarly to Natali and Pavolini's approach [7], the survey considered as OW schemes all the benefits and services provided by social partners (employers and trade unions) to employees or his/her dependents. These

[2] Harmonized European Tendency Surveys use panels extracted from the Italian Statistical Register of Active Enterprises (ASIA) stratified (by firm size, sector and geographical area) according to the Robust Optimal Allocation with Uniform Stratum Threshold criterion of stratification and allocation for units with fewer than 1,000 employed person, whereas all the larger firms are considered. The Ad-hoc module has the same sample of the Business surveys and data are weighted using the ratio between the number of enterprises in the Business register (by each sampling stratum) and the number of enterprises in the sample.

[3] The samples consider 4,200 firms in manufacturing industry and 2,000 in market service.

measures refer to both collective occupational welfare schemes and company-based welfare schemes (regulated and managed by employers) not considering fringe benefits. Besides the firm structural variables (location, industry, size), the 2017 Ad hoc module surveyed the provision of the following OW forms by enterprises: training or retraining activities, initiatives for the reconciliation of lifetime of the personnel, support measures to the costs of services for early childhood or for special needs (e.g., health problems of the employees or his/her family members), revenue support measures, funding of supplementary health insurances and complementary pension schemes.

We classified the enterprises into different groups based on the set of our variables [1]. In the SAS software Cluster procedure we used, each observation begins in a cluster by itself and the two closest clusters are merged to form a new cluster that replaces the two old clusters. The measurement of the distance between observations in the agglomerative methods depends on the type of available data and different measures have been proposed to measure the 'distance' for a mixture of binary, categorical and quantitative data (as in our case) [2]. We used the median method to hierarchically clustering the observations in our data set. In this method, developed by Gower [4], the dissimilarity between cluster A and cluster B is represented by the distance between the determined median for the enterprises in cluster A and the median for the cases in cluster B. We clustered the enterprises using three structural variables (location of the firm in four territorial areas, firm size in five classes, 15 divisions of the Nace Rev. 2 classification of economic activities for manufacturing industry and four divisions for market services) and a variable indicating if the firm received tax incentives for the provision of OW measures and what kind of tax benefit the firm received.

3 Main results

Overall 58.5% of enterprises in the manufacturing industry and 64.4% in the market services are involved in at least one of the surveyed OW schemes. Training and retraining programmes[4] are the most commonly provided services (26.7% in market services and 22.4% in the manufacturing industry), besides the flexibility measures for the reconciliation of life of the personnel (22.3% in market service and 21.1% in the manufacturing industry). Funding for supplementary health insurances and complementary pension schemes are supplied by 8.8% and 7.2% of the manufacturing enterprises, and by 5.8% and 2.6% of market services firms, respectively. Revenue support measures for consumption (e.g., advances or loans) involve 9.6% of the manufacturing enterprises and 5.8% of the market services ones. The measures supporting the early childhood services costs (nursery schools, vouchers) are provided very rarely (2.2% in market services and 1.5% in manufacturing industry).

[4] This item excluded compulsory activities on safety matter.

We confirm the empirical literature findings related to the dualization in the OW provision by firm size and geographical area of location. As far as the size is concerned, large enterprises (250 employees and over) show a higher level of provision (73.9% in the manufacturing industry and 77.9% in the market services) than medium-sized enterprises (62.7% and 58.0%) or the small ones (55.5% and 50.5%). As regards as the area, the provision in the North (61.2% in the manufacturing industry and 67.0% in the market services) is higher than in the Centre (54.2% and 64.2%, respectively) or in the South (50.6% and 51.7%).

Coming to the study of the effect of tax incentives, OW initiatives undergone a significant development due to the tax incentives introduced by the 2016 Budget law. Enterprises who benefited from tax breaks on the basis of the new regulation on productivity bonuses in 2016 are 3.8% in the manufacturing industry and 1.5% in the market services. However, a further 3.2% of manufacturing firms and 1.8% of market services firms benefited from other (already existing) tax incentives for the adoption of OW schemes. The incentives provided by the 2016 Budget Law were mainly used by medium and large enterprises both in the market services (23.0% and 28.0%, respectively) and in the manufacturing industry (9.0% and 13.1%, respectively). This growth favoured initiatives like health insurance funding, flexi-time activities for the reconciliation of life and the complementary pensions funding within large firms; whereas small and medium-sized firms focused on the adoption of flexi-time measures, income sustains measures and pension benefits.

Cluster analysis allowed distinguishing three groups of enterprises, similar in both sectors, having provided occupational welfare measures in the considered period (from February 2016 to February 2017) but having had different access to tax incentives. Cluster 1 and 2 regroup enterprises having benefitted by tax incentives, but they slightly differ because the enterprises in cluster 1 (37.2% in the manufacturing and 64.9% in the market services) received only tax benefits envisaged by the 2016 Budget law, whereas those in cluster 2 (30.5% of the manufacturing firms and 24.0% of the market services) reported an extensive use of both tax benefits envisaged by the 2016 Budget law and other existing tax benefits (with a less extensive use in the case of enterprises in the market services). In Cluster 1 we found large enterprises, located in the North-east, operating in medium-high-technology manufacturing industry (in particular, in the Machinery and equipment not elsewhere considered, or Other manufacturing) besides large enterprises operating in the knowledge-intensive services sector, located in the Centre and South. As far as the human resources strategy, they have prevalently adopted the reduction of the employees; thus, they show decreasing trends in employment and a low level of employment turnover (less than 5% of newly employed out of total employed). The flexi-time initiatives and the child support measures are their prevalently provided OW activities, accompanied by the training activities and the support to the revenue in the case of market service firms (Table 1). In Cluster 2 are high-technology manufacturing medium enterprises (50-249 employed) located in the North-west (operating in Rubber and plastic or Fabricated metal, except machinery and equipment sectors) and knowledge-intensive service firms, operating in Information and communication and Support services. They declared a human resource strategy of pure replacement of the exits and show a

slightly increasing number of employed, with a low employment turnover (less than 5%) and a medium level of newly employed having a tertiary degree (10%-29%). Their prevalently provided OW initiatives are training programmes, child support, supplementary pension schemes and revenue support for manufacturing firms, and training programmes, child support and funding of health programs for market services enterprise.

Table 1: Characteristics of enterprises in the clusters by sector - Italy, 2017

	Manufacturing			**Market services**		
	Cluster 1	**Cluster 2**	**Cluster 3**	**Cluster 1**	**Cluster 2**	**Cluster 3**
Location	NE	NW	C/S	C/S	-	NW/NE
Size	250 and over	50-249	5-9	1000 and over	-	less than 50
Nace Rev 2 divisions	Machinery and equipment n.e.c., Other manufacturing	Rubber and plastic, Fabricated metal except machinery and equipment	Food-beverage, Textiles-wearing apparel, leather, wood	-	Information and communication, Support services to enterprises	Transportation and storage, Holiday and accommodation

Source: elaborations by the author on Istat, Ad Hoc module on Labour and business suveys, 2017

Enterprises in Cluster 3 provided OW initiatives without receiving any tax benefit (32.4% in the manufacturing industry and 11.1% in the market services). They are low-technology manufacturing small enterprises (operating in sectors like Food and beverage, Textiles and wearing apparel, Leather, Wood), located in the Centre and the South, and less knowledge-intensive services SMEs (operating in Transportation and storage ad Holiday and other short-stay accommodation sectors) located in the North. Having declared a human resource strategy of replacement of the exits, they show stable employment, a relevant employment turnover (15% and

over) with a low share of newly employed having a tertiary degree (< 10%). Their prevalently provided OW initiative is the funding of health programmes for manufacturing enterprises and the flexi-time initiatives for market services ones.

4 Conclusions

This analysis showed that a significant share of enterprises took advantage of the recent tax incentives. Large enterprises (those in Cluster 1), especially operating in the market services, have benefitted more of them. Unfortunately, they had already a high level of provision. However, it is comforting that the medium enterprises (Cluster 2) used all the tax incentive opportunities provided by the State, even if small enterprises in both sectors (being prevalently in Cluster 3) seem not having enjoyed from tax incentives. A second relevant finding is that we verified that enterprises benefitting from the tax benefits (Cluster 1) supplied a wider range of OW services than those not benefitting of any incentive (Cluster 3). Thus, the answer to our research question is that the undertaken political economy measures have, at least partially, succeeded in their goal of facilitating OW spread. It would, therefore, be appropriate to maintain the tax incentive measures at the medium term.

The determinants of eco-innovation: a country comparison using the community innovation survey.

Le determinanti della eco-innovazione: un confronto tra Paesi basato sui dati CIS.

Ida D'Attoma and Silvia Pacei

Abstract We study the driving forces behind the adoption of different types of eco-innovation in German manufacturing sectors compared to Romania over 2012-2014, through an empirical analysis of the community innovation survey (CIS). To this end, we consider a measure of eco-innovation performance that counts different types of eco-innovation that enterprises have undertaken. Moreover, we consider a wide and comprehensive set of potential drivers, including "technology push", "regulatory push-pull" and "firm specific factors" clusters of drivers. Due to the count nature of our dependent variable and to the large presence of zeros, we estimate a zero-inflated negative binomial model. Preliminary findings show interesting differences in the determinants of eco-innovation in the two countries.

Abstract *In questo lavoro si studiano le determinanti dell'eco-innovazione, mettendo a confronto il settore manifatturiero tedesco con quello rumeno negli anni 2012-2014. A questo scopo si usano i dati dell'indagine sull'innovazione della comunità europea (CIS), e si misura il fenomeno attraverso il numero delle diverse tipologie di eco-innovazione che l'impresa realizza. Si considerano diverse potenziali determinanti, tra cui fattori legati alla tecnologia, alla normativa e caratteristiche specifiche dell'impresa. Data la natura della variabile oggetto di studio e l'elevata presenza di zeri si considera un modello Zero Inflated Negative Binomial. I risultati mostrano differenze interessanti fra le determinanti dell'eco-innovazione nei due Paesi.*

Key words: eco-innovation, eco-innovation drivers, CIS data, zero-inflated negative binomial regression.

1 Introduction

Eco-innovation is commonly understood as innovations that are associated with environmental benefits. Differently from traditional innovation, eco-innovation 'emphasizes the firms' mitigation of negative impacts on the natural environment' [7]. It is acknowledged that a positive relationship between eco-innovation and firm performance and growth exists, thus motivating the identification and the analysis of trigger factors for eco-innovation. The early study of [8] found that the more enterprises eco-innovate, the greater the positive impacts on their performance. Firms implementing eco-innovation tend to be recognized in a positive sense [1] by consumers that are nowadays increasingly aware of environmental topics. Not only to obtain or enhance social legitimacy but also to react or pre-empt their rival's environmental moves, corporations are inclined to use eco-innovation strategies to exploit emerging opportunities [7].

The main purpose of this study was to analyse the main factors enhancing firms focusing on a different number of eco- innovations in Germany and Romania. We constructed a count measure of eco-innovativeness and then we analysed its determinants by estimating a zero-inflated negative binomial model [3,4].

This paper contributes to the previous literature in several ways. First, additional quantitative evidence is provided regarding the determinants for eco-innovation. Second, few studies have focused on a cross-country analysis. Instead, we considered the cases of Germany and Romania, thereby expanding the geographical scope of econometric research on eco-innovation in Europe, which has to date largely focused only on Germany. Third, differently from the large body of literature that used to consider a binary measure of eco-innovativeness, we considered a multidimensional eco-innovation construct that keeps track of all eco-innovations that enterprises simultaneously adopt.

2 Data and Variables

This study was based on firm-level data from the 2014 European Union Community Innovation Survey (CIS) of Germany and Romania in the period 2012-2014. The sample covers 3250 manufacturing firms with more than 10 employees across different industries for Germany and 4325 manufacturing firms for Romania.

The CIS defines an eco-innovation as "a new or significantly improved product (good or service), process, organizational method or marketing method that creates

environmental benefits compared to alternatives". The definition is not only confined to the technological sphere but it also encompasses organizational and market aspects.

The outcome of our model was the number of eco-innovations adopted by a firm and ranged from 0 (no eco-innovation strategy were in place) through 10 (all environmental strategies were implemented)[1]. For what concerns explanatory variables, we followed a relatively recent body of literature that has focused on four main clusters of drivers: technology-push, regulatory-push-pull, market-pull, and firm specific factors [9,6]. As *technology-push* factors we considered the *degree of cooperation* defined as the number of innovation cooperation partners type with which the enterprise undertakes an active cooperation, the *innovation intensity* described by the ratio of the total expenditure on innovation and *technological capabilities* proxied by qualified employees. As *regulatory push-pull* factors, we took into account whether the enterprise has received public support for its innovation activity. Then, because CIS data did not allow us to directly consider the role of environmental regulations, as a proxy of environmental regulation we adopted the logarithm of CO2 air emissions intensities expressed as ratios relating carbon dioxide emissions to value added by manufacturing industries (classified by NACE Rev. 2) in each country considered. As *firm-specific* factors we considered firm size, industry, whether the firm belongs to a group, the foreign market focus, the exporting behaviour, the employee growth rate and the turnover growth rate. No market-pull factors were available. Moreover, we envisaged the forms of innovation protection as an important trigger factor of eco-innovation. In fact, in light of the double externality problem, even when a firm successfully reaches the market with an eco-innovation, the profit appropriation could result still difficult especially in case the eco-innovation is accessible to potential imitators [5], thus requiring protection.

3 Methodology

Due to the count nature of our dependent variable Y and the large presence of zeros, we use the zero-inflated Negative Binomial regression model (ZINB) [4,5]. In our case in fact, the Negative Binomial model may not accurately assign probability to the outcome $Y = 0$. The ZINB model assumes that a separate process is simultaneously influencing the outcome. Therefore, the ZINB model is a "two-part" count data model, as it considers two data generation processes. For each observation i the first process, represented by d_i, gives zero counts with probability πi (when $d_i = 0$), and with the complementary probability $1 - \pi_i$ (when di=1) the

[1] The CIS 2014 includes ten types of eco-innovations: material use reduction; energy saving; air, water, noise or soil pollution reduction within enterprise; substitution of polluting and hazardous materials; substitution of fossil energy with renewable energy; waste, water and material recycling ; CO2 emissions reduction; air, water, noise or soil pollution reduction during the consumption by the end user; recycling of a product after use; extending product life through longer - lasting, more durable products

second process Y_i provides counts according to a negative binomial with mean λ_i. Also the second process may generate zero counts.

The model can be represented as follows:

$Y_i = 0$ with probability π_i
$Y_i \sim NB(\lambda_i)$ with probability $1 - \pi_i$

so that, the probabilities connected to the two possible outcomes are:

$Prob[Y_i = 0] = \pi_i + (1 - \pi_i)R_i(0)$
$Prob[Y_i = j > 0] = (1 - \pi_i)R_i(j)$

where

$R_i(y)$ = the negative binomial probability = $\Gamma(\theta + y_i)/[y_i!\,\Gamma(\theta)]u_i^{\theta}[1 - u_i]^{y_i}$
$\theta = 1/\alpha$, where α is the overdispersion parameter
$u_i = \theta/(\vartheta + \lambda_i)$
$\lambda_i = exp(\boldsymbol{\beta}'\boldsymbol{x_i})$

with $\boldsymbol{x}_i$ as the vector of covariates and $\boldsymbol{\beta}$ the vector of related coefficients.

For probability π_i we use a logistic probability model:

$\pi_i \sim Logistic(\nu_i)$

and we define $\nu_i = \tau log(\lambda_i) = \tau\boldsymbol{\beta}'\boldsymbol{x_i}$. This implies the assumption of the same determinants for the two processes, thus requiring the estimation of only one more parameter, τ.

The joint density can be written as follows:

$P(y_i, d_i|\boldsymbol{x_i}) = (1 - d_i)\pi_i + d_i(1 - \pi_i)R_i(y)$

while the conditional mean function is $(1 - \pi_i)\lambda_i$.

4 Results

Our response variable is a count variable and represents the number of eco-innovations adopted by a firm[1]. With reference to Germany, 11% of firms in the data reported only one type of eco-innovation, whereas about 70% reported two or more types, as many as 4.4% reported all 10 and about 20% reported zero eco-innovations. The presence of zeros is higher in the Romania case, where about 57%

[1] The Cronbach's Alpha coefficient of our dependent variable was 0.83 and 0.89 for Germany and Romania, respectively.

of manufacturing firms reported zero eco-innovations, about 5% only one type, about 36% reported two or more types and only about 2% reported all 10.

Table 1 reports results of the estimated zero inflated negative binomial model for Germany and Romania, respectively. The Vuong statistic is 7.3 for Germany and 4.4 for Romania. In both cases it favors the zero-inflated negative binomial model.

Partial effects are the derivatives of the conditional mean function. Effects are averaged over units. To estimate our model, we use the software LIMDEP.

Source: Own elaboration of the CIS 2014 data.

The following variables were significant at 1% or 5% level for the Germany case: degree of cooperation, innovation intensity, environmental regulation, size, high-tech sector and level of protection. As far as the degree of cooperation is concerned, a partial effect of 1.5 indicates that a firm with a one unit change in the cooperation intensity is expected to have on average 1.54 more eco-innovations. This result might be due to the fact that eco-innovations are more complex and demanding than other types of innovation, thus requiring more resources picked up from external partners and sources of knowledge. In line with literature, innovation intensity was found to have a positive effect on eco-innovation. A firm with a one unit change in the internal and external R&D effort is expected to have 1.47 more eco-innovations. Environmental regulation was found to be an important stimulus to eco-innovation: if CO2 air emissions intensity increases of 1%, a firm is expected to have on average 0.15 more eco-innovations. The number of eco-innovations adopted by a firm increased as size classes increased (the smallest class dummy 1-49 employees was excluded from the model). Furthermore, for a one unit change in the level of protection, a firm is expected to have on average 0.33 more eco-innovations.

Conversely, firms in the high-tech sector are expected to have 1.15 less eco-innovation compared to the reference category (low-tech sector).

As far as Romania is concerned, similarly to Germany, a firm that experienced a one unit change in the cooperation intensity is expected to have more eco-innovations (+1.32). Differently from Germany, the following variables were significant at 1% or 5% level: export, foreign multinational and medium high-tech sector.

World ranking of urban sustainability through composite indicators

Una graduatoria della sostenibilità urbana nel mondo basata su Indicatori Compositi

Elena Grimaccia, Alessia Naccarato and Silvia Terzi

Abstract Urban population worldwide is steadily increasing creating huge problems of sustainable development. The 2030 Agenda chose to devote a whole goal to urban sustainability: Goal 11 of the Sustainable Development Goals (SDG). Despite such attention, not many empirical studies are based on SDGs indicators, due to scarce international comparability of the available data.
This paper draws on data from the very SDG dataset, with the aim of computing an Urban Sustainable Development Index, using different normalisation, aggregation and weighting systems for the construction of composite indicators (CIs). Our attention will focus on the comparison among the rankings derived from each synthetic index, thus assessing the rank robustness of the CI.
Abstract. *La popolazione urbana nel mondo è in costante crescita, creando enormi problemi di sviluppo sostenibile. L'Agenda 2030 ha scelto di dedicare un intero obiettivo alla sostenibilità urbana: il Goal 11 degli Obiettivi di Sviluppo Sostenibile (SDG). Nonostante tale attenzione, non sono molti gli studi empirici basati su indicatori SDG, a causa della scarsa comparabilità internazionale dei dati disponibili. Il nostro lavoro attinge direttamente al set di dati SDG, con l'obiettivo di calcolare un Indice di sostenibilità Urbana, utilizzando diversi metodi di normalizzazione, aggregazione e ponderazione per la costruzione di indicatori compositi (IC). Lo studio si concentrerà sul confronto tra le classifiche derivate da ciascun indice sintetico, valutando così la robustezza delle graduatorie dell'IC.*

Key words: urban sustainability, composite indicators, sustainable development, principal component analysis.

1. Introduction

Sustainability is today at the centre of the scientific and public debate. Our current economic paradigm, based on transformation of material basis poses a serious threat in terms of resource availability and pollution (Matthews et al., 2000). Furthermore, since 2007, more than half the world's population lives in cities or urban settlements and UN estimates that by 2030, cities will be home to 60% of the global population, a share that will further increase to about 68.4% by 2050 (UN, 2018). This means that between 2010 and 2050, between 2.5 to 3 billion people will be added to the urban population worldwide; with the highest growth in East Asia, South Asia, and sub-Saharan Africa. Given the estimates, the question of sustainable urbanisation is critical for most of the countries. The Sustainable Development Goal 11 of the United Nations Agenda 2030 - known as the 'urban SDG: to make cities and human settlements inclusive, safe, resilient and sustainable' - addresses directly the urban level with 10 targets and 15 indicators developed by the UN (UN, 2017). Nowadays, cities contribute about 80% of global GDP. However, cities also account for about 70% of global energy consumption, 70% of global carbon emissions, as well as over 70% of resource use, making it even more compelling for policy makers to design sustainable policies for urban settlements.

Sustainability is a complex multidimensional phenomenon that needs to be synthetized into a simple and readable measure that policy makers can use. Composite indicators (CI) summarise complex and multidimensional phenomena, and are useful tools to ease interpretation and to allow benchmarking. However, care must be taken in their construction and interpretation to avoid misleading policy messages (Floridi et al., 2011).

CIs (also referred to as synthetic indices) aggregate standardised or normalised variables with the aim of capturing different and relevant aspects of a possibly latent multidimensional reality (Becker et al 2017). CIs are heavily linked to normative assumptions in variable selection and weighting. Here 'normative' is understood to be 'related to and dependent on a system of norms and values'. The statistical analysis of CIs is essential to provide stakeholders reliable instruments for policies (OECD 2008, Saisana et al., 2011, Luzzati and Gucciardi 2015).

The present paper aims at computing an Urban Sustainable Development Index, using different normalisation, aggregation and weighting systems for the construction of CI. Our attention will focus on the comparison among the rankings derived from each synthetic index, thus assessing the rank robustness of the CIs.

2. Methodological framework

The theoretical context of our CIs in based on the UN 2030 Agenda framework, benefitting from the huge work of the numerous High Level Committees, that have defined the goals and chosen the target indicators (Hak, 2015, UN, 2015).

Indicators may be measured in different measurement units and on different scales, so prior to any aggregation, normalisation of the data is required. Among the different normalisation methods (Talukoler et al., 2017, Seth and McGillivray, 2018), we used the rankings of each indicator, that is the simplest normalisation technique; it is not affected by outliers but it causes loss of information on the level of country performance in absolute terms. We also applied a standardisation (or z-scores), that converts indicators to a common scale with a mean of zero and unit standard deviation. Finally, we used a min-max method, by subtracting the minimum value and dividing by the range of the indicator value in order to have an identical range [0, 1].

In the following weighting and aggregation step, the standardised indicators are combined together. The weight assigned to an indicator in a CI reflects its relative importance. However, the real weight of the non-standardised variable also depends on the transformation. Consequently, even equal weighting allows the original variables to have smaller or greater effects on the composite indicator.

Most existing CIs are linear, i.e. weighted arithmetic averages (Paruolo et al., 2012), but linear aggregation rules have been criticised because weaknesses in some dimensions are compensated by strengths in other dimensions; this characteristic is called 'compensatory'. Non-compensatory and non-linear aggregate ranking rules have been supported by some literature on multicriteria decision making (Munda and Nardo 2009). Geometric aggregations are, therefore, better suited if the modeller wants some degree of non-compensability between individual indicators or dimensions. Furthermore, linear aggregations reward base-indicators proportionally to the weights, while geometric aggregations reward those countries with higher scores.

Mathematical weights derived from Principal Component Analysis (PCA) are commonly used to assign weights to single variables, often using the first factor as the 'best' composite indicator (Booysen, 2002, Krishnakumar and Nagar 2008). The index obtained accounts for the largest amount of total variance in the individual indicators, and the first factor will be also correlated with at least some of the individual indicators.

3. Composite Indicators of Urban Sustainability

The SDG 11 on Sustainable cities and communities, with the aim of making cities "inclusive, safe, resilient and sustainable" consists of a number of targets, including: adequate, safe and affordable housing; accessible and sustainable transport systems for all; inclusive and sustainable urbanisation; to reduce the number of people affected by disasters; to reduce the environmental impact of cities. We selected five variables, for the period 2014-2017, measuring five different aspects of urban sustainability: 1.proportion of urban population living in slums, informal settlements or inadequate housing ("Slums", negative polarity[1]); 2.number of deaths, missing persons and

[1] We speak of 'negative polarity' when the variable and the latent construct of urban sustainability, in the theoretical framework, have negative correlation.

directly affected persons attributed to disasters per 100,000 population ("Disasters", negative polarity); 3.proportion of urban solid waste regularly collected ("Waste") 4.annual mean levels of fine particulate matter ("Particulate", negative polarity); 5.proportion of local governments that adopt and implement local disaster risk reduction strategies, in relation with the Sendai Framework for Disaster Risk Reduction ("Sendai").

The analysis was developed with reference to UN countries. We applied various procedures to address missing data. We chose to include only indicators available for at least 90% of the 149 UN Member States. And we included in the data set Only countries having data for at least 70% of the indicators. To impute missing values, we performed a cluster analysis (based on the values of the 3 Human Development Index sub-indicators) and replaced missing values on target indicators with cluster average values.

The indicators included in the SDG11 are quite heterogeneous, which leads to weak correlations. Notice that the sign of the correlations are consistent with theorical expectations.

Table 1: Correlations among SDG11 indicators

SDG11 indicators	Slums	Disasters	Waste	Particulate	Sendai
Slums	1				
Disasters	0.2790	1			
Waste	-0.1938	-0.0161	1		
Particulate	0.4790	0.3963	-0.1547	1	
Sendai	-0.1223	0.0007	0.1133	-0.0679	1

4. Results

In order to build a CI of Urban Sustainability, we applied the standardisation and aggregation methodologies stated above, and we obtained five different CIs. The first one has been constructed by a linear aggregation of the rankings of the different variables; the second is the geometric aggregation of the rankings; the third uses a normalisation through the z-scores and then a linear aggregation; the fourth a min-max standardisation and then a linear aggregation, and the last applies PCA weights. For the variables where a larger value corresponded to a lower urban sustainability (negative polarity), the normalisation or standardisation had reverse sign. After normalization or standardisation were ranked in ascending order. Computing the median of the five rankings obtained according to the five different procedures, we ranked countries in descending order of Urban Sustainability. In figure 1, we plot, for each country, the median rank and its range.

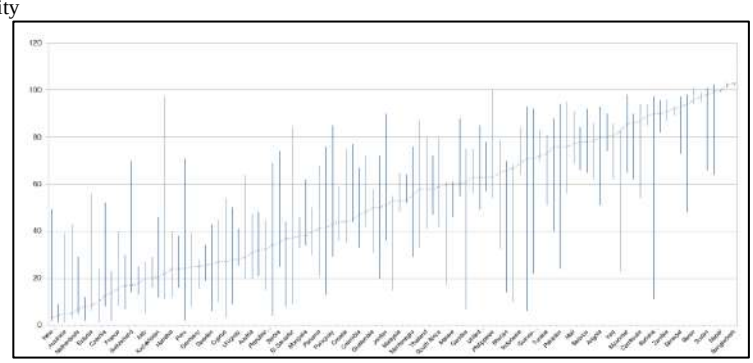

Figure 1: Composite indicators of Urban Sustainability: median, min and max of world Countries

Among the best performing countries, we found Japan, Oceanian countries and some North European countries, while China, South-Est Asian Countries, and Sub-Saharan African countries present the lowest levels of urban sustainability. However, the different rankings provided homogenous results only for some of the countries. In fact, most high and middle-range countries –in particular Lebanon, many Balkan countries, and some South American countries – present high variability across the different rankings. As expected, the higher correlations are between the two classical aggregation methods (standardisation and min-max) and among the linear and geometric aggregations of rankings. The CI based on PCA weights presents smaller rank correlations with the other methods and the greatest sum of the absolute distances from the median ranking. Also in terms of distances among the different rankings, we must conclude that the rankings are sensitive to transformation and aggregation procedures. This is probably due to low correlations among the original variables. However, a deeper insight would be useful.

Table 2: Rank correlations according to the different methodologies

	Linear aggregation of rankings	Geometric aggregation of rankings	Linear aggregation of min-max	Linear aggregation of z-scores	PCA weights
Linear aggreg. rankings	1				
Geometric aggreg. rankings	0.963	1			
Linear aggreg. min-max	0.819	0.783	1		
Linear aggregat. z-scores	0.879	0.832	0.967	1	
PCA weights	0.548	0.570	0.293	0.352	1
Deviation from the median ranking	*474*	*662*	*963*	*732*	*1987*
MAD (median absolute deviation)	*2*	*4*	*6.5*	*4*	*12*

Final remarks

The result obtained so far is to rank worldwide countries on the basis of the indicators selected by the UN for monitoring Goal 11 of the SDGs stated in the 2030 Agenda. Applying different normalisation, aggregation and weighting systems our aim was to assess the robustness of the suggested composite indicator. We conclude however that the rankings are sensitive to the chosen transformations and aggregations. The next step of our research will be to exploit model-based CIs or methods that account for association among original variables.

Machine Learning and Data Science

A novel approach for Artificial Intelligence through Lorenz zonoids and Shapley Values

Un approccio basato sugli Zonoidi di Lorenz e gli Shapley Values nell'ambito dell'Intelligenza Artificiale

Paolo Giudici and Emanuela Raffinetti

Abstract In the era of big data and data science, Artificial Intelligence systems play a basic role. If on the one hand, Artificial Intelligence models deeply affect the decision process, on the other hand the lack of transparency of their black-box approaches may lead to distrust in Machine Learning methods. Explainability thus becomes a crucial issue, to understand how inputs in a model generate the outputs. In this paper, we provide a Shapley-Lorenz zonoid approach to assess the marginal contribution associated with each additional covariate in all the possible model configurations. In this way, the assessment of each effect contribution results more accurate and interpretable, leading to select the most parsimonious model with the minimum loss of information.

Abstract *Nell'era del data science, i sistemi di Intelligenza Artificiale svolgono un ruolo fondamentale. Se da un lato, i modelli di Intelligenza Artificiale influenzano profondamente il processo decisionale, dall'altro la mancanza di trasparenza dei loro approcci può pregiudicare la fiducia nei confronti dei metodi di Machine Learning. Di conseguenza, la spiegabilità rappresenta un aspetto cruciale soprattutto nello stabilire come gli input in un modello possano generare gli output. Mediante l'utilizzo degli Zonoidi di Lorenz e degli Shapley values, viene proposto un nuovo approccio per la valutazione del contributo marginale associato all'inclusione di ciascuna covariata con riferimento a tutte le possibili configurazioni di modello. In questo modo, la valutazione del contributo di ciascun effetto risulta maggiormente accurata e interpretabile, portando a selezionare facilmente il modello più parsimonioso che comporta la minima perdita di informazione.*

1 Introduction

Researchers in data science are paying close attention on the subject of the eXplainable Artificial Intelligence (XAI) and its possible fields of application. The notion of XAI is increasingly discussed and required by both public and private organizations in order to provide transparent and effective machine learning methods (see, e.g. [1], [2]). The idea is to introduce a suite of techniques that, on the one hand, allows to improve the interpretability of the models and, on the other hand, to preserve an adequate level of prediction accuracy.
The emerging aspect is that explainability represents a crucial issue for all practitioners to better understand, trust, and deal with powerful artificial intelligence systems. This led many scholars to promote new XAI methods in order to manage applications in the field of finance, among others, focused on credit risk management and default risk analysis (see e.g., [3] and [4]). For instance, in [4] an explainable AI model based on similarity networks (see [7] for more details) and Shapley values is proposed to measure credit risks associated to the use of credit scoring platforms. Shapley values were originally introduced by [8] as a solution concept in cooperative game theory. They correspond to the average of the marginal contributions of the players associated with all the possible orders of the players.
In the model explanation process, Shapley values can be exploited for measuring the average marginal contribution of each feature to the prediction of a machine-learning model (see, e.g. [9]). In line with these contributions, recently [5] introduced a novel model selection measure which is based on the employment of the Lorenz Zonoid tool (see, [6]) and on a mutual notion of variability more robust to the presence of outlying observations.
In this paper a new measure providing each explanatory variable marginal contribution in explaining the variability of the response variable in all the possible covariate model-configurations is proposed by combining the Lorenz Zonoid tool with the Shapley value based-approach. In this way, the assessment of each effect contribution results as more accurate and interpretable, leading to easily select the most parsimonious model with the minimum loss of information.

2 Background: Shapley values and Lorenz zonoids

An overview on the Shapley value and Lorenz zonoid tools is reported in order to illustrate the main features exploited for the construction of our proposal.

Shapley values
Shapley values were originally introduced by [8] as a pay-off concept from cooperative game theory. When referring to the machine learning models, the players of the cooperative game ,aimed at generating a pay-off, are replaced by the X_k variables within a model, aimed at generating predictions $\hat{f}(X)$. Following [9] and by using a notation coherent with that considered for the construction of our proposal, the

marginal contribution from variable X_k is expressed in the form of Shapley values as

$$\phi_S^{X_k}(\hat{f},X) = \sum_{X' \subseteq \mathscr{C}(X) \setminus X_k} \frac{|X'|!(n_k - |X'| - 1)!}{n_k!} [\hat{f}(X' \cup X_k) - \hat{f}(X')], \quad (1)$$

where $\mathscr{C}(X) \setminus X_k$ is the set of all the possible configurations of $m-1$ models excluding variable X_k, $|X'|$ denotes the number of variables included in the model, n_k is the number of the available variables, $\hat{f}(X' \cup X_k)$ and $\hat{f}(X')$ are the predictions associated with all the possible model configurations including variable X_k and excluding variable X_k, respectively. The quantity within the squared parentheses defines the contribution of variable X_k to the model prediction for any single observation.

Lorenz zonoids

The Lorenz zonoid was introduced by [6] as a generalization of the Lorenz curve in d dimensions. In the case of $d = 1$ the Lorenz zonoid corresponds with the Gini coefficient.

Suppose to consider a response variable Y and a set of explanatory variables $X_1, \ldots, X_j, \ldots, X_h$, with $j = 1, \ldots, h$. In order to evaluate the relationships between Y and the $X_1, \ldots, X_h$ explanatory variables, a linear regression model is applied, and the associated linear predicted values, denoted with $\hat{Y}_{X_1,\ldots,X_h}$, are determined. The Lorenz zonoids of Y and $\hat{Y}_{X_1,\ldots,X_h}$ can be defined as (see, e.g. [5])

$$LZ_{d=1}(Y) = \frac{2Cov(Y, r(Y))}{n\mu} \text{ and } LZ_{d=1}(\hat{Y}_{X_1,\ldots,X_h}) = \frac{2Cov(\hat{Y}_{X_1,\ldots,X_h}, r(\hat{Y}_{X_1,\ldots,X_h}))}{n\mu}, \quad (2)$$

where n is the total number of observations, μ is the response variable Y mean value, $r(Y)$ and $r(\hat{Y}_{X_1,\ldots,X_h})$ are the rank scores corresponding to the Y and $\hat{Y}_{X_1,\ldots,X_h}$ variables. Given a sample data of size n, formulas in (2) can be defined as

$$LZ_{d=1}(y) = \frac{2Cov(y, r(y))}{n\bar{y}} \text{ and } LZ_{d=1}(\hat{y}_{y_1,\ldots,y_h}) = \frac{2Cov(\hat{y}_{x_1,\ldots,x_h}, r(\hat{y}_{x_1,\ldots,x_h}))}{n\bar{y}}, \quad (3)$$

where y and $\hat{y}_{x_1,\ldots,x_h}$ are the vectors of the observed and predicted values, $r(y)$ and $r(\hat{y}_{x_1,\ldots,x_h})$ are the ranks of the observed and predicted values, and $\bar{y}$ is the sample mean.

In [5], the Lorenz zonoids were exploited giving rise to new dependence measures suitable in assessing the contribution of each explanatory variable to the predictive power of a linear model. Specifically, a Marginal Gini Contribution (*MGC*) measure, allowing to measure the absolute explanatory power of any single covariate, and a Partial Gini Contribution measure (*PGC*), allowing to measure the additional contribution of a new covariate to an existing model, were developed as follows.

Let X_j be one of the h explanatory variables ($j = 1, \ldots, h$). The marginal contribution provided by the single covariate X_j is

$$MGC_{(Y|X_j)} = \frac{LZ_{d=1}(\hat{Y}_{X_j})}{LZ_{d=1}(Y)} = \frac{Cov(\hat{Y}_{X_j}, r(\hat{Y}_{X_j}))}{Cov(Y, r(Y))}. \quad (4)$$

Let $\hat{Y}_{X_1,\ldots,X_h}$ and $\hat{Y}_{X_1,\ldots,X_{h-1}}$ be the predicted values provided by a full linear regression model, including all the covariates, and a reduced linear regression model model, excluding covariate X_h. The additional contribution related to the inclusion of covariate X_h can be determined as

$$PGC_{Y,X_h|X_1,\ldots,X_{h-1}} = \frac{LZ_{d=1}(\hat{Y}_{X_1,\ldots,X_h}) - LZ_{d=1}(\hat{Y}_{X_1,\ldots,X_{h-1}})}{LZ_{d=1}(Y) - LZ_{d=1}(\hat{Y}_{X_1,\ldots,X_{h-1}})}. \quad (5)$$

Sample and Covariance-based versions of formulas in (4) and (5) can be found in [5].

3 Proposal: a Shapley-Lorenz based approach

In line with the need of achieving both high predictive accuracy and interpretability, a new methodology which combines the Shapley value approach with the Lorenz zonoid tool is introduced. Specifically, the marginal contribution associated with each additional covariate in different model configurations can be formalized as

$$LZ^{X_k}_{d=1}(\hat{Y}) = \sum_{X' \subseteq \mathscr{C}(X) \setminus X_K} \frac{|X'|!(n_k - |X'| - 1)!}{n_k!} [LZ_{d=1}(\hat{Y}_{X' \cup X_k}) - LZ_{d=1}(\hat{Y}_{X'})], \quad (6)$$

where $LZ_{d=1}(\hat{Y}_{X' \cup X_k})$ and $LZ_{d=1}(\hat{Y}_{X'})$ describes the variability explained by the models including the $X' \cup X_k$ variables and the X' variables, respectively.
As shown in [5], $LZ_{d=1}(\hat{Y}_{X' \cup X_k})$ and $LZ_{d=1}(\hat{Y}_{X'})$ in equation (6) may be expressed as function of the covariance operator, leading to

$$LZ_{d=1}(\hat{Y}_{X' \cup X_k}) = \frac{2}{n\mu} Cov(\hat{Y}_{X' \cup X_k}, r(\hat{Y}_{X' \cup X_k})) \quad \text{and} \quad LZ_{d=1}(\hat{Y}_{X'}) = \frac{2}{n\mu} Cov(\hat{Y}_{X'}, r(\hat{Y}_{X'})). \quad (7)$$

Given a data sample of size n, denoting with $\bar{y}$ the sample mean, $\hat{y}_{X' \cup X_k(i)}$ and $\hat{y}_{X'(i)}$ the predicted values provided by the model including and excluding the X_k covariate and ordered in non-decreasing sense, the formulas in equation (7) become

$$LZ_{d=1}(\hat{y}_{X' \cup X_k}) = \frac{2}{n\bar{y}} Cov(\hat{y}_{X' \cup X_k}, r(\hat{y}_{X' \cup X_k})) = \frac{2}{n\bar{y}} \left[\frac{1}{n} \sum_{i=1}^{n} i\hat{y}_{X' \cup X_k(i)} - \frac{n(n+1)}{2n} \right] \quad (8)$$

and

$$LZ_{d=1}(\hat{y}_{X'}) = \frac{2}{n\bar{y}} Cov(\hat{y}_{X'}, r(\hat{y}_{X'})) = \frac{2}{n\bar{y}} \left[\frac{1}{n} \sum_{i=1}^{n} i\hat{y}_{X'} - \frac{n(n+1)}{2n} \right]. \tag{9}$$

Generally, the marginal contribution associated with all the possible model configurations including the explanatory variable X_k is specified as

$$\begin{aligned} LZ_{d=1}(\hat{Y}_{X'\cup X_k}) - LZ_{d=1}(\hat{Y}_{X'}) &= \frac{2}{n\mu} Cov(\hat{Y}_{X'\cup X_k}, r(\hat{Y}_{X'\cup X_k})) - \frac{2}{n\mu} Cov(\hat{Y}_{X'}, r(\hat{Y}_{X'})) \\ &= \frac{2}{n\mu} \left[Cov(\hat{Y}_{X'\cup X_k}, r(\hat{Y}_{X'\cup X_k})) - Cov(\hat{Y}_{X'}, r(\hat{Y}_{X'})) \right]. \end{aligned} \tag{10}$$

After some mathematical manipulations, the sample version of equation (10) can be re-written as

$$\begin{aligned} &LZ_{d=1}(\hat{y}_{X'\cup X_k}) - LZ_{d=1}(\hat{y}_{X'}) = \frac{2}{n\bar{y}} \left[Cov(\hat{y}_{X'\cup X_k}, r(\hat{y}_{X'\cup X_k})) - Cov(\hat{y}_{X'}, r(\hat{y}_{X'})) \right] \\ &= \frac{2}{n\bar{y}} \left[\frac{1}{n} \left(\sum_{i=1}^{n} i\hat{y}_{X'\cup X_k(i)} - \sum_{i=1}^{n} i\hat{y}_{X'(i)} \right) \right] = \frac{2}{n^2\bar{y}} \left[\sum_{i=1}^{n} i \left(\hat{y}_{X'\cup X_k(i)} - \hat{y}_{X'(i)} \right) \right]. \end{aligned} \tag{11}$$

Based on formula in (11), the marginal contribution due to the different model configurations including the covariate X_k is defined as

$$LZ_{d=1}^{X_k}(\hat{y}) = \sum_{X' \subseteq \mathscr{C}(X)\setminus X_K} \frac{|X'|!(n_k - |X'| - 1)!}{n_k!} \left\{ \frac{2}{n^2\bar{y}} \left[\sum_{i=1}^{n} i \left(\hat{y}_{X'\cup X_k(i)} - \hat{y}_{X'(i)} \right) \right] \right\}. \tag{12}$$

4 Application

As an applied example, we refer, without loss of generality, to the cryptocurrency data illustrated in [5]. The analysis focuses on the Coinbase Bitcoin as the target variable and Oil, Gold and SP500 as explanatory variables. Three different scenarios are built, according to the additional inclusion of each considered covariate in all the possible configuration models. First, the marginal contribution associated with the inclusion of variable SP500 and, subsequently, those related to the inclusion of variables Gold and Oil, are provided according to sample version of formula in (6).

For the sake of clarity, when considering the SP500 as the additional explanatory variable, the marginal contribution is derived as

$$LZ_{d=1}^{SP500}(\widehat{Coinbase}) = (1/3)(LZ(\hat{y}_{SP500,Gold,Oil}) - LZ(\hat{y}_{Gold,Oil}))$$
$$+ (1/6)(LZ(\hat{y}_{SP500,Gold}) - LZ(\hat{y}_{Gold})) + (1/6)(LZ(\hat{y}_{SP500,Oil}) - LZ(\hat{y}_{Oil}))$$
$$+ (1/3)(LZ(\hat{y}_{SP500})).$$

Analogously, we obtain the marginal contributions due to the Gold and Oil variables. Results are displayed in Table 1.

Additional covariate (X_k)	$LZ_{d=1}^{X_k}(\widehat{Coinbase})$
SP500	0.336
Gold	0.097
Oil	0.075

Table 1 Marginal contribution of each covariate in all the possible model configurations

From Table 1, variable SP500 provides the highest marginal contribution in explaining the daily Coinbase Bitcoin prices in different model configurations, while the minimum contribution is given by the variable Oil.

A warning signal for variable importance interpretation in tree-based algorithms

Un segnale di allarme per l'interpretazione dell'importanza delle variabili in algoritmi basati su alberi

Anna Gottard and Giulia Vannucci

Abstract Tree-based learning algorithms are largely utilized in several scientific domains. Each algorithm specifies a proper variable importance measure that captures the magnitude of the predictive importance of an explanatory variable. In applied studies, such measures are sometimes interpreted as importance relative to the data generating process, but this can be misleading. To prevent erroneous interpretation of the variable importance there is a need of a measure capable of detecting when the predictive variable importance differs from the explanatory one. We propose a measure that can act as a warning signal of this situation.

Abstract *Gli algoritmi basati su alberi sono ampiamente utilizzati in molte discipline scientifiche. Ogni algoritmo specifica una propria misura di importanza delle variabili, che cattura la grandezza dell'importanza preditiva di una variabile esplicativa. In alcuni studi, tali misure vengono talvolta interpretate come importanza relativa al processo generatore dei dati, anche se questo può essere fuorviante. Per prevenire un'interpretazione erronea dell'importanza delle variabili c'è bisogno di una misura in grado di rilevare quando l'importanza delle variabili predittiva è diversa da quella esplicativa. Proponiamo una misura che può agire da segnale di pericolo di questa situazione.*

1 Introduction

Tree-based algorithms refer to a class of predictive models widely employed in several scientific domains. Besides being conceptually simple, capable of dealing with non-linearities and interactions and suitable also in high-dimensional settings, they are appreciated for their simple interpretation. Tree-based algorithm interpretation is usually based on a variable importance measure, that captures the magnitude of the contribution of each feature to the response prediction. The predictive importance is sometimes confused with an explanatory importance [4, 7]. Some examples of application of tree-based models to identify the relevant variables can be found, among many others, in [5] and [12]. The correct interpretation of these models raises a lot of interest in the scientific community. As a matter of facts, when tree-based algorithms are employed in real contexts, it is essential to know if they induce biases and prejudice, or lead to unfair and wrong decisions [8]. In [7], it has been shown that interpreting variable importance as representative of the direct effects in an explanatory sense can lead to incorrect scientific and practical conclusions. In this work, we explore more cases where this issue comes out, and we propose some measures that can be used as a warning signal of the misleading use of variable importance. These measures are based on the distance between the conditional and unconditional variable importance proposed, respectively, by [3] and [14].

2 An issue in variable importance interpretation

To show a situation where the variable importance can be misleadingly interpreted, we consider here two data generating processes described by the following system of equations and depicted by the two directed acyclic graphs in Figure 1.

$$\begin{cases} X_1 = \varepsilon_1 \\ X_j = aX_1 + \varepsilon_j \quad \text{for } j = 2,3,5 \\ X_4 = aX_2 + \varepsilon_4 \\ X_6 = aX_3 + \varepsilon_6 \\ Y \ = bX_4 + bX_5 + bX_6 + \varepsilon_Y. \end{cases} \tag{1}$$

$$\begin{cases} X_j = \varepsilon_j \quad \text{for } j = 1,2,3 \\ X_4 = aX_2 + \varepsilon_4 \\ X_5 = aX_1 + \varepsilon_5 \\ X_6 = aX_3 + \varepsilon_6 \\ Y \ = bX_4 + bX_5 + bX_6 + \varepsilon_Y. \end{cases} \tag{2}$$

These data generating processes concern a response variable Y, three variables, X_4, X_5 and X_6, having a direct effect on Y, and three variables, X_1, X_2 and X_3, having an indirect effect on Y. For both data generating processes $Y \perp\!\!\!\perp (X_1, X_2, X_3) \mid (X_4, X_5, X_6)$, but a different association is assumed among the background variables. In particular, the generating process (2) assumes X_1, X_2 and X_3 to be pairwise independent, while the generating process (1) assumes them correlated. We conducted a minimal simulation study on 100 data sets with size 500 generated from (1) and (2). All the datasets are sampled assuming independent errors ε_ℓ, $\ell \in \{1, \ldots, 6, Y\}$, with a standard normal distribution and $a = b = 3$.

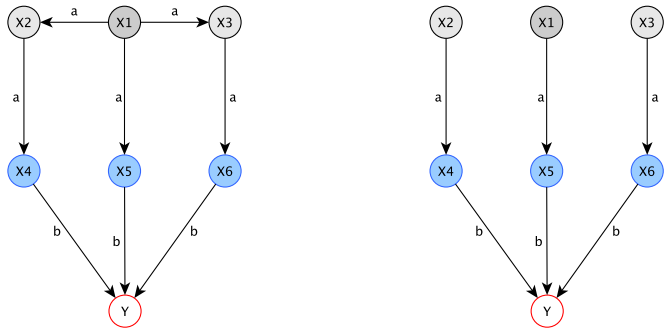

Fig. 1 Directed acyclic graphs relative to the data generating processes described in (1) on the left and (2) on the right

In Figure 2 we show the Monte Carlo distributions of the variable importance measures for the CART algorithm [2] (R package: `rpart`). This variable importance measure, proposed by Breiman [3] for the random forests, is based on the difference of the prediction accuracy before and after permuting the observed values of X_j. In the following, we will call this measure *unconditional variable importance* (VI^{u}).

$$VI^{\mathrm{u}}(X_j) = \frac{1}{H}\left\{\sum_{i=1}^{H}\left[Y_i - \widehat{Y}_i(X_{j,\mathtt{perm}})\right]^2 - \sum_{i=1}^{H}\left[Y_i - \widehat{Y}_i(X_j)\right]^2\right\} \tag{3}$$

where H is the size of the test set, $\widehat{Y}_i(X_{j,\mathtt{perm}})$ is the prediction on the test set when X_j is permuted, while $\widehat{Y}$ is the ordinary test set prediction. Following [3], in the plot the measures are rescaled to sum to 1. The simulation study indicates that for data generated by (2), X_4, X_5, X_6 are found to be the most important variables. Conversely, for data generated by (1), the background variable X_1 appears as the most important. Therefore, the mere presence of association among the background variables X_1, X_2 and X_3 induces an incorrect identification of the importance of variables to describe the data generating mechanism. This makes misleading to interpret the variable importance measures in an explanatory sense. As shown in [7], algorithms for tree construction based on a greedy splitting strategy exhibit a bias in the correct identification of relevant predictors, in the presence of irrelevant variables with high marginal association. In these situations, an explanatory variable which has an indirect effect on the response is preferred by the tree-based algorithms to forecast the response variable, inducing a discrepancy between the predictive and explanatory interpretation of feature importance. Our purpose is to give a measure that can signal this type of misleading interpretation.

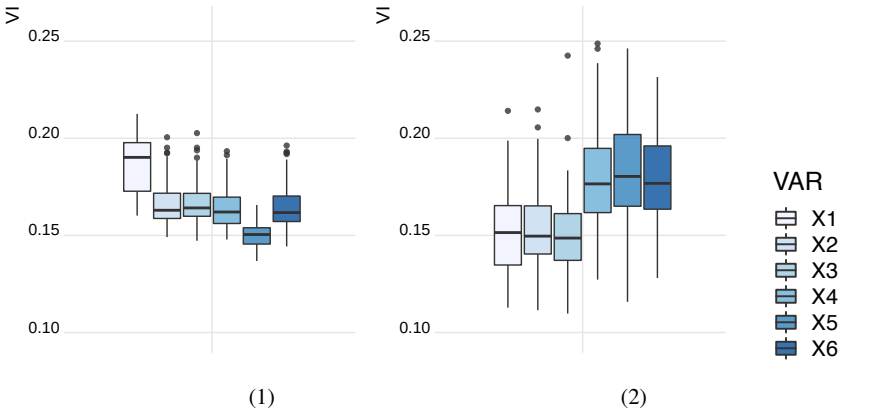

Fig. 2 Boxplot of the Monte Carlo distributions of the variable importance measures under the data generating processes described in (1) on the left and (2) on the right

3 Measures of warning

As the data generating process is usually unknown, it is not possible to know a priori if the observed set of variable importance measures can be safely interpreted in an explanatory sense. In this section, we propose some measures that can act as an alarm bell for possible misleading interpretation and potential unfairness in using tree-based algorithms. These measures of warning are based on the discrepancy between the variable importance measure in (3) and the variable importance measure proposed by [14], that permutes X_j only within a grid of values of the feature space.

$$VI^{\mathrm{c}}(X_j) = \frac{1}{H}\left\{\sum_{i=1}^{H}\left[Y_i - \widehat{Y}_i(X_{j,\mathtt{perm}|\boldsymbol{X}_{-j}})\right]^2 - \sum_{i=1}^{H}\left[Y_i - \widehat{Y}_i(X_j)\right]^2\right\} \tag{4}$$

where $\boldsymbol{X}_{-j}$ is an element of the permutation grid. As it can be seen in Figure 3 this measure of variable importance is more robust to the issue presented in Section 2.

A simple visual comparison of discrepancy between the two sets of variable importance measures can be used as a warning signal. As an alternative, one can compare variable importance ranks, checking for ranking inversions. However, only ranks inversions for the most important variables can be considered relevant, while inversions among variables with negligible importance can be due to sampling or permutation variability.

To obtain a proper measure of the discrepancy between these variable importance measures, notice that they have a different scale and cannot be directly compared. However, they carry interesting relative information if considered compositional, by scaling each vector to sum to 1. Let us denote $\boldsymbol{V}^{\mathrm{c}}$ and $\boldsymbol{V}^{\mathrm{u}}$ the vector of the compositional version of the conditional and unconditional variable importance in 4 and 3, respectively. The sample space of each vector is the standard simplex $\mathbb{S}^p = \{(v_1, \ldots v_p) \mid \sum_{i=1}^{p} v_i = 1, \text{ where } v_i \geq 0\}$. A Euclidean distance between these

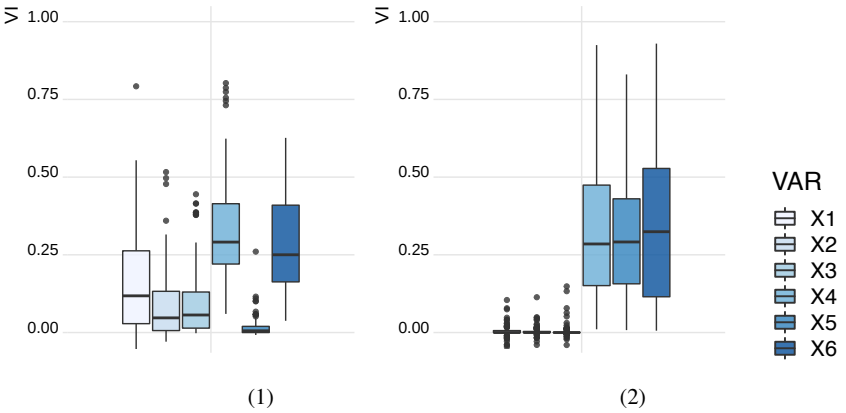

Fig. 3 Boxplot of the Monte Carlo distributions conditional variable importance measures under the data generating processes described in (1) on the left and (2) on the right

two vectors is ill-suited because of their compositional nature, and an Aitchison geometry [1] can be adopted instead. A possible distance between the two variable importance vectors is

$$d_a(\boldsymbol{V}^{\mathrm{u}}, \boldsymbol{V}^{\mathrm{c}}) = \sqrt{\frac{1}{2p}\sum_{i=1}^{p}\sum_{i=1}^{p}\left(\ln\frac{v_i^{\mathrm{u}}}{v_j^{\mathrm{u}}} - \ln\frac{v_i^{\mathrm{c}}}{v_j^{\mathrm{c}}}\right)}, \tag{5}$$

or a similar formula where the denominators are replaced by the geometric means, when using the so-called centred log-ratio transformation. These distances can be adopted whenever all the entries of the compositional vectors are strictly positive. At the presence of zero variable importance measures, [1] suggests to add small amounts to the zero entries. Even if this solution is not sub-compositionally coherent, it works quite well in our case, where the main issue concerns the most important variables. [6] and [9] transformations can be considered as another option. Alternative metrics could be used that treat compositional data as directional data. See for instance [13], [10] and [11] for this approach.

4 Concluding Remarks

Machine learning algorithms are powerful tools for prediction tasks. Interpretable machine learning is raising the attention of the scientific community, due to its spread out of the ordinary technological application field, guaranteeing fair and accurate predictions. Among the machine learning algorithms, the tree-based ones are considered the more easy interpretation, because of the tree diagrams and variable importance measures. However, these measures are more and more frequently interpreted in an explanatory sense. In this paper, we showed a situation in which this kind of interpre-

tation is misleading, in line with what suggested by [7] and proposed some measures that can act as an alarm bell of this issue. In the paper, we limited the discussion to the case of regression trees, but what presented is valid also for classification trees, random forests and boosted trees.

Assessment of the effectiveness of digital flyers: analysis of viewing behavior using eye tracking

Valutazione dell'efficienza dei volantini digitali: analisi del comportamento visivo tramite eye tracking

Gianpaolo Zammarchi[1], Claudio Conversano[2], Francesco Mola[3]

Abstract Digital flyers are commonly used by retailers to promote their products and special offers. However, only a small number of studies have explored how visual information presented by digital flyers is processed by consumers. We designed three tasks to evaluate differences in the way a group of university students recruited at the University of Cagliari looked at digital flyers of two different retailers advertising technology products. The viewing behavior was assessed using the eye tracking technology, which allows to register the sequence of observations made by a subject when looking at a visual stimulus. The analysis of metrics such as time to completion and number of fixations, as well as Markov Chain analysis conducted on fixations, showed differences in the performance of the two flyers. These differences will be further explored to detect relevant aspects to improve the effectiveness of digital flyers. Additional analyses are currently ongoing to identify clusters of subjects sharing similar viewing behavior as well as characteristics of the areas of interests (AOI) associated with a higher number of fixations during free observation.

Abstract *I volantini in versione digitale vengono sempre più utilizzati dai rivenditori per promuovere i propri prodotti ed offerte speciali. Tuttavia, solo un numero ridotto di studi ha esplorato il modo nel quale le informazioni visive presentate nei volantini digitali sono processate dai consumatori. studenti dell'Università di Cagliari ha osservato i volantini digitali di due diversi rivenditori di prodotti tecnologici. Il comportamento visivo è stato valutato tramite l'eye tracking, una tecnologia che consente di registrare la sequenza di osservazioni durante l'osservazione di uno stimolo visivo. L'analisi dei tempi di completamento e del numero di fissazioni, così come un'analisi sulle fissazioni condotta tramite Markov Chain, ha permesso di evidenziare alcune differenze nelle performance dei due volantini. Queste differenze verranno ulteriormente esplorate per identificare accorgimenti che consentano di migliorare l'efficacia di un volantino digitale. Inoltre, ulteriori analisi sono in corso per identificare cluster di partecipanti che presentino un comportamento visivo simile oltre che caratteristiche delle aree di interesse (AOI) associate ad un maggior numero di fissazioni durante una fase di osservazione libera.

Key words: flyers, eye tracking, digital marketing, Markov Chain

1 Introduction

Nowadays almost every company exploits the potential of Internet using digital marketing techniques in order to reach a higher number of people and decrease costs. However, retailers keep using traditional approaches such as paper flyers (also known as door drop flyers) to advertise their products and special offers. Digital flyers represent a clever way to combine traditional and innovative approaches, through the creation of a flyer that shows a higher number of products and their characteristics compared to a classic internet ad, still having the chance to reach a higher number of people compared to paper flyers.

Eye tracking is a technology that allows to evaluate with high precision the sequence of observations made by a subject. This technology has successfully been used to evaluate how people interact with a web page [1,2,5,8]. However, only few studies have applied it to evaluate how visual information is processed by the consumers during the observation of flyers [3]. Data on visual observations might allow to identify differences in the observation of distinct visual stimuli (e.g. to measure differences in the effectiveness of two digital flyers) as well as clusters of subjects that share similar patterns of observations.

In this study we used eye tracking to analyze the viewing behavior of a sample of university students recruited at the University of Cagliari, Italy, aiming to identify differences in the performance of digital flyers from two different retailers. We followed a research path characterized by the four steps described in the following section.

2 Research path

2.1 Design of the tasks

This study aims to explore the differences between different types of flyers using the eye tracker. We selected the latest flyers from two major retailers promoting technology products. We created three tasks based on the products advertised, paying attention to choose pages that contained the same type of objects.

The tasks involved finding a specific product (unique for each task) that met the features communicated to the participant right before the test (Table 1). To complete the task, the participant had to search for the object satisfying the features on a specific page of one flyer and then on the other one (the two flyers were presented in random order). The search started immediately after communicating to the participant the criteria needed to choose the object and ended when the subject communicated the name of the right object. This procedure was repeated for the second flyer. In case of error in the identification of the object, the participant was told to keep searching and the number of errors was registered. During the test, the participants had to use only their eyes (no mouse, no keyboard) to locate the object. Before the task was started, the study procedures were explained to each subject.

Table 1: Description of the tasks

Task	***Description of the Task***
Task 1	Find the washer machine with the lowest price
Task 2	Find the smartphone with the best percentage of discount
Task 3	Find a TV screen measuring at least 40 inches, with the lowest original price

2.2 Sampling

Participants were recruited among university students, mainly from Economics and Law departments, randomly selected in group study rooms (in different days of the week and different times of the day). Each student performed the three tasks and information about age, gender, residency and university course were collected.

2.3 Assessment of eye movements

For each participant, eye movements during the task were gathered with a screen-based Tobii X2-60 Compact eye tracker, which captures gaze data at 60 Hz, applied to a 25-inch monitor. For each participant, the instrument was calibrated according to the specific height and distance from the screen. The velocity-threshold fixation identification (I-VT) algorithm implemented in Tobii Studio v. 3.3.1 was used to classify eye movements into different types (e.g. saccade, fixation, etc.). The algorithm classifies eye movements based on the velocity of the directional shifts of

the eye. Among different types of eye movements, we chose to focus on fixations, which are considered the metric of most interest in similar researches [7].

2.4 Statistical analysis

Normality of distribution of times and number of fixations during each task was evaluated using the Shapiro-Wilk test. Non-parametric tests were used in case of non-normal distribution. Correlation between times and number of fixations was checked using Pearson's or Spearman's correlation test. For each task, times and fixations between the flyers of the two retailers were compared using the paired samples t-test or Wilcoxon test. Analyses were adjusted for multiple testing according to Bonferroni ($p = 0.017$ i.e. 0.05 / 3 tasks). A qualitative analysis of the scanpaths for each participant was also conducted. To this aim, scanpaths for each participant were created using circles to plot the sequence of the different fixations. The dimension of each circle was proportional to the duration of the corresponding fixation. A preliminary analysis with Markov Chain was conducted on Task 3 to further analyze gaze transitions among AOIs. Seven AOIs were drawn around the main objects of the flyers and named with letters from A to G. These were considered to be the states of the Markov Chain. Using coordinates on the screen (X, Y) a letter was assigned to each fixation to obtain a sequence needed for the computation of transitions between states. Two stationary distributions were obtained and compared using the verify Homogeneity function in the Markov Chain R package [6], in order to assess the presence of differences regarding the viewing behavior within the two flyers. Analyses were conducted using R v. 3.6.2 [4].

3 Results

3.1 Comparison of the effectiveness of the two flyers

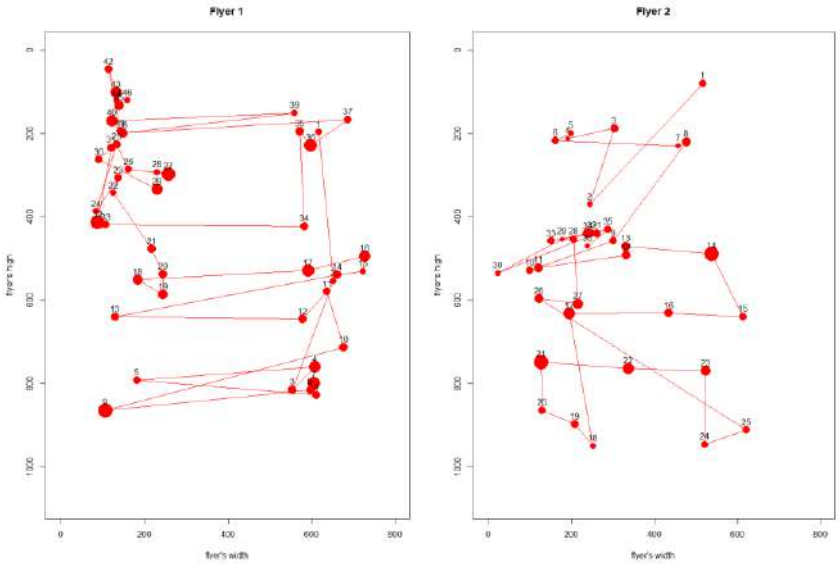
A total of 25 university students completed the three tasks. Three students were excluded due to technical problems during the task, leading to a final sample of 22 participants. In our sample, 41% of the participants were women and mean age (± standard deviation) was 23.86 ± 3.56. Distribution of times and number of fixations was normal for Task 2 and 3 but not for Task 1. Therefore, for the latter task non-parametric methods were used. For all tasks, a strong correlation between time and number of fixations was observed (Task 1: correlation coefficient: 0.84, $p < 0.001$; Task 2: correlation coefficient: 0.96, $p < 0.001$; Task 3: correlation coefficient: 0.71, $p < 0.001$). A better performance of Flyer 2 was observed during Task 1. Specifically, participants completed this task in a faster way and with a lower

number of fixations when looking at Flyer 2 compared to Flyer 1 ($p < 0.001$ for both). Additionally, participants completed Task 3 in a faster way when looking at Flyer 2 compared to Flyer 1, although this difference was not significant after adjusting for multiple testing ($p = 0.03$) . No difference was observed for Task 2. In the preliminary Markov Chain analysis, transition matrices between the different AOIs were computed using fixations made in the pages of the two flyers used for Task 3. The two stationary distributions were significantly different ($\chi^2 = 380.95$, $p < 0.001$), supporting the hypothesis that, on a global level, participants looked at the flyers in a different way while searching information.

3.2 Scanpaths analysis

Scanpaths for each participant were represented using filled circles to plot the sequence of the different fixations. As an example, scanpaths related to Task 1 for a participant are reported in Figure 1. The scanpaths show a lower number of deviations and changes of direction during the observation of Flyer 2 compared to Flyer 1, in line with the quantitative results showing a better performance of Flyer 2 as regard to time and number of fixations required to complete the task in the whole sample.

Figure 1: Representation of the scanpaths of a participant for Flyer 1 and 2 (Task 1)



4 Discussion

Our results showed significant differences in the performance of digital flyers from two retailers. These findings might be explained by differences in the layout of the two flyers. In fact, while both flyers showed a similar number of objects of the same type, the second flyer represented them using a more orderly design (the pictures of the promoted objects had similar dimensions and were evenly distributed across the page). Conversely, as regard to the task for which no differences were detected, the design of the pages selected for this task was similar among the two flyers. Additional analyses to identify clusters of participants with similar viewing behavior, as well as characteristics of areas of a page with higher density of fixations during free observation, are currently ongoing. These analyses will allow to further characterize which aspects of a digital flyer might be associated with higher effectiveness.

At risk mental status analysis: a comparison of model selection methods for ordinal target variable

Analisi dello stato mentale a rischio: analisi di confronto dei metodi per la selezione di modelli per variabile target ordinale

Elena Ballante, Silvia Molteni, Martina Mensi, Silvia Figini

Abstract The presence of an ordinal variable poses several problems that are not deepen in the literature. In this work we aim to analyse a dataset on mental state at risk, a delicate and extremely debatable definition in the psychiatric field, in order to produce a model that is of double value. On the one hand it allows to understand which are the most influential characteristics on the mental state, on the other hand it allows to predict the correct diagnosis and possibly also to assess the risk of a possible transition to the psychotic state. With this aim we focus on model selection methods in the framework of ordinal target variable.
La presenza di una variabile ordinale pone diversi problemi che non trovano trattazioni approfondite in letteratura. In questo lavoro ci proponiamo di analizzare un dataset sullo stato mentale a rischio, definizione delicata ed estremamente dibattuta in ambito psichiatrico, al fine di produrre un modello che sia di duplice valenza. Da una parte che permetta di capire quali siano le caratteristiche maggiormente influenti sullo stato mentale, dall'altra che permetta di prevedere la corretta diagnosi ed eventualmente anche di valutare il rischio di una possibile transizione allo stato psicotico. Con questo obiettivo il lavoro si focalizza sulla fase di selezione del modello nell'ambito di variabile target ordinale.

1 Introduction

Despite advances in pharmacological and psychotherapeutic interventions over the last decades, psychotic disorders continue to be among the most severe disorders in medicine. In children and adolescents, schizophrenia is one of the ten main causes of disability-adjusted life years (DALYs) in 10 to 14-year-old boys and 15 to 19-year-old girls [15]). The identification of people at high-risk of developing psychosis is one of the most promising strategies to improve outcomes. Indeed, retrospective studies indicate that the onset of full psychosis is commonly preceded by a prodromal phase lasting up to several years [16, 24]. Recently, the importance of research in persons at high risk has been increasingly recognized to such an extent that Attenuated Psychosis Syndrome has been introduced in section III ("Emerging Measures and Models") of the Diagnostic and Statistical Manual of Mental Disorder, fifth Edition. Some concerns raised regarding the introduction of this new syndrome need to be addressed with special attention in children and adolescents, where research on the high risk state is still in its infancy [23]. In particular, criticism about pathologization of non-ill behaviours and experiences has been voiced. In fact, during adolescence, the assessment of psychiatric symptoms and disorders is challenging. Several authors have underlined the difficulty in discriminating between normal behaviours and psychiatric symptoms [26]. Normative adolescent experiences can make the clinical picture blurred and lead to false positive psychotic diagnoses [10].Overall, in children and adolescents research on the high risk state and attenuated psychotic symptoms is still in its infancy and the clinical validity of at risk criteria appears understudied. Furthermore, only few studies have evaluated the psychopathological and neuropsychological characteristics of adolescents with attenuated psychotic symptoms (APS).

In this context an accurate data analysis is fundamental for knowledge extraction and prediction: it is extremely important to deploy adequate models and to perform a suitable selection procedure.

If there are several models that are suitable for the analyses, it can be noted that the evaluation measures for model selection are few and inadequate to the problem under analysis.

Performance indicators can be used to assess the performance of a model in terms of accuracy, discriminatory power and stability of the results. The choice of indicators to made model selection is a fundamental point and many approaches have been proposed over the years (see e.g. [6, 18]).

Multi-class classification models are generally evaluated averaging binary classification indicators (see [22]) and in the literature there is not a clear distinction among them with respect to multi-class nominal and ordinal targets (e.g. [13]).

While in the model definition stage for ordinal target variable there are different approaches in the literature (see [1, 3]), for the model selection there is a lack of adequate tools ([9]).

In our opinion, performance indicators should consider the nature of the target variable, especially when the dependent variable is ordinal. In medical application is also fundamental to take into account the uncertainty that the model assign to the

prediction in order to obtain the maximum of interpretability. This leads us to apply and compare different measures to select the best model to predict the mental status, contexts characterized by a multi-class ordinal target variable.

The rest of the paper is organized as follow: Section 2 describes data at hand and the analysis performed, Section 3 describes preliminary results obtained.

2 Data description and analysis

The dataset is composed by 240 observation (corresponding to 240 patients under examination). The target variable is the membership to one of three categories: subject not at risk, at risk, psychotic. This variable is clearly ordinal and in this context is extremely important to consider the order of levels.
The covariates considered are some personal information like age at onset, sex, ethnicity, some medical history of the patients and familiarity to mental illnesses, some information about symptoms, duration of the psychotherapy and of the drugs assumption, the IQ index (Intelligence Quotient) and the SOFAS (Social and Occupational Functioning Assessment Scale).
On this dataset, five different models are implemented and compared: Ordinal logistic regression [20], Classification tree [7], Support vector machine [12], Random forest [8], k-Nearest Neighbour [11].
In the model selection step we compare the information given by an index for ordinal target proposed in [4] with standard indexes used in literature that are AUC (Area Under the ROC curve), accuracy (expressed in terms of correct classification) and MSE (Mean Square Error) (see [13] and [19] among others), another index for ordinal target variable proposed in [9] and the total misclassification cost used in [21]. The index proposed in [4] is defined basing on a classification function, i.e. a function which represents the actual classification made by the model under evaluation, compared with an exact classification function that is the goal of each model. This index takes into account the ordinal structure of the target variable and the probability assigned from the model at each observation. This first aspect has obvious advantages in this context, whereas the second aspect is extremely useful in medical application, when we need to consider the uncertainty of the prediction as well as the prediction itself. In the rest of the paper we refer to this index as OPI (Ordinal Probability Index). The AUC for multi-class classification is defined in [17] as a generalization of the AUC (based on the probabilistic definition of AUC); it suffers of different weaknesses also in the binary classification problem ([14]) and it is cost-independent, assumption that can be viewed as a weakness when the target is ordinal.
Accuracy (percentage of correct predictions over total instances) is the most used evaluation metric for binary and multi-class classification problems ([25]), assuming that the costs of the different misclassifications are equal.
Mean square error (MSE) measures the difference between prediction values and

observed values in regression problems using an Euclidean distance. MSE can be used in ordinal predictive models, converting the classes of the ordinal target variable y in integers and computing the difference between them and it does not takes into account the ordering in a predictive model characterized by ordinal classes in the response variable. Furthermore, it is well known that in imbalanced data characterized by under-fitting or over-fitting the mean square error could provide trivial results (see [22]).
Total misclassification cost is simply defined as the sum of absolute values of the differences between the real class and the predicted class, transformed integer values as in MSE. It was used in [21] to prune a new classification tree algorithm in ordinal framework.
Ordinal Index proposed in [9] is based on confusion matrix and on the concept of non-discordant pair of points, i.e. when the relative order of the predicted classes of two observations is the same of the relative order of the real classes. The advantage of this method with respect to AUC, accuracy and MSE is that consider the ordinal structure of the target variable, but it does not take into account the probabilities assigned to the prediction like the first index proposed.

3 Preliminary results

Data at hands are composed by 240 observations and fifteen covariates both qualitative and quantitative as possible explanatory variables and predictors. The target variable has three ordered level (not at risk, at risk, psychotic). On this dataset six different predictive models are implemented:

- Ordinal logistic regression (Ord Log),
- Classification tree (Tree),
- Support vector machine (SVM),
- Random forest (RFor),
- k- Nearest Neighbour (kNN),
- Naive Bayes (NBayes).

In order to select the best model a 5-fold cross validation is implemented. The models are compared in terms of out of sample performance on the basis of OPI, AUC, accuracy, MSE, the ordinal index (Ord Ind) and misclassification cost (Misc Cost). Table 1 reports the mean values of the metrics under comparison derived from the cross validation exercise. For sake of clarity, Table 2 shows the resulting ranks for the models, using the results obtained for the four metrics under comparison.

The performances achieved on the model under comparison underline that there is a group of models with worst performances (Ord Log, Tree, kNN) and a group of model with better performances (SVM, RFor, NBayes). On the basis of OPI, Accuracy, MSE, Ord Ind and Misc Cost the Random Forest model is the best one. Looking at AUC the best model is Naive Bayes but the performance exactly the

Model	OPI	AUC	Accuracy	MSE	Ord Ind	Misc Cost
Ord Log	0.176	0.847	0.713	0.316	0.372	12.6
Tree	0.215	0.850	0.685	0.399	0.410	14.6
SVM	0.150	0.987	0.760	0.310	0.335	11.2
RFor	0.138	0.902	0.774	0.282	0.315	10.4
kNN	0.351	0.735	0.624	0.404	0.451	16.4
NBayes	0.165	0.912	0.756	0.301	0.341	11.2

kNN	6	6	6	6	6	6
NBayes	3	1	3	2	3	2.5

Table 2 Results in terms of ranking.

same of Random Forest in terms of De Long test ($p > 0.2$).
On the basis of the results obtained in Table 1 a further analysis considers the results obtained using Random Forest. A necessary aspect to consider is the analysis of features involved in the classification process. The next steps will be divide the data in 60% and 40% to deploy and train the single model selected on the dataset, on this model the variable importance can be analyse in order to understand which aspects have more weight in the classification. Random Forest model produces as output an index of variable importance; on the basis of the data at hand the variable with higher degree of importance are also interesting in the clinical domain, as for example SOFAS score, CGIS score, depressive disorders. Also SES score is one of the variables with greater importance, underlining the influence of the socio-economic level on mental status.
A further analysis will consider longitudinal behaviour of the patient thus providing the opportunity to model also time dependent covariates. Moreover in a different dataset we have information about the transition to psychosis of some patient included in this study and further analysis will focus on this groups of patients that make the transition to psychosis in order to evaluate the performances of the model selected only on this category.

Categorical Encoding for Machine Learning

Quantificazione delle variabili qualitative per il Machine Learning

Agostino Di Ciaccio

Abstract In recent years, interest has grown in addressing the problem of encoding categorical variables, especially in deep learning applied to big-data. However, the current proposals are not entirely satisfactory. The aim of this work is to show the logic and advantages of a new encoding method that takes its cue from the recent word embedding proposals and which we have called Categorical Embedding. Both a supervised and an unsupervised approach will be considered.

Abstract *Negli ultimi anni è cresciuto l'interesse nell'affrontare il problema della quantificazione delle variabili qualitative soprattutto nel deep learning applicato a grandi insiemi di dati. Le soluzioni proposte non sono però del tutto soddisfacenti. Obiettivo di questo lavoro è mostrare la logica e i vantaggi di un nuovo metodo di codifica che, prendendo spunto dalle recenti proposte di word embedding, abbiamo chiamato Categorical Embedding. Sarà considerato sia un approccio supervisionato che non-supervisionato.*

Key words: categorical encoding, deep learning, word embedding

1 Introduction

Usually, Big-Data include tens or hundreds of variables, which have mixed measurement levels with many categorical variables, sometimes with high cardinality. The treatment of many categorical variables, especially when combined with quantitative variables, is a complex topic that has no easy solutions. The problem has been considered in many areas of classical statistics (see for example Azzalini 2001)

This theme is particularly relevant in machine learning applied to large datasets. In fact, the only method that can naturally handle many variables with a mixed

[1] Agostino Di Ciaccio, University of Rome "La Sapienza"; agostino.diciaccio@uniroma1.it

measurement level is the decision tree (although software often does not take this potential into account).

The purpose of this work is to show the logic and the advantages of a new encoding method that takes its cue from the recent proposals of *word embedding* in Natural Language Processing (NLP) (Bengio et al. 2003) and which we call *categorical embedding*. Some applications to real datasets will show the interest of our proposal.

2 Encoding Categorical variables

Applying neural networks to categorical data requires some form of encoding. Perhaps the most used method is *one-hot* encoding, i.e., for each category, adding a new binary feature indicating it. However, in the case of high cardinality variables, such technique leads to a large number of new features. Moreover, the new variables are perfectly independent, and this is unrealistic. The categories can have relationships and similarities that could be extracted from the context. An example is the variable "*day of the week*" which is a cyclic ordinal feature. If we represent the days of the week through 7 one-hot vectors (or at least 6, but in Machine Learning it is not necessary to drop one dummy) we obtain a spatial representation of the variable in 7 dimensions in which every pair of categories is at Euclidean distance $\sqrt{2}$ from each other. This representation is not meaningful: it could be more coherent to represent the days of the week on a circumference in a smaller two-dimensional space.

On the other hand, even a 'circular' representation does not take into account that the days of the week can be distinguished between 'working' and 'non-working' and this distinction is often more relevant for the analysis. In table 1 we have reported the distances between the days of the week obtained by considering the encodings given by the Glove's word-vectors (Pennington et al. 2014) obtained by analysing millions of documents by an NLP model. If our analysis concerns, e.g., the sales forecast of a supermarket or the level of particulates in the air of a great city, this is certainly a coherent coding.

Table 1: Distances between the days of the week in the 50-dimensional Glove word-vectors

	Tuesday	Wednesday	Thursday	Friday	Saturday	Sunday
Monday	0.002	0.004	0.002	0.007	**0.086**	**0.074**
Tuesday		0.002	0.002	0.009	**0.087**	**0.077**
Wednesday			0.003	0.008	**0.079**	**0.069**
Thursday				0.007	**0.085**	**0.074**
Friday					**0.072**	**0.062**
Saturday						0.009

It is therefore not obvious that the 'natural' order of the categories should be kept in our coding. If we want to maintain the natural order, we could use the matrix of "*hot-vectors of order*" as suggested in the Optimal Scaling approach (Gifi 1981, Di Ciaccio 1988).

In general, also categorical variables with high cardinality can have a satisfactory representation in a small space, correctly representing their relationship. Consider, for

example, the 102 Italian provinces: the one-hot encoding would provide a representation in a big dimensional space while we know that a representation in a two-dimensional space, using for example the geographical position of the principal city, could be sufficient for our analysis. In general, there is no encoding which is optimal independently of the objective of the analysis and the model applied. The biggest distinction between the encoding methods is based on the approach that can be supervised or unsupervised.

An old but interesting proposal is Optimal Scaling (Gifi 1981) which can generate quantifications both in a supervised and unsupervised approach. In an unsupervised approach, two well-known equivalent methods can be derived: Homogeneity Analysis (HA, Gifi 1981) and Multiple Correspondence Analysis (MCA, Benzecri 1973). By these methods, the categories are 'optimally' encoded maximizing the eigenvalues of the correlation matrix. In the French approach the problem is solved analytically, while in the Gifi approach the problem is solved numerically. This numerical variant offers a large amount of flexibility.

Let m the number of categorical variables and j the index of the generic variable ($j=1,2,\ldots,m$), k_j the number of categories of the j-*th* variable, $\mathbf{G}_j = \left[\mathbf{g}_1, \mathbf{g}_2, \ldots, \mathbf{g}_{k_j}\right]$ the indicator matrix of dimension $n \times k_j$. Let p be the number of dimensions, which needs to be fixed a priori, and r the generic dimension ($r=1,2,\ldots,p$). Each variable can be associated with a matrix $\mathbf{C}_j$ of dimension $k_j \times p$ containing the *category quantifications*. The quantification for the j-*th* variable on the r-*th* dimension is given by

$$\mathbf{v}_{jr} = \mathbf{G}_j \mathbf{c}_{jr} = \sum_{h=1}^{k_j} c_{jhr} \mathbf{g}_{jh} \qquad (1)$$

Hence, the vector of the quantified data is a linear combination of the indicator variables and the set of possible quantifications defines a subspace R^{k_j}. In fact, the quantification $\mathbf{v}_{jr}$ is a linear combination of an orthogonal base of R^{k_j}. If the variable is ordered, the constraints on the quantifications define a polyhedric convex cone (Gifi 1981) and a similar approach based on b-splines can manage also quantitative data (Di Ciaccio 1990). Define the matrix $\mathbf{X}$ containing the so-called *object scores* with dimension $n \times p$, to obtain the scores and the quantifications, we can minimize the following equation by an *alternating least squares* algorithm:

$$\sigma(\mathbf{X}, \mathbf{C}_1, \ldots, \mathbf{C}_m) = \sum_{j=1}^{m} tr(\mathbf{X} - \mathbf{G}_j\mathbf{C}_j)'(\mathbf{X} - \mathbf{G}_j\mathbf{C}_j) = \sum_{j=1}^{m} \left\|\mathbf{X} - \mathbf{G}_j\mathbf{C}_j\right\|^2 \qquad (2)$$

subject to the normalization constraints $\mathbf{X}'\mathbf{X}=n\mathbf{I}$ and $\mathbf{J}\mathbf{X}=\mathbf{X}$, where $\mathbf{J}$ is the projector on the subspace orthogonal to the unit vector.

In a classical, supervised, regression model we want to predict a quantitative response variable Y using m predictor variables. If the predictor variables are categorical, we can use the expression (1), with $p=1$, to quantify the variables obtaining the loss function:

$$\left\|\mathbf{y} - \sum_{j=1}^{m} \boldsymbol{\beta}_j \mathbf{G}_j \mathbf{c}_j\right\|^2 = min \qquad (3)$$

Assuming $\varphi(\mathbf{y}) = \mathbf{y}$, with the appropriate constraints, this loss function corresponds to the Morals model (Gifi 1981) and the solution can be identified through an alternating least square procedure, which is sometimes called backfitting.

Morals calculates a single quantification of each categorical variable. A way to extend (3) to consider p quantifications is:

$$\left\|\mathbf{y} - \sum_{r=1}^{p}\sum_{j=1}^{m}\boldsymbol{\beta}_{rj}\mathbf{G}_j\mathbf{c}_{rj}\right\|^2 = min \qquad (4)$$

Other encoding methods for ML have been proposed in the literature (see for example Potdar et al. 2017) mainly for the supervised case. The *Scikit-learn* software library allows to apply 15 different methods.

3 Categorical encoding

In this paper we propose a method to encode categorical variables that uses dense matrices of reduced size through an '*embedding*' of the categories in a low dimension space. A well-known form of embedding is *word-embedding* (Bengio et al. 2003). Embedding in NLP is a vector representation of the words in such a way that the words that frequently appear in similar contexts are close to each other.

With the most used software libraries for Neural Networks (e.g. Tensorflow, www.tensorflow.org) it is now available the '*Embedding layer*' for NLP. This layer transforms a sequence of words into their vectorial representation introducing an array of quantification parameters. This operation can be defined as in (1) in which the one-hot vectors identify the different words in a vocabulary and the vectors of parameters $\mathbf{c}_r$ are the corresponding vectorial representations in a p-dimensional space. The *Embedding layer* is the first layer in a predictive model and the parameters are determined by backpropagation, trying to maximize the fit of the model to the target.

This layer performs the same kind of transformation as the Optimal Scaling. The difference lies in the objective function and in the method of estimating the parameters given by the *gradient descent*. Let $t = \sum_{j=1}^{m} k_j$, using the approach of (4), it is possible to search for a vectorial representation of the t categories inside a p-dimensional space to optimize the prediction of a target Y. The embedding of categories was considered also by two previous works (Guo et al. 2016, Stefanini 2020) in which the authors proposed the '*entities embedding'*. This approach consists of a distinct embedding phase for each categorical variable where the encoding is defined as in (1), each feature embedding is optimized independently and could have a different dimension.

From a computational point of view, in our approach there is no need to create the inefficient indicator super matrix $G = (G_1| \ldots |G_m)$ with dimensions $n \times t$ and sparsity equal to $1-m/t$. It is sufficient to create the t-dimensional '*vocabulary*' of the categories and index it. Then all the categories in the data will be substituted by the corresponding numerical index. At this point we can introduce the array $\mathbf{C} = (C_1| \ldots |C_m)$ of parameters with dimension $t \times p$ containing the quantification of the categories in the *vocabulary*. The value of p can be small (≤ 10) also with high cardinality variables. It is an hyperparameter in the fitting of the model.

In an unsupervised approach, the categorical variables can be quantified by other NLP algorithms. The best-known method is *word2vec* (Mikolov et al. 2013) but also more recent proposals are available. Without a target variable, it is possible to estimate the array $\mathbf{C}$ by defining a Neural Network model that, for each unit, predict the category of a variable by knowing the categories of the other variables. The obtained

quantifications can be then used in a supervised model. This approach, which has allowed great progress in NLP, can manage big-data and categorical variables with high cardinality. One advantage of the unsupervised approach is that it does not necessarily require the analysis of many data, since the encodings can be obtained indirectly also on other data sets. Furthermore, the encodings do not use the target and therefore there is not risk of overfitting, but, in predictive models, these encodings are not optimized for the specific target that is analysed.

4 A comparison

Some of the most used encoding techniques have been compared with our proposal. Each of these methods has important drawbacks. Target encoder has a risk of '*target leakage*', in fact, it uses some information from target to predict the target itself, increasing the chance of overfitting on the training data. One-Hot Encoder, in the case of high cardinality leads to a large number of orthogonal features. Furthermore, this method alters the relationship between categorical and quantitative variables and can create memory problems. The Helmert contrast encoder can lead to overfitting and requires that the levels of the categorical variable are ordered and target is quantitative. In computational terms, we can remark that target-based methods are the fastest, while one-hot and categorical encoding take longer to calculate, depending on the cardinality of the categorical variables.

We considered the application to two different well-known datasets. The *Human Resources dataset* consists of 54,808 examples, 14 categorical and quantitative features and one binary target. The *Allstate Claims Severity* dataset is composed of 131 features, including 116 categorical variables and one continuous target observed on 188,318 examples.

In tab. 1 we have compared some encoders in a supervised approach. Considering a predictive aim, in each analysis we added to the encoder the same simple neural network with 4 internal layers. To regularize the network, dropout layers have been introduced.

Table 1: Comparison of encoding methods in two supervised analysis

Allstate Claim Severity data	MSE on Train (70%)	MSE on Test (30%)
One-Hot encoder	0.6584	0.6581
Helmert encoder	0.6583	0.6580
Target encoder	0.6582	0.6581
Categorical Encoder	**0.2688**	**0.3199**

Human Resources data	AUC on Train (70%)	AUC on Test (30%)
One-Hot encoder	0.9181	0.8991
Helmert encoder	0.9345	0.8929
Target encoder	0.8053	0.8070
Categorical Encoder	**0.9085**	**0.9033**

The usefulness of each encoder can therefore be assessed based on the predictive capacity of the model obtained. We can see that the categorical encoding (with p=10) is more effective in both cases, but mostly on the dataset with many categorical variables and high cardinality.

5 Conclusions

In Neural Networks, the One-Hot is the most common encoding technique for categorical data and, often, it leads to good results. On the other hand, this encoding has many drawbacks that can degrade the predictive performance of the Neural Networks model. Also, the alternative methods proposed in the literature have not proved particularly effective. The approach we have shown in this paper seems to bring clear advantages when there are many categorical variables with high cardinality. Using this approach, we can also build unsupervised models to analyse the relationship between categorical variables as in MCA. Some early applications in this regard show encouraging results.

Dynamic Quantile Regression Forest
Regression Forest Quantilica Dinamica

Mila Andreani[1] and Lea Petrella[2]

Abstract The potential of machine learning algorithms in the assessment of market risks has not been completely investigated in the literature, such as in the forecasting Value-at-Risk (VaR). In this paper we introduce the Dynamic Quantile Regression Forest, a model combining Quantile Regression Forests with a dynamic VaR. The model is dynamic as the quantile prediction of the previous random forest becomes part of the training set used to train the next random forest. Thus, it is possible to estimate the response variable conditional distribution by accounting for the evolution of the quantile over time among other covariates.

Abstract *Le potenzialità degli algoritmi di machine learning per la valutazione dei rischi di mercato sono ancora poco conosciute, in particolar modo per quel che concerne il calcolo del Value-at-Risk (VaR). Lo scopo di questo lavoro, dunque, è quello di introdurre la regression forest quantilica dinamica, un modello che unisce le regression forest con il calcolo dinamico del VaR, ossia tenendo conto dell'evoluzione del quantile nel tempo: in questo senso il modello è definito dinamico in quanto permette di stimare la distribuzione condizionata della variabile tenendo conto, fra le altre covariate, anche dell'evoluzione del quantile nel tempo.*

1 Introduction

Numerous contributions in literature point out the high predictive accuracy of machine learning algorithms in the economic and financial fields [1,8]. However, it is necessary to account for the complexity of such tools when it comes to compare them to traditional econometric models in terms of computational effort. As a matter of fact, many machine learning models require a long time to be tuned before being implemented, whereas traditional models might deliver similar results in a more timely manner.

Yet, the Random Forest algorithm introduced by [4], represents an efficient compromise between predictive accuracy and computational effort. Random Forest is an ensemble machine learning tool composed of decorrelated decision trees. Each tree is trained with a subset of the training set sampled with replacement from the original dataset with a method called *bagging*. The term "random" is related not only to the random sampling of the training subset, but also on the randomly chosen variable used to make the splits in each decision tree. The final prediction is computed as the aggregation of each tree prediction. The main advantage of random forests is related to the high training speed and the low number of parameters to be tuned in order to deliver reliable predictions (*number of trees, node size, number of features to choose from for each split*).

Random forest can be used both for classification and regression tasks, and the latter model has been further developed by [6], who introduced the quantile regression forest. This model allows to predict quantiles by estimating the whole conditional distribution of the variable, and, in this sense, it is possible to use this model to forecast the Value-at-Risk, representing the quantile of the conditional distribution. However, other econometric models have been developed in order to compute the Value-at-Risk in a dynamic setting.

In particular, [7] proposed a model to compute the Conditional Autoregressive Value-at-Risk (CAViaR) via nonlinear quantile regression. This model is based on directly modelling the quantile as nonlinear function of its past values and other factors instead of estimating the entire conditional distribution of the variable. By doing so, it is possible to account for changes in the variable's distribution over time and to compute a dynamic Value-at-Risk. Despite the advantages of random forest, the state-of-the-art in the machine learning field doesn't account for the application of quantile random forests in computing VaR. Moreover, the only technique by which is possible to train machine learning tools in a dynamic setting is via "incremental learning". This method allows to train a model on several batches of a given dataset, but it doesn't allow to account for an autoregressive structure of the model, which is the idea behind the CAViaR model. For this reason, in this paper a new kind of random forest is proposed in order to account for a dynamic setting for forecasting Value-at-Risk. Moreover, the aim of this paper is also to design a model to compete with traditional econometric techniques in terms of predictive accuracy and computational effort.

2 The model

The main feature of machine learning is that the training phase is performed on a static training set. This means that a given dataset is divided into two parts, a training set and a test set. Subsequently, the algorithm is trained on the training set and tested on the test set. Thus, it is not possible to account for changes in the training set and, for instance, to consider an autoregressive structure in the model. Consequently, in order to forecast a dynamic quantile, it is necessary to change the way in which machine learning algorithms are trained and to develop a model that allows to update the training set each time a new prediction is made.

The dynamic quantile regression forest has been developed for this purpose: this model relies on updating the training set whenever the regression forest produces a prediction and subsequently training a new random forest on the updated training set. Thus, it is possible to account for an autoregressive structure as proposed by [7]. However, the random forest models the entire distribution instead of directly modelling the quantile. Specifically, given a set of observations Y_i with $i = 1, \dots, T$, and a set of regressors $X_{k1} \dots, X_{kT}$ with $k = 1, \dots, K$, a subset $Y_1 \dots, Y_t$ (in which t represents the window width) is used in order to initialize the random forest and to produce t quantile predictions via the CAViaR model. To do that consider one of the possible CAViaR models proposed by [5] i.e. the Symmetric Absolute Value:

$$q_t(\beta_1) = \beta_1 + \beta_2 q_{t-1}(\beta) + \beta_3 |y_{t-1}| \qquad (1)$$

The first random forest is trained on the subset $Y_1 \dots, Y_t$ using the $q_1 \dots, q_t$ estimated from the CAViaR in (1) with covariates given by $X_{k1}, \dots, X_{kt}$ with $k = 1, \dots, K$. The one-step-ahead q_{t+1} is computed implementing the quantile regression forest and added to the dataset. Subsequently, an additional quantile regression forest is fitted using $Y_1 \dots, Y_{t+1}$, q_{t+1} and $X_{k1} \dots, X_{k(t+1)}$ with $k = 1, \dots, K$. The procedure is repeated until the entire dataset $Y_1, \dots, Y_T$ is used to train the last random forest, which is fitted on the whole dataset comprehensive of the previous quantile predictions. Consequently, the one-step-ahead quantile prediction will be a nonlinear function of its past values and the regressors.

3 Results

The model has been tested on T=1350 daily returns of the S&P 500 starting from 02-09-2010 and the VaR at 5% is predicted. The covariates are: Hang Seng index, CAC 40 index, FTSE 100 index, Dow Jones Index, NASDAQ 100 index, VIX, CBOE Equity VIX on Apple, CBOE Equity VIX on Amazon. The window width is equal to t=350 and the number of trees is set to 100. The first 350 observations are used to initialize the random forest using the CAViaR model in (1) and the remaining 1000

are used to estimate the quantile regression forest's predictions. The model proposed results to be:

-*accurate*: to measure the model accuracy in estimating the VaR, we use backtesting procedures like the conditional and unconditional coverage tests [2,3]. We show that our dynamic quantile regression forest produces both correct and independent exceedances, as shown in Table 1 (the expected exceedances are 50):

Table 1: Backtesting results

	Values
Actual exceedances	42
Unconditional coverage p-value	0.2304129
Conditional coverage p-value	0.1514733

-*competitive in terms of accuracy and computational effort:* the running time for our model is equal to 1 minute and 23 seconds and the prediction for the 1001-th quantile is equal to -0.023. Moreover, we compare the dynamic quantile regression forest with the four CAViaR models proposed in [7] (i.e., Symmetric absolute value, Asymmetric slope, Indirect GARCH (1,1), Adaptive) and the static quantile regression forest as proposed in [6]. The table below shows the quantile loss values for the models being compared and the ratio between our model's quantile loss, the CAViaR models' quantile loss and the static quantile regression forest quantile loss. Results show that our model produces a sensibly smaller quantile loss with respect to the Indirect GARCH (1,1) model and the static quantile regression forest, whereas it delivers similar results to the other three CAViaR models. Results are summarised in Table 2:

Table 2: Accuracy results

	% Loss	***Loss***
Dynamic quantile regression forest	-	0.0010227
Symmetric absolute value	108%	0.0009463
Asymmetric slope	107%	0.0009545
Indirect GARCH (1,1)	29%	0.0035005
Adaptive	108%	0.0009467
Static quantile regression forest	43%	0.0024011

4 Comparison with the static quantile regression forest

Moreover, according to the backtesting results the static quantile regression forest as proposed in [6] produces inaccurate estimates for the 5% VaR as shown in Table 3:

Table 3: Backtesting results for the static quantile regression forest

	Values
Actual exceedances	322
Unconditional coverage p-value	0
Conditional coverage p-value	0

As a matter of fact, Figure 1 highlights the relevance of introducing quantile predictions as regressors in the dynamic quantile regression forest. The figure shows that the quantile covariate positively affects the dynamic quantile regression forest's estimates in terms of Mean Squared Error and Node Impurity. As described in [5], the t-th node impurity measures the sum of squared errors between the observation value y_i and its mean in the t-th node $\mu(t)$ (i.e., the variance in the t-th node).

Figure 1: Dynamic Quantile Regression forest variable importance

Estimating the UK Sentiment Using Twitter
Stima del sentiment nel Regno Unito attraverso Twitter

Stephan Schlosser, Daniele Toninelli and Michela Cameletti

Abstract In the era of social networks and big data Twitter represents a tremendous and cheap source of data able to provide valuable information about any possible topic. Such a source requires techniques to transform text into sensible numerical indexes. In this paper we consider the daily sentiment score measured by two lexicons (AFINN and Bing) on tweets collected for UK from January 15th to February 15th, 2018. As the analysed daily tweets are geolocated at the NUTS sub-area level, we focus on the comparison of the two score distributions across regions and serially. Results show that the two lexicons perform very similarly. However, our analysis shows that the sentiment estimated using the tweets doesn't correlate with the individual well-being estimated using data from an European survey (ESS).

Abstract *Nell'epoca dei social network e dei big data Twitter rappresenta una fonte di dati straordinaria ed a basso costo, capace di fornire preziose informazioni riguardo ad ogni possibile argomento. Questa fonte di dati richiede, però, metodi in grado di tradurre il testo in indicatori numerici. In questo lavoro si prendono in considerazione i punteggi stimati attraverso due dizionari (AFINN e Bing) su tweet geolocalizzati a livello di NUTS raccolti per il Regno Unito tra il 15 Gennaio ed il 15 Febbraio 2018. Confrontando le distribuzioni regionali dei punteggi e la loro evoluzione storica, si notano risultati molto simili per i due dizionari. Tuttavia non sembra esserci correlazione tra i livelli rilevati mediante sentiment analysis ed il livello di benessere emerso usando i dati dell'indagine ESS.*

Key words: Twitter, sentiment analysis, lexicon, spatial distribution, ESS

1 Introduction and literature review

Social media are considered, at least potentially, new important data sources for research on various topics and for decision making in several fields (Kapoor *et al.*, 2018; Stieglitz *et al.*, 2018; Batrinca & Treleaven, 2015), despite currently affected by several issues of different types (Peng *et al.*, 2018; Bello-Orgaz *et al.*, 2015).

Currently, Twitter is one of the main big data sources: it is one of the most spread social network, worldwide, with about 330 million monthly active users (2019, first quarter; https://www.statista.com), 145 million daily users (http://shorturl.at/jnPS0) and 1.3 billion of accounts (http://shorturl.at/hszRW). Twitter users produce 500 million of tweets, daily (https://business.twitter.com/). These short posts (up to 140 characters long) are already used in several field, such as: political studies (Jungherr, 2015; Bose *et al.*, 2019), public health (Annice et al., 2013; Bates *et al*., 2014) and sentiment analysis (Mäntylä *et al*., 2018; Saura *et al*., 2019).

In a recent research, we experimented methods to retrieve tweets fully geolocated (Schlosser *et al*., 2019; Schlosser *et al*., *forth.* 2020). These methods allow us to retrieve all tweets sent in a wide geographical area (United Kingdom, excluding Northern Ireland, i.e. UK, from here on) and to assign them to NUTS sub-areas (the NUTS 1 level of UK; https://ec.europa.eu/eurostat/web/nuts/background). In particular, in this paper we analyse tweets collected in UK from January 15th, 2018 to February 15th of the same year, using a method defined as Method 2 (or M2; for details see Schlosser *et al*., 2019), that resulted as the best approach for tweet collection and geolocation among the three tested alternatives.

The main purpose of this paper is twofold. On the one hand we want to apply two different lexicons (AFINN and Bing) in order to estimate the level of sentiment observed on the collected tweets; in particular, we aim at understanding if the results obtained with the two lexicons are comparable, both considering the main statistics and the distribution of the output scores and the longitudinal perspective (i.e. analysing the relative changes in the sentiment time series). On the other hand we want to check whether the two lexicons are able to produce results comparable to the ones obtained using a more traditional data source, such as the European Social Survey (ESS; link: http://www.europeansocialsurvey.org/).

2 Data & Method

For this research we use tweets collected by means of a method based on the "theory of circle" (see M2 in Schlosser *et al*., 2019). By setting circles in order to cover in the most efficient way the area of a country (in our case UK), we are able to geolocate at the NUTS level all the collected tweets, allowing us to develop a spatial analysis of the sentiment observed in the different UK NUTS. In this paper we use 40,330,747 tweets collected in 2018 from January 15th to February 15th.

After a preliminary standard phase of cleaning (deleting stop words, hashtags, links, and so forth), we apply to all tweets two different lexicons: AFINN (Nielsen, 2011) and Bing (Bing, 2015). The current version of the first method (AFINN-en-165) is based on a dictionary including over 3,300 words; it ranks the words included in a tweet and belonging to the dictionary using a score between -5 and +5 and 0 neutral terms. The second lexicon, based on a dictionary including 6,788 words, assigns a score equal to -1 (for negative worlds), 0 (for neutral terms) or +1 (for positive worlds). Thus, we compute the sentiment of each tweet by summing the scores assigned by each of the two lexicons. This score estimates the level of sentiment of each tweet.

In addition to this, we also work on ESS data, analysing, in particular, the results of a question answered by a representative sample of 2,201 UK respondents that participated in the 9th wave of the survey (reference year: 2018). This question is no. B27: "*All things considered, how satisfied are you with your life as a whole nowadays?*". The evaluation scale ranges from 0 (="Extremely dissatisfied") to 10 (="Extremely satisfied"). Our scope is to understand whether the AFINN & Bing sentiment scores are able to reproduce the levels observed from the ESS data.

3 Main results

As **first step**, we analysed the sentiment score distribution by NUTS and by lexicon: this leaded us to identify four different regions, shown in Figure 1 together with the corresponding average Bing scores (whereas the average scores by NUTS are shown in Table 1). The AFINN lexicon produces very similar results (summary statistics reported in Table 1 are different, but the relative positions of the NUTS are very similar, as shown later), thus we do not show them here.

Figure 1: Regions based on the Bing score and corresponding NUTS (with unweighted avg. of Bing sc.).

Purple region (Bing avg: **0.215**) includes:
- UKM (Scotland)

Orange reg. (Bing avg: **0.243**) includes:
- UKG (West Midlands);
- UKF (East Midlands);
- UKE (Yorkshire and the Humber);
- UKD (North West);
- UKC (North East).

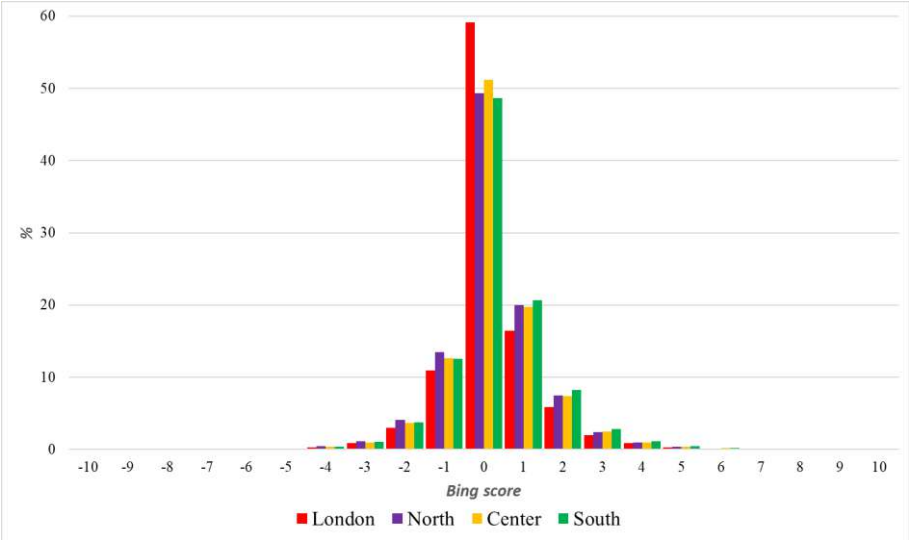
Green region (Bing avg: **0.284**) includes:
- UKL (Wales);
- UKK (South West);
- UKJ (South East);
- UKH (East of England).

Red region (Bing avg: **0.185**) includes:
- UKI (London).

The distribution of the Bing and AFINN scores enables us to identify four well-defined regions: the lowest average levels (Bing: 0.185; AFINN: 0.598) are observed for London, whereas the highest levels (Bing: 0.284; AFINN: 0.861) are observed in the Southern region (Wales, South West, South East and East of England).

The percentage distribution of the Bing score by region is shown in Graph 1. There are no big differences in the Bing score between the four regions. However, we notice a higher concentration of neutral tweets (score = 0) for the London area, whereas negative scores are more common in the North and positive scores are more likely to be observed in the South (as already highlighted in Figure 1). Similar patterns can be observed studying the AFINN scores.

Graph 1: Distribution of the Bing score by region (percentages).



As **second step**, we analyse if, using the two lexicons, we observe a similar behaviour of the sentiment over time. In particular, we were mainly interested in understanding if the two methods were able to similarly measure relative movements of the sentiment over time. Thus, we studied the relative changes observed between consecutive time points. Analysing this variable, we observed very high and significant correlations (all $p<0.001$) between AFINN and Bing scores daily relative changes for all the four zones; the Pearson correlation coefficient is equal to: 0.9530 for London, 0.9557 for North, 0.9816 for Center and 0.9830 for South. This means that the relative changes detected by using the two lexicons are very similar: the two lexicons seem to confirm each other's results.

Finally, as **third step** we compare, globally and by NUTS, the scores obtained applying the sentiment analysis and the scores from the ESS question no. B27. The summary statistics by NUTS are shown in Table 1, as long as the corresponding NUTS ranking.

Table 1: Sentiment scores (AFINN & Bing lexicons) and ESS average score by NUTS

	AFINN			*Bing*			*ESS*		
NUTS	***Mean***	***Std.dv.***	***Rank***	***Mean***	***Std.dv.***	***Rank***	***Mean***	***Std.dv.***	***Rank***
UKL	0.859	3.035	2	0.284	1.259	2	7.585	1.943	1
UKK	0.907	3.023	1	0.300	1.272	1	7.442	2.010	2
UKJ	0.822	2.970	5	0.271	1.256	4	7.330	2.031	7
UKH	0.856	3.031	3	0.281	1.272	3	7.427	1.864	4
UKG	0.764	2.966	7	0.253	1.220	6	6.804	2.210	11
UKF	0.702	2.893	10	0.226	1.193	9	7.430	1.963	3
UKE	0.829	3.067	4	0.263	1.264	5	7.374	1.938	6
UKD	0.711	2.926	8	0.227	1.197	8	7.222	2.208	9
UKC	0.771	3.128	6	0.246	1.256	7	7.259	2.370	8
UKM	0.710	3.028	9	0.215	1.243	10	7.380	2.276	5
UKI	0.598	2.676	11	0.185	1.114	11	7.072	2.291	10
ALL	**0.769**	**2.978**		**0.247**	**1.231**		**7.313**	**2.095**	

AFINN and Bing lexicons provide with very similar results, showing a Pearson correlation coefficient between scores equal to 0.9895 (p<0.001). The Spearman correlation coefficient computed on the ranks confirms these results (0.9727; p<0.001). Nevertheless, using ESS data we do not obtain a significant correlation both taking into account the average scores and the ranks. The Pearson correlation coefficient is 0.493 (p=0.123) vs the AFINN score and 0.433 (p=0.183) vs the Bing score. The Spearman correlation coefficients computed on ranks highlight nonsignificant linkages as well: 0.555 (p=0.077) vs the AFINN rank and 0.536 (p=0.089) vs the Bing rank. It seems that the scores obtained by analysing tweets are not able to reproduce the levels obtained using the ESS data. But this was partially expected, given that the ESS data are referred to the whole year, whereas the tweets are linked to just a specific month.

4 Discussion, limitations and further research

Our main results highlight similar performances of the AFINN and of the Bing lexicons, considering the score distribution, the relative changes of the sentiment time series and the NUTS ranking as well. This seems to confirm that our method of collection is robust with respect to the lexicon, leading to significantly non-different results. Nevertheless, if we compare the sentiment level with the scores observed from the ESS data, it seems that we are not able to reproduce the same relative levels in the geographical distribution. This is, of course, a consequence of our analysis: first, by definition, sentiment does not correspond to the subjective well-being that the ESS question we consider aims at measuring. Thus, this preliminary analysis should be refined, for example focusing on just one or few of the dominions that characterize the subjective well-being. Moreover, the comparison relies on two

different reference periods. Studying tweets, we are able to produce daily time series, but we just consider one month, whereas the ESS data are referred to the overall year. The relative levels of sentiment observed in a specific month could be completely different from the levels referred to the full year.

In order to try to overtake such limitations, we suggest, as further research ideas, to include a pre-screening or a filtering of tweets by scope (e.g. advertising vs private posts) and/or by specific topics (work, health, safety, and so forth). In order to fix the issue of the different time periods, we also propose to develop a more general analysis relying on annual average levels of the sentiment that should guarantee a higher level of comparability.

Forecasting local rice prices from crowdsourced data in Nigeria

Previsione sui prezzi locali del riso dai dati di crowdsourcing in Nigeria

Ilaria Lucrezia Amerise and Gloria Solano Hermosilla

Abstract The ability to anticipate food prices is important in developing economies for decision-making by governments, agri-food chain actors and other institutions. Farmers and agri-businesses decide based on price expectations, while well-being of households is affected by food price changes, since food makes up a large portion of household budget in developing regions. This study assesses the use of crowdsourcing in price forecasting. The Reg-ARMA approach is used to build simultaneous prediction intervals for daily retail prices of local rice in Nigeria submitted by citizens using a mobile app. Results show that the proposed approach generates effective and efficient point and interval forecasts, which can be of help to policy makers, managers, marketers, planners and researchers.

Abstract Nelle economie in via di sviluppo, la capacitá di previsione dei prezzi dei prodotti alimentari é importante nel processo decisionale dei governi, degli attori della catena agroalimentare e di altre istituzioni. Questo studio valuta l'uso del crowdsourcing nelle previsioni dei prezzi. L'approccio Reg-ARMA viene utilizzato per costruire intervalli di previsione dei prezzi al dettaglio giornalieri del riso locale in Nigeria, inviati dai partecipanti attraverso un'app mobile. I risultati mostrano che questo approccio genera previsioni puntuali e intervallari in modo efficace ed efficiente, che possono essere di aiuto per i politici, i manager, i responsabili marketing e i ricercatori.

Key words: Simultaneous prediction intervals, Regression with time series errors, food price forecasting, mobile app crowdsourcing, citizen volunteers

1 Introduction

The ability to anticipate food price changes is important in developing regions for governments and other organizations to plan and adjust food security and market interventions, but also for food supply chains actors. Farmers and agri-businesses decide based on price expectations, while well-being of households in developing countries can be greatly affected by food prices changes, since food makes up a significant portion of household expenditure. But many developing countries lack the ability to track food prices with sufficient frequency and granularity to anticipate changes [5]. Today, alternative data sources and new technologies around the world offer big potential to complement official statistics [2] and have given rise in Africa to several ICT and/or citizen science projects to track geo-located food prices in real-time. Prior research has explored the use of web scraping (e.g. twitter) and google trend indices to predict food prices [5] yet more limited has been the attention to crowdsourcing. The objective of this paper is to evaluate whether the use of daily crowdsourced market prices can help to produce accurate forecasts. We use 16-months daily local rice prices contributed by citizen volunteers on the Food Price Crowdsourcing Africa (FPCA) platform[7] in Kano and Katsina states (Nigeria) to estimate Reg-ARMA processes. We forecast rural and urban daily observations 4/6 months ahead (120-180 days). Then, we compute the monthly average, which can be compared with the National Bureau of Statistics (NBS) data. Nigeria is the main rice producer in Africa and a major consumer [8]. Its government is trying to encourage rice production to promote self-sufficiency and food security and since 2015 banns imports. Katsina state, however, is still under food security stress (IPC v3.0). Small-scale farmers that account for 80% of rice production could benefit from improved price predictions when negotiating and selling their rice. In the rest, Section 2 describes the FPCA; Section 3 introduces the time-series forecasting methods. Section 4 includes the empirical application and Section 5 presents the discussion and conclusions.

2 Data

We use data collected in 2018-19 by the European Commission Joint Research Centre FPCA platform [7]. The crowd source volunteers using a mobile app in Kano and Katsina states (urban and rural) in northern Nigeria submitted daily market prices of several commodities for a reward. Volunteers owned a smartphone with GPS and followed web instructions. Radio spots and flyers served to publicize the FPCA. The system was built based on Open Data Kit and deployed on a compatible server. Automatic routines were in place to process, quality check and validate data, which fed into a web-dashboard updated twice a day. The 737 volunteers submitted 40,000 valid local rice retail prices that translated into more than 400 urban/rural daily observations. The consistent data flow reveals nuances of price data, prior to and after harvest, which hints to reliability of the crowdsourcing system. Main price declines

occurred during harvests, yet around Oct-19, prices were unusually high compared to previous year.

3 Methods

3.1 Assessing point forecast accuracy

The main problem with assessing the reliability of forecasts is that the magnitude of forecast errors cannot be evaluated until the actual values have been observed. To simulate such a situation, we split local rice time series into two parts: the "training" period, which ignores a number of the most recent time points and the "validation" period, which comprises only the ignored time points. Both the time series have undergone a pre-stage consisting: 1) imputation of some missing values by using na.interpolate included in the R package forecast by Hyndman [4]; 2) Rescaling a few outliers by using the method discussed in [1]. The prices observed in the period from 10/11/2019 to 07/12/2019 ($H=28$ days) are set-aside to serve as a benchmark for forecasting purposes. Local rice prices from 21/09/2018 to 09/11/2019 act as training period. There are a number of indices that assess predictive accuracy. For our current purpose, we prefer an index that varies in a fixed interval and makes good use of the observed residuals. This is the relative absolute error of forecast (RAEF)

$$RAEF = 100\left[1 - H^{-1}\sum_{h=1}^{H}\frac{|A_{n+h} - \widehat{A}_{n+h}|}{|A_{n+h}| + |\widehat{A}_{n+h}| + \varepsilon}\right] \quad h = 1,2,\cdots,H \quad t = 1,2,\cdots,n \tag{1}$$

where ε is a small positive number (e.g. $\varepsilon = 0.00001$) which constitutes a safeguard against division by zero. Coefficient (1) is independent on the scale of the data and, due to the triangle inequality, ranges from zero to 100. The maximum is achieved in the case of perfect forecasts: $L_{n+h} = \widehat{L}_{n+h}$ for each h. The lower the $RAEF$ is, the less accurate the model is. The minimum stands for situations of inadequate forecasting such as $\widehat{H}_{n+h} = 0$ or $\widehat{L}_{n+h} = -L_{n+h}$ for all h.

3.2 Simultaneous prediction intervals

In predicting local rice prices for marketing, planning, development and policy-making it is not only important to generate point forecasts for several steps ahead, but providing an assessment of the uncertainty associated with forecasts can be equally important. The problem is thus to integrate point forecasts with prediction intervals (PIs) which apply simultaneously to all possible future values of the predictors.

A reasonable strategy can be as follows: Given the availability of H future values, we can construct two bands such that, under the condition of independent Gaussian distributed random residuals, the probability that consecutive future prices $A_{n+h}, h = 1,2,\cdots,H$ lie simultaneously within their respective range is at least is γ

$$P\left[\bigcap_{h=1}^{H}\left(A_{1,h,\gamma} \leq A_{n+h} \leq A_{2,h,\gamma}\right)\right] \geq \gamma \tag{2}$$

where

$$\begin{cases} A_{1,h,\gamma} = \widehat{A}_{n,h} - \theta_{H,\nu,\gamma}\widehat{\sigma}_h \\ A_{2,h,\gamma} = \widehat{A}_{n+h} + \theta_{H,\nu,\gamma}\widehat{\sigma}_h. \end{cases} \tag{3}$$

The multiplier $\theta_{H,\nu,\gamma}$ is the γ-th quantile of the of the maximum absolute value $|t|$ of the H-variate Student t probability density function with ν degrees of freedom. See [3]. In short, $\theta_{H,\nu,\gamma}$ is the solution of

$$\int_{-\theta}^{\theta}\int_{-\theta}^{\theta}\cdots\int_{-\theta}^{\theta} f(t_1,t_2,\cdots,t_h;\nu)\,dt_1 dt_2\cdots dt_H = \gamma \tag{4}$$

The critical values can be found solving iteratively $u_{H,\nu,\gamma}$ using the command *pmvt* of the *R* package *mvtnorm*, which provides the multivariate t probability. See [6].

The most important characteristic of PIs is their actual coverage probability (PIAC). We measure PIAC by the proportion of true prices of the validation period enclosed in the bounds

$$PIAC_\gamma = 100H^{-1}\sum_{h=1}^{H} c_{h,\gamma} \quad \text{where } c_{h,\gamma} = \begin{cases} 1 & \text{if } A_{n+h} \in \left[A_{1,h,\gamma}, \quad A_{2,h,\gamma}\right] \\ 0 & \text{otherwise} \end{cases} \tag{5}$$

If $PIAC_\gamma \geq \gamma$ then rural and urban prices tend to be covered by the constructed bounds, but this may also imply that the estimates of the variances in the forecast errors are positively biased. A $PIAC_\gamma < \gamma$ indicates under-dispersed forecast errors with overly narrow prediction intervals and unsatisfactory coverage behavior.

All other things being equal, narrow PIs are desirable as they reduce the uncertainty associated with forecasts. However, high accuracy can be easily obtained by widening PIs. A complementary measure that quantifies the sharpness of PIs might be useful in this context. Here, we use the score function.

$$R_{h,\gamma} = \left(\frac{\gamma}{2}\right)\frac{\left(C^2_{h,\gamma} - C^1_{h,\gamma}\right)}{A_{n+h}}, \quad h = 1,2,\cdots,H. \tag{6}$$

This expression reflects a penalty proportional to the narrowness of the intervals that encompass the true values at the nominal rate. The penalty increases as γ decreases, to compensate for the tendency of prediction bands to be broader as the confidence level increases. Of course, the lower $R_{h,\gamma}$ is, the more accurate PI will be. The average value of the score width across time points

$$ASW_\gamma = \frac{1}{H}\sum_{h=1}^{H} R_{h,\gamma} \tag{7}$$

can provide general indications of PIs performance.

3.3 Empirical analysis

Table 1 shows the results obtained with the Reg-ARMA method applied to the data of the training period for the prices in the validation period. The Reg-ARMA approach offers several improvements over OLS. The auto-correlation is almost inexistent because the p-value of the LB statistics is now larger that 99%. Also, the quality of the fitting is increased as proven by a lower AICc and a higher $\bar{R}^2$ than those observed for OLS.

Table 1 OLS and Reg-ARMA estimation and forecasting.

	β_0	t	$\gamma_{1,1}$	$\gamma_{2,1}$	$\gamma_{1,2}$	$\gamma_{2,3}$	$\gamma_{1,5}$	RAEF	PIAC	ASW
A										
Reg-A	4491.4	4785.9	-989.0	-1745.4	878.8	619.8	257.0			
$\bar{R}^2$:	0.979	AICc:	2431.9	LB:	1.3			84.5%	88.1%	11.6
B										
Reg-A	3797.9	8488.9	-1202.1	-2135.2	284.7	-287.1				
$\bar{R}^2$:	0.981	AICc:	2458.8	LB:	6.7			77.7%	65.0%	14.1

In both cases the amelioration is quite substantial. In addition, as can be readily seen from Figure 1, the coverage rate is now significantly higher compared to OLS. The cost of these enhancements is a larger width of the simultaneous forecast intervals, which, as it is well known determine broader brackets than marginal (and wrong) classical OLS intervals. Furthermore, the stability of the RAEF index across the two estimation methods, is a demonstration that the predictive accuracy does not deteriorate when Reg-ARMA method is used. Nonetheless, we must remark that, both OLS and Reg-ARMA methods, yield prediction intervals whose actual coverage rate resulted to be less than the nominal level (90%) (the latter are better than the former). We explain this result as due to a change in the evolutionary trajectory of prices, which in the last year, has not been following the trends of previous years. This is an obvious consequence of the need of bracketing future values within the same scheme used for past observations. Thus a constraint is imposed on the forecasting tool: strong local fluctuations or outliers cannot appear in the set of future values even if we know that they are there; thus, some failures are inevitable.

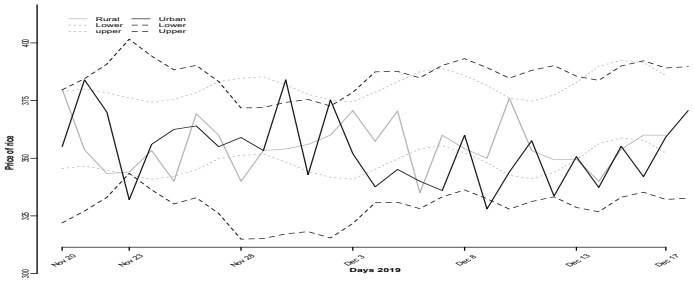

Fig. 1 Prediction intervals (PIs) of daily urban and rural prices of local rice in Kano and Katsina states (Nigeria)

4 Discussion and conclusion

Our method is an example of the use of crowdsourcing for accurate price predictions that could help empowering smallholder farmers and low-income consumers in developing countries, but also governments and other organisations. In this paper, we have assumed that the regression residuals arise from an auto-regressive moving average stochastic model. This way, we have not only eliminated serial correlation from the regression residuals, but also constructed valid simultaneous prediction intervals to contain future local rice prices. Further research could exploit the combination of crowdsourced prices with other determinants of staple food prices. Further, we believe that including this functionality in price monitoring platforms could help to enhance their possibilities to support better decision-making.

Generalized Mixed Effects Random Forest: does Machine Learning help in predicting university student dropout?

Random forest generalizzati a effetti misti: il machine learning aiuta a prevedere l'abbandono degli studenti universitari?

Massimo Pellagatti, Chiara Masci, Francesca Ieva and Anna Maria Paganoni

Abstract We develop a new statistical method, called Generalized Mixed Effects Forest (GMEF), which embeds a Random Forest (RF) regression algorithm in a Generalized Mixed Model. Our model is new to the literature and can deal with any type (continuous or discrete) of both response variable and covariates and it does not assume any parametric function on the fixed-effects part of the model. GMEF is able to model hierarchical data, which is very important in the case of a nested structure of the observation, which might affect not only the final response itself, but also the effect that other covariates have on it. We apply this method to data from Politecnico di Milano to predict university student dropout, aiming to open a new perspective to university tutoring systems.

Abstract *In questo lavoro, sviluppiamo un nuovo modello statistico, chiamato Random Forest a effetti misti generalizzato (GMEF), che innesta una random forest di classificazione in un modello di regressione generalizzata a effetti misti. Il modello GMEF è nuovo in letteratura, può trattare variabili risposta e covariate sia continue che discrete e non assume nessuna funzione parametrica sulla parte degli effetti fissi del modello. Inoltre, GMEF si adatta a dati annidati, tenendo in considerazione la loro struttura gerarchica, che può influenzare non solo la risposta, ma anche l'effetto delle covariate del modello. Nel caso studio, applichiamo il modello GMEF ai dati del Politecnico di Milano, per prevedere l'abbandono degli sudenti e aprire nuove prospettive per il sistema di tutoraggio dell'università.*

1 Introduction and motivation

The Student Profile for Enhancing Tutoring Engineering (SPEET) [9] project is an international ERASMUS$^+$ project that aims at determining and categorizing the different profiles for Engineering students across Europe and at opening new perspective to university tutoring systems. Politecnico di Milano is one of the six partners of the project and our aim is to extract useful insights from educational data collected by Politecnico di Milano (PoliMI) and use them to predict student dropout. This data are collected in big databases that, for each student, provide many information regarding their collateral information, their previous studies and their complete career at PoliMI. Our aim is to predict student dropout as soon as possible, by means of this information. Students at PoliMI are also naturally nested within different engineering degree programs in which the student dropout phenomenon might be different and might have different drivers. While investigating the learning process, it is necessary to disentangle the effects given by each level of data hierarchy.

In the light of this aspects, multilevel models take into account the hierarchical nature of data and are able to quantify the portion of variability in the response variable that is attributable to each level of grouping [3]. In this perspective, Generalized Linear Mixed Models (GLMM) fit a multilevel model on a binary response variable, imposing a linear effect of covariates on a transformation of the response variable [1]. The goal of our work is to exploit the advantage of generalized mixed-effects models to handle nested data, but developing a method that does not impose a parametric functional form in the relationship between the response and the covariates, since the educational context is a complex process where many factors interact among each others. Tree-based methods such as the CART model and its ensemble methods, i.e. random forest, learn the relationship between the response and the predictors by identifying dominant patterns in the training data [6, 7]. In addition, these methods allow a clear graphical representation of the results that is easy to communicate. We propose a novel method able to preserve the flexibility of classification RF model and to extend it to a clustered data structure, where multiple observations can be viewed as being sampled within groups: the generalized mixed-effects random forest (GMEF). In the literature this is not the first time in which tree-based methods are adopted to deal with longitudinal and clustered data. In [4, 8] regression tree methods for longitudinal or clustered data are proposed, but they both deal with a Gaussian response variable and they are not suitable to a classification problem. In [5] the approach presented in [4] is extended to non-gaussian data and a generalized mixed effects regression tree (GMERT) is proposed, but embedding a simple classification tree instead of a more robust method as a RF and a similar work is proposed in [2]. Indeed, this is the first time in the literature in which we extend a classification tree-based ensemble method to the case of a nested data structure.

2 Methodology

Let considering a generic GLMM. This model is an extension of a generalized linear model that includes both fixed and random effects in the linear predictor [1]. Therefore, GLMMs handle a wide range of response distributions and a wide range of scenarios where observations are grouped rather than being completely independent. For a GLMM with a two-level hierarchy, each observation j, for $j = 1,\dots,n_i$, is nested within a group i, for $i = 1,\dots,I$. Let $y_i = (y_{1i},\dots,y_{n_i i})$ be the n_i-dimensional binary[1] response vector for observations in the $i-$th group. The GLMM model is the following:

$$\begin{aligned}
&\mu_{ij} = \mathbb{E}[Y_{ij}|\mathbf{b}_i] \qquad\qquad j = 1,\dots,n_i, \quad i = 1,\dots,I \\
&g(\mu_{ij}) = \eta_{ij} \\
&\eta_{ij} = \sum_{p=1}^{P+1} \beta_p x_{ijp} + \sum_{q=1}^{Q+1} b_{iq} z_{ijq} \\
&\mathbf{b}_i \sim \mathcal{N}(\mathbf{0}, \Psi)
\end{aligned} \tag{1}$$

where $\mu_{ij} = p_{ij}$, $g(\mu_{ij})$ is the logit link function, i.e. $g(\mu_{ij}) = logit(\mu_{ij}) = logit(p_{ij}) = \log\left(\frac{p_{ij}}{1-p_{ij}}\right)$; β is the $(P+1)-$dimensional vector of coefficients and $\mathbf{x}_{ij}$ is the $(P+1)-$dimensional vector of fixed-effects covariates (including 1 for the intercept); $\mathbf{b}_i$ is the $(Q+1)-$dimensional vector of coefficients relative to the $i-$th group and $\mathbf{z}_{ij}$ is the $(Q+1)-$dimensional vector of random-effects covariates (including 1 for the intercept).

In our GMEF model, the fixed-effects part is not linear as in model (1) but it is replaced by the function $f(X_i)$ that is estimated through a RF algorithm. Thus, the model formulation is the following:

$$\begin{aligned}
&\mu_{ij} = \mathbb{E}[Y_{ij}|\mathbf{b}_i] \qquad\qquad j = 1,\dots,n_i, \quad i = 1,\dots,I \\
&g(\mu_{ij}) = \eta_{ij} \\
&\eta_{ij} = f(\mathbf{x}_{ij}) + \sum_{q=1}^{Q+1} b_{iq} z_{ijq} \\
&\mathbf{b}_i \sim \mathcal{N}(\mathbf{0}, \Psi).
\end{aligned} \tag{2}$$

The algorithm to implement GMEF is inspired by the GMET algorithm [2], but the main difference is that we use a random forest instead of a simple classification tree.

[1] We consider here the case of a binary response, but the model can handle any response variable in the exponential family.

3 Case study: GMEF for student dropout prediction

The PoliMi dataset within the SPEET project consists of 24,536 concluded careers[2] in Bachelor of Science (BSc) that began between A.Y. 2010/2011 and 2015/2016. Students are nested within I = 19 degree programs. A descriptive analysis shows that a high percentage - about 30% - of students leaves the PoliMI before obtaining the degree. Therefore, our goal is to find out which student-level indicators could discriminate between dropout and graduated students. We consider that student j is nested within degree program i. The model takes the form:

$$\begin{aligned} &\mu_{ij} = \mathbb{E}[Y_{ij}|\mathbf{b}_i] \qquad\qquad j = 1,\dots,n_i, \quad i = 1,\dots,19 \\ &g(\mu_{ij}) = \eta_{ij} \\ &\eta_{ij} = f(\mathbf{x}_{ij}) + b_i \\ &\mathbf{b}_i \sim \mathcal{N}(\mathbf{0}, \sigma^2_\Psi). \end{aligned} \tag{3}$$

where the response variable Y is the career status, a two-level factor we code as a binary variable: status = 1 for careers definitely completed with graduation and status = 0 for careers definitely concluded with a dropout; the random-effects structure simplifies to a random intercept, b_i, that represents the value-added, either positive or negative, of the $i-$th degree program. The set of fixed-effects covariates is shown in Table 1. We select only the career information at the first semester of the first year because our aim is to obtain a good prediction as soon as possible[3].

3.1 Results

We consider 70% of the sample as training set and 30% as test set. We apply GMERF model, setting 0.02 as convergence tolerance for the random-effects and 500 as number of trees for the RF (selected by cross-validation). The algorithm converges in 8 iterations. Figure 1 reports the importance rankings of the fixed-effects covariates extracted from the RF, the partial dependence plots of the three most important ones and the 19 estimated random intercepts with their confidence intervals. We observe that the information about student career at the university results to be the most importance predictor. In particular, looking at the partial dependence plot, the higher is the `WeightedAvgEval1.1`[4], the lower is the dropout probabil-

[2] We exclude active careers from the sample, i.e. we consider only students who graduated or dropped their studies (at any time during the follow-up time).

[3] A comparison analysis shows that the gain in prediction accuracy that we obtain if using the whole first year instead of the first semester information is too low to justify the waiting of the prediction of at-risk students until the end of the first year.

[4] We let the mean of the exams score start from 0 because we take into consideration students who did not pass any exam, whose mean is therefore 0.

Variable	Description	Type of variable
`Sex`	gender	factor (2 levels: M, F)
`Nationality`	nationality	factor (Italian, foreigner)
`PreviousStudies`	high school studies	factor (*Liceo Scientifico*, *Istituto Tecnico*, Other)
`WeightedAvgEval1.1`	weighted average of the evaluations during the first semester of the first year	real number
`AvgAttempts1.1`	average number of attempts to be evaluated on subjects during the first semester of the first year (passed and failed exams)	real number
`TotalCredits1.1`	number of ECTS credits obtained by the student during the first semester of the first year	natural number

Table 1 List and explanation of the student-level covariates included in the GMEF model.

ity; the higher is the `AvgAttempts1.1`, the lower is the dropout probability; the higher is the `TotalCredits1.1`, the lower is the dropout probability. Regarding the random intercepts, degree programs with estimated $\hat{b}_i$ whose confidence interval is totally positive (or negative) have on average students more (or less) likely to dropout, all else equal. The GMEF model applied to PoliMI data has, on the test set, Accuracy index equal to 0.9101 and a Sensitivity index equal to 0.8133.

4 Conclusions

We propose a multilevel tree-based ensemble model for a non-gaussian response (GMEF algorithm) and we apply it to PoliMI data to predict student dropout at the university. The GMEF model is new to the literature and can be applied to different classification problems relative to data with a hierarchical structure. In the case study, it provides easily interpretable results and has very good predictive power.

HateViz: a textual dashboard Twitter data-driven

HateViz: una Dashboard Twitter data-driven

Emma Zavarrone[1], Maria Gabriella Grassia[2], Marina Marino[3], Rocco Mazza[4], Nicola Canestrari[5]

Abstract The paper introduces *HateViz* dashboard, an interactive platform Twitter based about hate speech against women. Starting from texts collected from Twitter, using R packages, the aim of dashboard is to provide to the community of decision-makers an easy-to-use tool to monitor this important phenomenon. The dashboard mixes three methods: textual mining, latent topic models and textual network analysis and proposes a new approach for explaining the network based on topics and terms. Joint usage of topic modelling and textual network approach results in a better description of semantic content of each topic.

Abstract *Il paper vuole introdurre la dashboard HateViz, una piattaforma interattiva che si appoggia a Twitter, riguardante l'hate speech contro le donne. Partendo dalla raccolta da Twitter di testi scaricati tramite pacchetti di R, l'obiettivo della dashboard è di fornire alla community dei decision-makers uno strumento semplice da utilizzare per monitorare un fenomeno così importante. HateViz unisce tre metodologie: textual mining, latent topic model e analisi delle reti testuali, e propone un nuovo tipo di approccio per spiegare il network formato da topic latenti e lemmi. L'uso congiunto degli approcci di topic modelling e delle misure di rete fornisce una migliore interpretazione del contenuto di ogni topic.*

1 Introduction

The paper focuses on the data visualization of the hate speech against women inside the Italian Twitter community. *HateViz* is the proposed shiny dashboard, to represent an alternative way for reading the social-political changes (Fig. 1). Hate speech based communication is increasing with the massive production of user generated content on social network. The literature defines hate speech as content that disparages a person or a group on the basis of some characteristic such as ethnicity, gender, sexual orientation (Davidson et al., 2017; Malmasi and Zampieri, 2018). Under this perspective, to provide the community of decision-makers with an easy-to-use tool to monitor these changes becomes more crucial. Starting from tweets, collected through API using R, the *HateViz* allows to explore the mining of contents extracted and study the lexical structure that link the principal discussion topics. The contribution at the state of the art is a new point of view studies that focus on communities' discourse and a development of a representation tool for our results. This paper is structured as follows: section 2 show the methods and the data visualization tools used, section 3 more specifically discusses the results of the research, and in section 4 there are the future works.

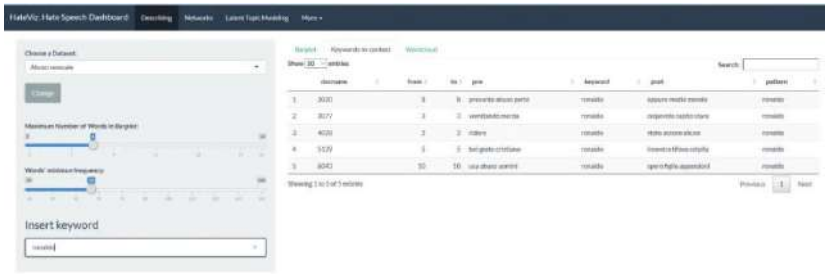

Figure 1: The dashboard user interface

2 Methodological approach

The *HateViz* mixes three methods: textual mining, latent topic models and social network analysis and proposes a new approach for explaining the network based on topics and terms. Figure 2 shows the dashboard's flowchart: (1) content extraction and corpus pre-processing; (2) descriptive study of texts: most frequent words and co-occurrence network analysis; (3) applying a model to extract and identify the latent topics within the contents collected; (4) using network analysis's both a better interpretation of each topic and the semantic relationships between the extracted topics and documents' terms. The corpus was built with a random sample of tweets in Italian language and the pre-treatment operations (bag of words approach) have been applied. A final Document-Term Matrix has been generated without sparse words and empty documents. DTM allows to describe the corpus of tweets through common visualizations such as barplot of most frequent words and wordcloud. In addition, the

DTM can be read like an affiliation matrix in which to analyse the relationships between words and the texts. We converted this in co-occurrence matrix to transform the collection of text into a visual maps of words, a similar approach has been applied by Segev (2020). In this step *HateViz* uses the networks and its centrality measures (Faust, 1997): degree and closeness. The search of semantic structure has been realized from a DTM through the Latent Dirichlet Allocation model (Blei et al., 2003; Griffiths and Steyvers, 2002; 2003; 2004; Hofmann, 1999; 2001). LDA is the method used both to extract latent topics and to construct the *terms-topics* matrix. The model is a generative and Bayesian inferential model and it allows to infer the latent structure of topics through by recreating the documents in the corpus considering the relative weight of the topic in the document and the word in the topic, in an iterative way. At the base of the LDA we find the following assumptions: a) documents are represented as mixtures of topics, where a topic is a probability distribution over words; b) the topics are partially hidden, latent precisely, within the structure of the document (Steyvers and Griffiths, 2007). At first glance, the main methodological challenges faced lie in the construction of a two-mode matrix of reduced order able to represent the terms topics network. The original contribution is the network construction, we operated a selection of terms based on a probability threshold derived from the model (LDA) results.

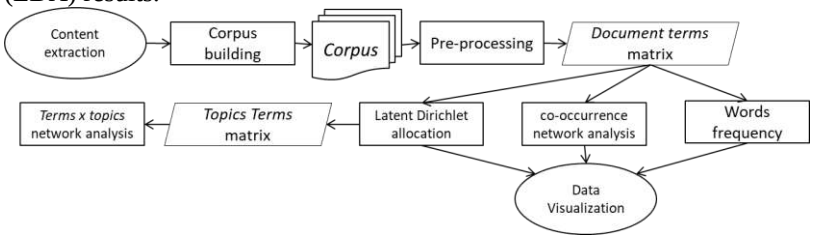

Figure 2: The *Hateviz* dashboard's flowchart

3 Results

The main outcome of the dashboard (Fig. 2) is to show results from the analysis in an easy and interpretable way. *HateViz* has an intuitive layout with a clear division between the control panel on the left and the plotting space on the right. The interactive control panel allows the selection of the datasets from different keywords and the customed plot output from different analysis: 1. Barplot of frequencies; 2. Keywords in context; 3. Co- occurrence network analysis; 4. Wordcloud of terms; 5. Latent Topics; 6. Terms Topics Network (A beta version of shiny web app is already on line at link: https://rccmazza.shinyapps.io/Donne4/). The dashboard has been developed on 403.612 tweets extracted from July 2018 to May 2019. The complete database is composed by seven sub-datasets, each one selected from specific keywords. *HateViz* allows an analysis for each textual dataset built with extraction keywords. The wordcloud in Figure 4 shows three semantic dimensions: the first one is banally referable to the cases of news commented by users on the social; the second

one to an institutional and regulatory dimension, in fact there are words referred to the need for stronger penalties; in the last one we find the ways in which violence against women can be realized. From the representation of the network and the centrality measure, it is possible to make some observations. Looking at the position in the graph, terms in a central position like “donne” (women), “stupro” (rape), “accuse” (charges) or “vittime” (victims) indicates a strong link and relations with most of the other lemmas, meaning that these words are the main core of the network.

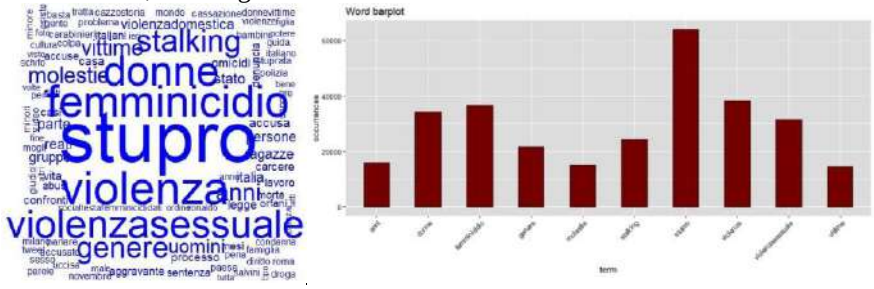

Figure 4 a. Wordcloud **b.** Barplot

Terms	***Abs. degree***	***Nor. Degree***	***Terms***	***Abs. degree***	***Nor. Degree***
abuso	70	1.000	colpa	65	0.929

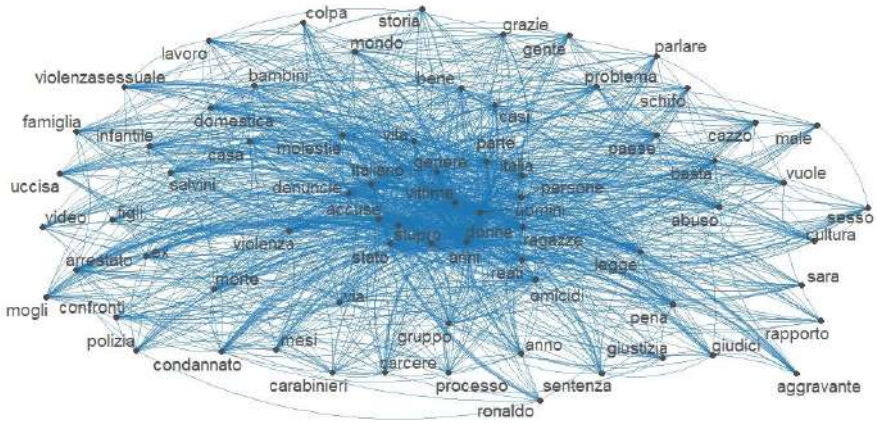
Table 1: Degree centrality values calculated on total co-occurrence matrix

Even marginal terms, arranged along the borders of the graph, for example “aggravante” (aggravating), have lot of connections within the network and with central terms.

Figure 5 *Co-occorence network (high sparsity cut)*



The topics extracted with the LDA model are 5. The dimensions emerged from model take up some latent themes. Using jointly topic modeling and SNA allows to better define the content of each topic. Specifically, it emerges five main themes:

1. First topic: a reference to the implementation of judgement, some examples of terms in this topic are “polizia” (police), “arrestato” (arrested), “denuncie” (denunciation/charge);
2. Second topic: referring to the public attention on social media, involving terms like “tweet”, “foto” (pictures), “gente” (people), “visto” (seen);
3. Third topic: a reference to the cultural dimension of the phenomenon, with terms like “genere” (gender), “uomini” (men), “donne” (women), “amore” (love);
4. Forth topic: a reference to the institutional dimension, involving terms like “ministro” (minister), “salvini”, “italia” (italy), “italiani” (italian)
5. Fifth topic: referred to legal and trial aspects, with terms like “reato” (crime), “omicidi” (murder), “pena” (sentence).

Through the words-topic network (Zuo, Zhao and Xu, 2015) it is possible to observe how the terms are associated with the referred topic. The network is composed by latent topics identified through the LDA technique giving the opportunity to examine how the terms from corpus are associated with them. A topic that takes a central position in the network represents the main semantic area identified in the dataset. A term, which represents a node connecting different topics indicates that is not only present in both thematic groups to which it is connected, but also represents a connection between semantic areas associated with each topic.

Terms	***Closeness centrality***
Vittime	0.699
Molestie	0.694
Ragazze	0.689
Stato	0.694

Table 2: Closeness centrality values calculated on two mode matrix

The words-topics graph shows how topic1 (implementation of judgement) and topic3 (cultural dimension) are positioned at the centre of the network, which means that they represent the most relevant semantics in the dataset. Its position in the network makes topic1 a bridge, a node connecting topic3 and topic5 (legal and trial aspects) with topic2 (public attention) and topic4 (institutional dimension), since topic1 is the node that connects the other topics, and without that node the whole network would collapse. It is possible to notice terms that belong to more than one topic, connecting them: topic1 and topic4 are linked by the term "ragazze" (girls); topic2 and topic1 are linked by the terms "stato" (country); topic1 and topic3 by the word "molestie" (harassment); topic3 and topic5 are linked by the term "vittime" (victims). In Tab. 1 there are the closeness centrality values for this hub terms.

4 Future works

This paper represents a work in progress, In the future we will extend the functionality of the application by implementation of machine learning tools that will intercept statements containing hate speech and can made a semantic map of it. The work presents this possible further development:

- Deep learning algorithm to report hate speech contents
- Control measure about the correct content identification

How to perform cyber risk assessment via cumulative logit models

Valutazione del cyber risk con modelli logit cumulativi

Silvia Facchinetti, Silvia Angela Osmetti and Claudia Tarantola

Abstract Cyber risk assessment is a field with a growing amount of research. Information on monetary losses due to a cyber attack is difficult to gather due to the sensitive nature of the data. An evaluation of the severity of the attack on an ordinal scale is easier to obtain. We apply a cumulative logit model to identify the variables that mostly affect the severity of an attack. A systemic risk indicator based on social network analysis is proposed and included in the model.

Abstract *La valutazione del cyber risk è un tema di ricerca molto attuale. Informazioni sulle perdite monetarie dovute a un attacco informatico sono difficili da reperire a causa della natura sensibile dei dati. È più facile ottenere una valutazione della gravità dell'attacco su scala ordinale. Applichiamo un modello logit cumulativo per identificare le variabili che influenzano maggiormente la gravità di un attacco. Un indicatore di rischio sistemico basato sull'analisi dei social network è proposto ed incluso nel modello.*

Key words: criticality index, cumulative logit model, cyber risk, social network

1 Modelling cyber risk data

Institutions should be encouraged to collect cyber incident data in order to employ statistical techniques to prevent such type of incidents and estimate their impact/gravity. Although quantitative loss data are rarely available, sometimes it is possible to obtain a qualitative appraisal of the attack severity based on an ordinal scale.

We consider a set of $2,679$ observations regarding serious cyber attacks occurred worldwide in the period 2017-2018. The data have been collected by the researchers of the *Hackmanac Project* and described in the Clusit Report on ICT Security[1]. An attack is classified as "serious" if it had a significant impact on the victims in terms of economic losses, damages to reputation and/or dissemination of sensitive data. Cyber risk severity (S) is described by an ordinal variable assuming values 1 (medium severity), 2 (high severity) and 3 (critical severity).

We apply a cumulative logit model to express the severity of a cyber attack as a function of a vector of covariates $\mathbf{x}$

$$logit[P(S \leq s)] = \alpha_s - \mathbf{x}^T \boldsymbol{\beta} \qquad s = 1,2 \tag{1}$$

where α_s is a specific intercept and $\boldsymbol{\beta}$ is the vector of the regression parameters. The larger the value of $\mathbf{x}^T \boldsymbol{\beta}$, the higher the probability to obtain an elevated level of cyber risk. Model (1) implies a constant relationship between the cumulative probabilities and the covariates. For a specific set of of covariates, the logit is altered only by the intercepts which are different for each category. This is known in the literature as the Proportional Odds (PO) assumption.

As covariates we consider the following categorical variables classified on a nominal scale: Type of Attack, Attack Technique, Continent. We use social network analysis and its centrality measures to construct a quantitative indicator (Closeness) of the diffusion of cyber attacks among the different victims. The nodes of the network correspond to the victims of cyber attacks, while the edges indicate the strength of their connections, see Figure 1.

The network in Figure 1 is constructed as follows. For each victim we calculate the weekly time series of the Criticality Index by [3], then we estimate the network based on the partial correlation matrix among the previous series. Variable Closeness corresponds to the network centrality measure proposed by the authors of [7].

2 Empirical results and discussion

Table 1 shows the estimates of the model coefficients obtained adapting model (1) to our data[2]. As expected, Closeness is significant and affects positively the severity

[1] Clusit is an Italian association for cyber security based in Milan.

[2] The baseline categories for the categorical variables Type of Attack, Attack Technique and Continent are Cybercrime, SQL Injection and Multiple continents, respectively.

Table 1 Cumulative logit model fitted to the cyber risk data.

Covariates		value	std.error	z.value	p.value
Type of Attack	Espionage/Sabotage	1.879	0.140	13.431	0.000
	Hacktivism	0.252	0.162	1.558	0.119
	Information Warfare	1.083	0.199	5.441	0.000
Attack Technique	0-day	-0.568	0.854	-0.665	0.506
	Multiple Threats	-1.470	0.761	-1.932	0.053
	Trivial Threats	-1.933	0.740	-2.613	0.009
	Unknown	-1.935	0.743	-2.606	0.009
Continent	Africa	0.367	0.377	0.974	0.330
	America	0.756	0.097	7.749	0.000
	Asia	0.883	0.143	6.161	0.000
	Australia/Oceania	1.197	0.292	4.093	0.000
	Europe	0.743	0.125	5.928	0.000
Closeness		0.985	0.452	2.179	0.029

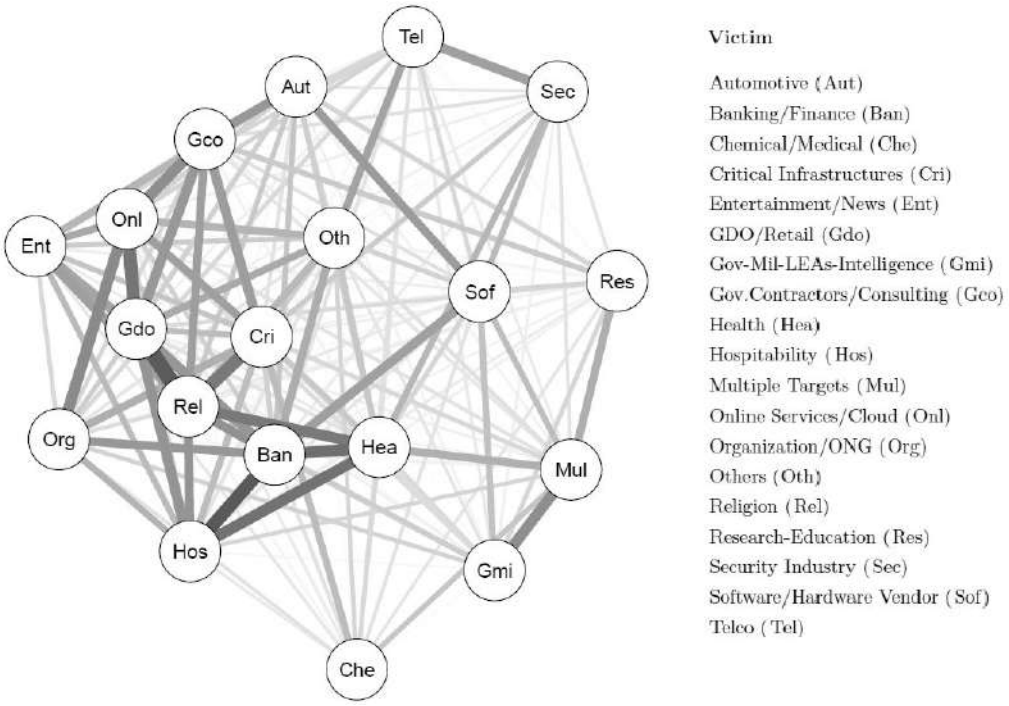

Fig. 1 Network model among the victims of cyber attacks.

level. In terms of real-world implications, if a victim strongly connected suffer a critical attack, it has an influence on the attack severity level of the other connected victims, with respect to the ones not strongly connected. Hence, strongly connected victims should have a collaborative approach to prevent critical cyber attacks. Otherwise, the gravity of the attacks they suffered and the related consequences could increase.

The Lipsitz global test [5] shows a good fit for the model, and the likelihood ratio test indicates a significant improvement over the baseline intercept-only model. For a detailed analysis of this data see [4].

We conclude this section with a discussion on the validity of the PO assumption. Testing the PO assumption is challenging both in a frequentist and Bayesian frameworks, especially when many categorical variables are involved. Usually the score test by [8] is used to check the PO assumption. However, as discuss in [2], it tends to reject the null hypothesis even when the PO assumption is reasonable. Hence, we computed the score test for each category of the covariates, separately (see [4]). These tests suggest that the PO assumption could be rejected for the categories Unknown and Espionage/Sabotage. A reasonable strategy for investigating whether these categories are really problematic could be to fit three separate logistic regressions, calculate the corresponding estimated Odds Ratios (ORs) and compare them with the OR obtained from the cumulative logit model.

The analysis performed suggest that the ordinal PO model is a fair summary of the patterns in the data in relation to the severity levels. However, it is possible to relax the PO assumption by specifying a more complicated cumulative logit model without proportional odds [1], or a partial proportional odds model [8]. For a recent contribution in the Bayesian setting see [6].

Machine learning prediction for accounting system

Classificazione predittiva per la contabilizzazione delle fatture elettroniche

Chiara Bardelli, Silvia Figini

Abstract Electronic invoicing has become mandatory for Italian companies since January 2019. Each invoice has to be structured in a predefined xml template which facilitates the accountants work. Thanks to this measure the information included in the invoice can be easily extracted and analysed giving the possibility to automate part of the accounting process: all sent or received invoices of a company have to be classified into specific accounting codes. This task can be easily translated into a machine learning multiclass classification problem where the accounting code is the target variable of our problem. In this work we propose two different approaches and compare them in terms of prediction accuracy. We remark that better performances can be achieved considering the hierarchical structure of the accounting codes, our target variable.

Abstract *Da gennaio 2019 la fatturazione elettronica è diventata obbligatoria per qualsiasi azienda italiana. Questa misura ha permesso di snellire il processo di contabilizzazione delle fatture, uniformando le informazioni contenute in esse in un template xml. La parte più corposa del processo di contabilizzazione rimane comunque la classificazione delle fatture utilizzando il piano dei conti econimici (un elenco di conti che descrivono la natura economica delle transazioni effettuate). Questa fase del processo può essere tradotta in un problema di classificazione di machine learning nel quale vogliamo predire il conto economico associato ad ogni linea di fattura. Proponiamo quindi due possibili approcci per trattare questo tipo di problema confontandoli in termini di accuratezza nella predizione. La struttura gerarchica a livelli del piano dei conti suggerisce l'applicazione di un algoritmo di classificazione gerarchico come lavoro futuro.*

1 Introduction and motivation

The accounting profession is faced with the numerous challenges of the digitalization era. Modern technologies lead to the automation of part of the workload of accountants. As a consequence, repetitive routine tasks can be replaced by algorithms that give the possibility to accountants to focus instead on all those activities that require human critical thinking and creativity [4]. One of the tasks which can be easily automated is the process of recording financial transactions contained in supplier or customer invoices. When an invoice is received or issued by a company, the accountant has to decide which codes should be charged. This task can be easily translated into a predictive classification problem: input variables can be extrapolated from the invoices and accounting codes can be considered as the target variable.

Machine learning techniques have been extensively used for extracting features and information from scanned invoices by combining the classical OCR (Optical Character Recognition) methods to deep neural networks [5], [8]. Yet, since January 2019 all Italian companies have been asked by law to issue electronic invoices in a structured and fixed xml template. This aspect solves the main issue of extracting information from scanned documents allowing to focus on the automation of the classification of transactions included in the invoice ([1],[2]).

In this paper we apply a machine learning model to the content of the electronic invoice to predict the accounting codes. Each line of the invoice is represented by a numeric vector that combines textual description and other codes related to the line. We test performances of our classifier on sample data provided by a company which develops software for professional accounting. The main challenges of this problem are: (i) the reconstruction of the training set, and (ii) the complex structure of the accounting codes which are organized in a hierarchical taxonomy based on 5 levels for a total of 90 different labels leading to an imbalanced classification problem.

The rest of the paper is organized as follows: Section 2 defines the problem and the dataset; Section 3 introduces the methods applied to reconstruct the training set and to solve our predictive problem; in Section 4 the application and the most relevant results are displayed; finally, Section 5 contains some concluding remarks.

2 Description of the dataset

Given the information about a line of an invoice and the characteristics of the companies which are involved, the aim is to predict the accounting code related to the line. Multiple lines of an invoice can be associated to the same accounting code. For sake of simplicity, we assume that the lines inside an invoice are independent ignoring the grouping term which could influence the predictive output. In our classification task, we construct the prediction rule given the training sample $\{(y_i, \mathbf{x}_i)\}_{i=1}^{N}$ with:

- y_i, $i = 1,...,N$, categorical observations which represent the accounting codes associated to the i-th line of invoice

- $\mathbf{x}_i$, the vector of predictors related to the content of the invoice

The dataset considered in this study is the combination of two data sources: electronic invoices in xml format and accounting outputs result of the recording of the invoices. The match of these two different sources is possible only at document level. On the other hand, it is not possible to recreate directly the relation between a single line of an invoice and the associated accounting code. This problem of data reconstruction can be addressed exploiting the information about the amounts which are included both in the xml invoices (detailed amounts) and in the accounting outputs (aggregated amounts). Thanks to this information it is possible to translate it into a knapsack problem with equality constraints as explained in Section 3.1.

In our classification problem features consider information related to the content of the invoice and characteristics of the companies. In particular, we consider:

- textual description of the line of the invoice
- codes associated to the line (like VAT code)
- information about activities performed by companies:
  - ATECO code (classification of economic activity) provided by ISTAT
  - ISA categories based on the level of fiscal reliability

The dataset contains information about 9422 electronic invoices which provide more than 60000 lines to classify.

3 Methods

We describe methods applied for the reconstruction data problem, for the preprocessing of textual data and for the choice of the predictive classification algorithm.

3.1 Knapsack problem

The reconstruction data problem is represented as a multi knapsack problem with equality constraints [7] considering a single invoice at a time. Let $i = 1,...,N$ be the lines of the invoice and $j = 1,...,M$ be the index that identifies the accounting codes. The problem can be formulated as follows:

$$\max \sum_{j=1}^{M} \sum_{i=1}^{N} p_i z_{ij} \tag{1}$$

$$\text{s.t.} \quad \sum_{i=1}^{N} c_i z_{ij} = b_j, \quad \forall j \tag{2}$$

$$\sum_{j=1}^{M} z_{ij} = 1, \quad \forall i \tag{3}$$

where c_i is the detailed amount of the i-th line and b_j is the aggregated total of the j-th accounting code. The vector of weights p_i is considered equal to 1 for each i. The value of $z_{i,j}$ is 1 if line i-th is associated to the j-th accounting code, 0 otherwise.

The problem has been resolved through an heuristic which stops when the first feasible solution is found. First, the heuristic orders the amounts of lines in a vector in decreasing order and the aggregated amounts in an increasing order vector. Then, the algorithm starts to match first values in the first positions of the two vectors.

The algorithm has successfully matched the 88% of the lines of our initial dataset, which has been used for the training phase and the evaluation of the performances.

3.2 Data preprocessing

Textual data included in lines of invoices have been previously cleaned through standard preprocessing steps [6]. Finally, textual information has been tokenized to create array of words. In order to transform textual data information into a suitable feature space we compare two different procedures:

- Bag of Words (BoW) approach [10], a simple way to encode the array of words into a binary vector. The main drawback is that the length of the feature vector grows linearly with the number of distinct words, leading to infeasible sizes.
- Word2Vec algorithm [9], a language modeling technique which maps similar sentences into similar numeric vectors of fixed size.

This two different procedures have been combined to two different classification algorithms described in subsection 3.3.

3.3 Classification algorithm

The different nature of sent and received invoices made us split them in 2 different sub-datasets and analyse them separately to obtain 2 classification algorithms.

For each sub-dataset two different classification algorithms have been compared in this study: Support Vector Machine classifier (SVM) [10] and Random Forests (RF) [3]. To adopt the SVM classifier for multiclass classification, the one-vs-rest technique has been used. This procedure has a very high computational cost since the number of classes is very large (70 distinct classes for the received invoices).

4 Application to real dataset

To evaluate the performance of the two approaches the dataset has been split into training set (80 %) and test set (20 %). Tables 1 and 2 shows performances of the two

different combinations applied respectively to sent invoices and received invoices. As we expected, the algorithm trained on received invoices shows an accuracy rate lower than sent invoices, due to the fact that first are more diversified in terms of content and accounting codes associated. As far as the classification algorithm is concerned, Random Forests combined to Word2Vec performs better both for sent and received invoices. This can be explained by the limited vocabulary used in SVM combined with BoW: only 200 words have been considered because of the high computational costs.

Table 1 Performances evaluated on test set (sent invoices)

	Precision	Recall	F1-score
RF + Word2Vec	91 %	92 %	91%
SVM + BoW	87 %	84 %	86 %

Table 2 Performances evaluated on test set (received invoices)

	Precision	Recall	F1-score
RF + Word2Vec	82 %	85 %	82%
SVM + BoW	78 %	74 %	75 %

To investigate the hierarchical structure of the target variable, Random Forests algorithm has been trained for each level of the hierarchy in order to show the improvement of the performances and to motivate a deeper study on hierarchical classification algorithms. Figure 1 shows the accuracy rate for the different levels of the target variable. Both for sent invoices and received invoices the accuracy rates improve at lower levels (accounting codes associated to lower levels are more generic and easier to predict). This aspect can be exploited to guide the classification output through the structure of the accounting codes.

5 Conclusion

Part of the bookkeeping process deals with the classification of the transactions reported in invoices into specific accounting codes. This is often a time-consuming process, which can be translated in a machine learning classification algorithm. In this work we presented a possible procedure to handle with accounting data from the reconstruction of the dataset to the training of a machine learning classifier. We tested two different approaches and we noticed that Random Forests combined to Word2Vec can be considered a good candidate to solve our problem.

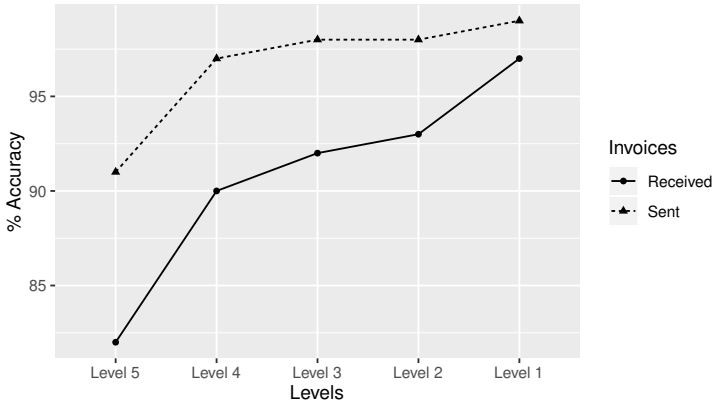

Fig. 1 Accuracy computed at different levels of the target variable with RF and Word2Vec.

One of the main difficulty is to handle the high number of different labels used in this dataset. A possible approach to solve this problem is to consider a hierarchical classification framework: the target variable is structured in a predefined hierarchy which takes the form of a rooted tree. This is also motivated by the results obtained for the classification at different levels of our target variable. We consider the application of hierarchical classification algorithm [11] as a possible future work.

Teaching statistics: an assessment framework based on Multidimensional IRT and Knowledge Space Theory

Un modello di valutazione della conoscenza per l'insegnamento della statistica: l'esperienza del progetto Erasmus+ ALEAS

Cristina Davino[a], Rosa Fabbricatore[a], Carla Galluccio[b], Daniela Pacella[a], Domenico Vistocco[a], Francesco Palumbo[a]

[a] University of Naples Federico II
[b] University of Florence

Abstract In recent years, there is an increasing need for technology-based platforms to assist traditional learning methodologies. However, it is challenging to set up a common assessment framework to evaluate user knowledge. To address this issue, we propose an approach to teaching undergraduate statistics that makes use of the psychometric Item Response Theory based on latent class categorization to evaluate the user ability based on the European learning outcomes - the Dublin descriptors. Additionally, we enclose the user assessment workflow in a formalized structure using the principles of Knowledge Space Theory to track the current user knowledge state adaptively. The methodological framework serves as a base for the app developed within the ALEAS ERASMUS+ Project.

Abstract *Di recente, è stata evidenziata una maggiore necessità di piattaforme tecnologiche come ausilio alle metodologie di apprendimento tradizionali. Tuttavia, è difficile istituire un quadro di valutazione comune per le conoscenze degli utenti. Pertanto, proponiamo un approccio all'insegnamento della statistica universitaria che si avvalga della teoria psicometrica Item Response Theory basata sulla categorizzazione in classi latenti, allo scopo di valutare la capacità dell'utente sulla base di obiettivi di apprendimento europei, i descrittori di Dublino. Inoltre, racchiudiamo il flusso di valutazione degli utenti in una struttura formalizzata utilizzando i principi della Knowledge Space Theory per tracciare in modo adattivo l'attuale stato della conoscenza dell'utente.*

Key words: Item Response Theory; Knowledge Space Theory; Statistics; Technology-enhanced learning; Intelligent tutoring systems

1 Introduction

The problem of assessing the student on a multidimensional level is one of the most challenging tasks in education (Deonovic et al., 2018). The student behaviour and responses should be evaluated on the one hand in comparison with the student population, on the other hand in comparison with the individual performance changes over time, so to measure the learning outcomes.

Recently, there is rising attention towards teaching statistics using technology. Although there are several technologies developed for teaching and assessing statistics, there are not many applications specifically targeting undergraduate students in non-scientific courses. Recently, Lopez Lamezon and colleagues demonstrated the advantages of using a virtual environment for teaching statistics in Medicine degree courses although not grounding their learning assessment upon specific educational theories (López Lamezón et al., 2018).

A complete assessment framework should be able to:

- detect the overall ability level of the student sample and to adapt to it;
- personalize the student experience selecting the most appropriate set of topics, questions and items to present according to each student's knowledge progress.

Concerning the first requirement, we exploit the Item Response Theory (IRT) (Rasch, 1960a). IRT allows modelling the probability that each student answers correctly to a particular item given her or his ability. It also allows estimating the difficulty of each item given the sample of answers. We categorize the items of each statistics subtopic according to the Dublin descriptors of the learning outcomes. Concerning the second requirement, we resort to Knowledge Space Theory (KST) (Doignon and Falmagne, 1985), widely used in the field of expert systems to the end of organizing the full knowledge required to master a specific subject into a direct acyclic graph structure. Nodes of the graph represents a competency. Each student is classified into a state and the system decides the following direction on her/his learning path. The proposal describes the core of ALEAS (Adaptive LEArning in Statistics), a learning platform developed as the intellectual output of the homonymous Erasmus+ project. ALEAS aims to be a complement to traditional teaching methodologies. It focuses on the assessment phase, primarily for university students enrolled in non-scientific degree curricula.

Over the knowledge structure for basic statistics knowledge, a directed acyclic graph consisting of several statistics subtopics is defined. Students' performance assessment is based on the multidimensional latent class IRT model with dichotomous items (Bartolucci, 2007).

The Dublin descriptors are the framework for qualifications of higher education courses in the European area; they qualify the expected outcome of any learning process. Our proposal focuses on the assessment of hard skills, and in particular statistics, and hence we consider the following three descriptors (Gudeva et al., 2012):

- *Knowledge and understanding (K)*: the ability to demonstrate knowledge and understanding with a theoretical, practical and critical perspective on the topic;
- *Applying knowledge and understanding (A)*: the ability to apply the knowledge identifying, analysing and solving problems sustaining an argument;

- *Making judgments (J)*: the ability to gather, evaluate and present information exercising appropriate judgment.

2 Methodology

A description of both the general KST framework and the IRT methodology will be provided in the following subparagraphs.
KST is a methodological framework that analyzes the performance over time of individual students (Doignon and Falmagne, 1985, 2016). It is particularly useful for the current knowledge assessment of the students, and also to adaptively select the most tailored items to present to the student given his or her ability. KST formalizes a structure of the domain into nodes of a directed acyclic graph aiming to assess each learner according to which subsets of the domain they master. The use of KST induces a twofold issue:

- to construct the structure of the knowledge domain investigating the relationship among the different subsets of the domain;
- to select the most appropriate questions that allow assessing the current knowledge subsets the student has mastered.

Several algorithms implement the progression rule from one to the next knowledge state. The probabilistic model considers each knowledge state having a likelihood function whose parameters are updated according to the student answers; while the expert model that we proposed for the ALEAS platform aims to construct a knowledge graph with the help of experts. We divided statistical knowledge into nodes, and we set constraints to the student progress path. In particular, to progress from one node to the other, a student has to obtain mastery - considered as the highest level of ability - in all the required nodes. The level of ability is evaluated through the multidimensional IRT model described below (Fabbricatore et al., 2019).
IRT is a model-based theory that aiming at estimating the probability that each student will answer correctly to each item of a set. IRT models founded on the idea that the probability that an individual provides a certain response to a certain item can be described as a function of the person's latent trait, plus one or more parameters that characterize a specific item. A latent trait is typically described by a continuous normal probability distribution (Bartolucci et al., 2015).

According to the traditional logistic IRT models with dichotomous items, the probability that the s-th subject (with $s = 1, \ldots, S$) will respond correctly to the item i (with $i = 1, \ldots, I$) in the most general form (4-parameter logistic model; 4PL) can be formalized as following:

$$P(X_{si} = 1 | \theta_s, \Gamma_i) = c_i + \frac{1 - d_i - c_i}{1 + e^{a_i(\theta_s - b_i)}} \tag{1}$$

where X_{si} is the response of the s-th subject on the i-th item with realization $x_{si} \in [0,1]$, $\theta_s \in \mathbb{R}$ is the ability of the s-th subject, and $\Gamma_i = (a_i, b_i, c_i, d_i)$ is the whole set of parameters of the i-th item. In particular, $a_i \in \mathbb{R}$ is the item discrimination parameter,

$b_i \in \mathbb{R}$ represents the item difficulty, and $c_i, d_i \in \mathbb{R}$ are the guessing and the ceiling error parameters respectively (Noventa et al., 2019). So, logistic IRT models are based on the idea that the correct response probability follows a logistic curve called the Item Characteristic Curve, and it is always directly proportional to the ability of the student (Rasch, 1960a; Birnbaum, 1969). Each item has its specific curve, which is defined by a set of parameters, between one and four. The four parameters refer to: *(i)* discriminating power (slope), *(ii)* item difficulty (location), *(iii)* guessing (lower asymptote) and *(iv)* ceiling (upper asymptote). Reduced models can be obtained constraining one or more parameters. This is the case of 2 parameter logistic IRT ($c_i, d_i = 0$ in equation 1) and 1 parameter logistic IRT ($a_i = 1$ and $c_i, d_i = 0$ in equation 1) models. In particular, only the error parameters (c_i, d_i) are considered for the model with 2 parameters. Such parameters take into account the case incidence on the probability of the correct answer. Models with 1 parameter also assume that all items have the same discriminative power (Rasch model; Rasch (1960b)).

In ALEAS, to perform the categorization of the items we adopted the model with 2 parameters, disregarding the guessing and the ceiling parameters. The choice was made taking into account that each item has four possible answers, lowering the impact of guessed answers. The model is applied to student responses, where we only take into account if the given response is correct or incorrect.

3 The proposed model for item and user categorization

The extension of traditional IRT models proposed by Bartolucci (2007) with the introduction of multidimensional latent class IRT models provides a suitable statistical tool to pursue our goals. Introducing the concepts of multidimensionality and discreteness of the latent traits, these models allow releasing both the IRT constraints of unidimensionality and continuous nature of the latent trait. In this view, we can simultaneously consider more latent traits each of which is represented by a discrete distribution with $\xi_1, \ldots, \xi_k$ support points defining k latent classes with weights $\pi_1, \ldots, \pi_k$. Latent class weights π_c (with $c = 1, \ldots, k$) represent the probability that a subject belongs to class c, and can be expressed as:

$$\pi_c = p(\Theta_s = \xi_c) \tag{2}$$

with $\sum_{c=1}^{k} \pi_c = 1$ and $\pi_c \geq 0$, where Θ_s ($s = 1, \ldots, S$) represents the discrete random variable of the latent trait of the sth subject. Multidimensionality, in this model, is introduced through a simple formulation in which each item is related only to one latent trait. In particular, items are divided in different subsets I_d (with $d = 1, \ldots, D$) based on D different dimensions, which, in our model, are represented by the three Dublin descriptors considered: K (knowledge and understanding), A (Applying knowledge and understanding), and J (making judgments).

Once the model has been defined, the next step is to estimate the parameters. We exploit a Maximum Marginal Likelihood approach making use of the Expectation-Maximization (EM) algorithm (Bartolucci et al., 2014).

In particular, the model tries to estimate (Expectation step) the probability of each individual belonging to one of the latent classes given his or her vector of responses; during the Maximization step it maximizes the log-likelihood that the individual belongs to that latent class. These two steps are repeated until convergence.

In order for the parameters of the model to be identified, a full matrix of individuals and responses must be supplied without missing values. Additionally, the model requires the constraint that, for each latent trait, one discriminating index is equal to 1 and one difficulty parameter is equal to 0 (Bartolucci et al., 2014).

Each user will thus be categorized into a latent class according to their response configuration. The number of latent classes k for the data can be estimated using information criteria such as the Bayesian Information Criterion or the Akaike information criterion (Gnaldi, 2017), or they can be defined according to the theoretical framework. For the present work, we established the number of classes to be $k = 3$, consistently with the number of dimensions defined by the Dublin descriptors, and hence with the theorized levels of ability. The model is applied using the R package `MultiLCIRT` (Bartolucci et al., 2014). The IRT model is applied separately for every node of the KST. The flow of information within each of the knowledge states of the KST is shown in Figure 1.

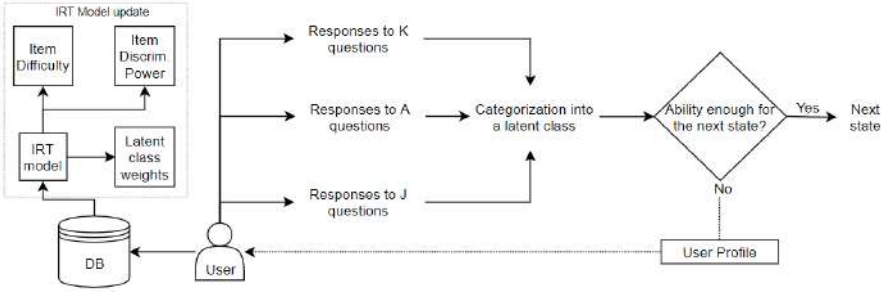

Fig. 1 Flow of information within a KST node and progress using the ability evaluated by the IRT model.

4 Conclusion

We proposed a methodological framework for the development of an intelligent tutoring system for assessing knowledge of statistics. The model targets undergraduate students and assesses them on a multidimensional level. To do so, we have presented a possible integration of a classical statistical and psychometric methodology - the

Item Response Theory, the Dublin descriptors of learning outcomes and a computational knowledge formalization - the Knowledge Space Theory for the structure of the user model.

The weight of words: textual data versus sentiment analysis in stock returns prediction

Il peso delle parole: dati testuali versus sentiment analysis per predire i rendimenti azionari

Riccardo Ferretti and Andrea Sciandra

Abstract The focus of this paper is to understand whether the words contained in a text corpus improves the explained variance of stock returns better than the use of the polarity of the same texts, obtained through a sentiment analysis using a generic ontological dictionary. The empirical analysis is based on the content of a weekly column in the most important Italian financial newspaper, which published past information and analysts' recommendations on listed companies. The use of textual data clearly increases the explained variance of stock returns but, through comparisons between data mining techniques, we observed minor differences in terms of MSE, by adding a selection of specific terms as features. In this context, the text mining approach proved to be very useful to improve the explanatory power of forecasting models, while it emerged the limited explanatory power of an automatic sentiment analysis based on a generic lexicon.

Abstract *Il focus di questo contributo è capire se le parole contenute in un corpus di testi migliorano la varianza spiegata dei rendimenti azionari rispetto all'uso della polarità degli stessi testi, ottenuta mediante una sentiment analysis utilizzando un dizionario ontologico generico. L'analisi empirica si basa sul contenuto di una rubrica settimanale del più importante quotidiano finanziario italiano, che ha pubblicato informazioni già note e raccomandazioni di analisti per una selezione di aziende. L'utilizzo di dati testuali chiaramente migliora la varianza spiegata dei rendimenti azionari ma, mediante il confronto tra diverse tecniche di data mining, abbiamo osservato modeste differenze in termini di MSE, quando abbiamo aggiunto alle variabili esplicative una selezione di parole. In questo contesto, l'approccio del text mining ha mostrato la sua utilità per migliorare la potenza esplicativa in modelli di previsione, mentre è emersa la scarsa capacità esplicativa di una sentiment analysis automatica basata su un dizionario ontologico generico.*

Key words: Text Mining, Sentiment Analysis, Stock Returns, Data Mining

Andrea Sciandra, Department of Communication and Economics, University of Modena and Reggio Emilia; email: andrea.sciandra@unimore.it

1 Introduction

This paper is part of a wider project whose main goal is to analyse the market reaction to the dissemination of analysts' recommendations published in print media, in order to explain the market reaction to 'buy' advice. Specifically, the hypothesis under consideration is that past analysts' recommendations induces abnormal movements in stock prices and returns.

Previous research found a positive market reaction to the publication of the past information when analysts grade the stock as a good opportunity. In particular, Cervellati et al. (2014) showed that the asymmetric market reaction supports the Barber and Odean (2008) Attention-Grabbing Hypothesis (AGH), assuming that naïve investors' behaviour affects the market. Therefore, AGH predicts positive and significant abnormal returns for positively recommended stocks and no reaction for negative ratings. In other words, the market reaction is motivated by an attention-grabbing phenomenon, because only the publication of positive recommendations induces a significant (positive) price movement.

Moreover, previous literature showed that investor mood varies systematically across calendar months and weekdays, with possible shifts in investor attention (Hirshleifer et al., 2020), affecting financial decision-making and asset prices. Hirshleifer et al. (2020) have also documented the 'day of the week' effect, which would explain how aggregate stock markets tend to do better at the end of the week than at the beginning of the week. In this regard, they found consistent results with the mood-based theory, by documenting several mood recurrence and reversal effects across calendar months and weekdays.

Our empirical analysis is based on the content of two similar weekly columns in the most important Italian financial newspaper, which published past information and analysts' recommendations on listed companies. One, named 'The Stock of the Week' appears on Saturday and the other, named 'Letter to the investor" appears on Sunday. It's important to stress that the these columns have the same author, the same content (past balance sheet and P&L data; single analyst recommendations, consensus forecasts, company's profile), and their characteristics have remained unchanged during our observation period.

The focus of this paper is to understand whether the words contained in this particular text corpus improves the explained variance of stock returns better than the use of the polarity of the same texts, obtained through a sentiment analysis using a generic ontological dictionary. Although with very different methods, this approach has long existed, as Li et al. (2014) have documented the use of textual analysis for studies on the influence of news on stock markets.

2 Data collection and processing

We collected all the 'Stock of the Week' and 'Letter to the investor' columns published from January 2005 to March 2010 that were devoted each week to a

domestic company listed on the Italian Stock Exchange. The final dataset consists of 214 records.

In order to explain the variance of the average returns (AR) on the stock exchange opening day following the publication of the column, we added some explanatory variables, including: the number of quoted analysts, the natural logarithm of the order size, the natural logarithm of market capitalization, a dummy variable indicating the presence of any confounding effect, a dummy variable indicating the day of the week of the column (Saturday or Sunday), the turnover ratio, the price-to-book and the past performance (applying the absolute value or not).

2.1 Pre-processing

The pre-processing phase of the column texts involves the following steps:

- text cleaning, in order to normalize text encoding, remove punctuation, handling capitalized words, etc.
- Stop words removing in Italian language (articles, prepositions, pronouns, etc.).

In this phase we used `TextWiller` package (Solari et al., 2019), one of the few R libraries for the Italian language.

Figure 1 shows a word cloud of the most frequent words after pre-processing.

Figure 1: Most frequent words (word cloud)

2.2 Textual analysis

A textual analysis allowed us to select some terms to be used as features in the predictive models and to calculate the tf-idf weighting (Salton & Buckley, 1988). This index should show how important a word is to distinguish each weekly column in our corpus. In particular, some simple text mining procedures allowed us to create the document-term matrix we used for the regressions. In this phase we chose not to

analyse the main multiword expressions (n-grams). We worked within the "bag of words" framework, as only tf-idf weighting was applied to the words and we don't assume any Natural Language Processing rule.

Following, we used an ontological dictionary to obtain a measure of polarity for each text. Among the few resources available for the Italian language, we chose the NRC[1] lexicon (Liu, 2012), through which we extracted a polarity score for each column. The new variable containing the sentiment of each text had 41 different levels and, with reference to the sign (polarity), a positive sentiment had been attributed to 90% of the texts (a text is considered positive if the number of "positive" words is higher than the number of "negative" words).

Since we had a big sparse document-term matrix (7840 terms), we decided to allow maximal sparsity at 75%, or 25% in relation to document frequency. The resulting matrix contains only 113 terms, since we removed all the terms which have at least a 75% of empty elements (terms occurring 0 times in a document).

3 Data analysis

Concerning the aims presented above, the data analysis phase involved applying two stepwise regressions - with and without the use of words as features - to compare the two approaches in terms of explained variance. Subsequently, some data mining methods (Hastie et al., 2009) will be tested to compare the predictive power of the basic model with only the polarity feature and the one with words as features in addition (113 new features). In both cases we expect, through the use of words, an improvement in terms of R-squared (also adjusted) and Mean Squared Error (MSE).

We chose the following fitting techniques that can lead to better predictive accuracy and interpretability: Stepwise regression, Principal Components Regression (PCR), Partial Least Squares (PLS), Elastic-net, and Lasso. We estimated by cross-validation the number of components in the subset selection procedures (PCR and PLS) and the regularisation parameter in the shrinkage method (Elastic-net).

The dataset was randomly divided into two parts: a training set, used to fit the models, made up of a sample of 75% of the observations, and a validation set, used to estimate the prediction error for model selection, made up of the remaining 25% of the observations.

[1] The NRC lexicon is a list of words and their associations with eight emotions and two sentiments: negative and positive. This lexicon includes sentiment values for 13,901 words and has translations for just over 40 languages (see https://saifmohammad.com/WebPages/NRC-Emotion-Lexicon.htm).

4 Results

A summary of the performances of the two stepwise regressions is reported in Table 1. The R-squared indices showed a remarkable increase (about 2.5 times) of explained variance by introducing textual variables among the features (21 out of 113 terms were selected in the second model).

Table 1: Explained variance of the two models

Stepwise regression model	***R-squared***	***Adjusted R-squared***	***F-statistic***	***p-value***
M1: basic explanatory variables	0.1901	0.1667	8.099	7.178e-08
M2: adding text variables	0.4793	0.4005	6.082	7.489e-15

The variable that defines the polarity of the texts of the column was not significant in the basic model, while it was significant at 5% ($p = 0.044$) with a negative sign (estimated coefficient = -0.048) in the model that included the terms.

Instead, through comparisons between data mining models, we observed minor differences in terms of MSE, as shown in Table 2.

Table 2: Performances of predictive models

Technique	***MSE (basic features)***	***MSE (adding textual data)***
Stepwise	5.003575	9.434886
PCR	5.293135	5.293065
PLS	5.285215	5.284997
Elastic-net	4.788059	4.344863
Lasso	4.477144	4.702495

Lasso showed the lowest MSE for the basic model, while Elastic-net had the best performance for the model including textual variables, although the difference in terms of MSE is limited in favour of the second (4.48 vs 4.34).

5 Conclusion

The text mining approach has proven to be very useful to improve R-squared with respect to our dependent variable, the average returns. In addition, the poor ability to be a good predictor of a sentiment feature, automatically obtained from a generic lexicon, has emerged. In these cases, it would be preferable to use a supervised learning method with human tagging (Ceron et al., 2017) or, at least, a thematic lexicon.

If we observed a clear improvement in terms of R-squared, data mining techniques did not show substantial improvements in terms of MSE, by introducing some terms as features.

The use of a generic lexicon is surely a limitation for this work, as well as the presence of a quite small sample (214 records), which may affect the stability of the estimates for the data mining methods, as we were sampling just over 50 cases (training set) to compare the accuracy of various regression techniques.

Unsupervised Energy Trees: clustering with complex and mixed-type variables

Energy Trees non supervisionati: clustering con variabili complesse e di tipo misto

Riccardo Giubilei, Tullia Padellini and Pierpaolo Brutti

Abstract In the spirit of the recently developed and successful Object Oriented Data Analysis, we introduce Energy Trees as a model to perform classification and regression using complex and mixed-type covariates. Energy Trees may be seen as a generalization of Conditional Trees, where the testing procedures that characterize both variable selection and stopping criterion are here performed by means of Energy Statistics. The use of Energy Statistics allows to compare variables that need not to be defined on the same space, thus permitting to simultaneously model complex and mixed-type covariates. In this contribution we show how, adapting the main scheme offered in the literature to perform unsupervised learning using tree-like methods, Energy Trees can also be used to perform clustering on structured and mixed-type data, giving rise to the proposed Unsupervised Energy Trees.

Abstract *Nello spirito della recente e popolare Object Oriented Data Analysis, presentiamo gli Energy Trees, un modello per fare classificazione e regressione con variabili complesse e di tipo misto. Gli Energy Trees sono una generalizzazione dei Conditional Trees, in cui i test che caratterizzano sia la selezione delle variabili che i criteri di stop sono implementati usando le Energy Statistics. L'utilizzo di queste ultime permette il confronto tra variabili che non sono definite sullo stesso spazio, consentendo di modellare contemporaneamente variabili complesse e di tipo misto. In questo contributo spieghiamo come, adattando lo schema principale presente in letteratura per fare apprendimento non supervisionato tramite alberi, gli Energy Trees possono essere utilizzati anche per fini di clustering su dati strutturati e di tipo misto, dando origine alla proposta di Energy Trees non supervisionati.*

1 Introduction

In many data analysis contexts, the quantities of interest are complex objects that live in non-Euclidean spaces. Examples include curves, graphs, shapes, images and strings. In these cases, one might be tempted to represent data using feature vectors that live in the Euclidean space in order to apply standard statistical techniques. However, it is not always easy to find a natural representation of this kind: sometimes the choice is made arbitrarily, other times it is not possible at all. For these reasons, the framework called *Object Oriented Data Analysis* (OODA) has been introduced with the idea of directly analysing the original data objects, however complex they can be. In the spirit of this framework, we define *Energy Trees* as a model capable of performing supervised classification and regression using complex and mixed-type variables as covariates. In this work, we show how Energy Trees can also be used for unsupervised classification (i.e. clustering) purposes, giving rise to the *Unsupervised Energy Trees* model.

2 Motivation

The need of analysing arbitrarily complex variables is increasing to the point that new and unifying frameworks of data analysis become necessary [24, 10]. Among these, Object Oriented Data Analysis (OODA), in the sense defined by [24], provides a thought-provoking approach to deal with populations of complex objects. The statistical scientific community has shown renewed and growing interest in OODA since the overview proposed in [12].

Object Oriented Data Analysis is defined as the *statistical analysis of populations of complex objects* [12]. In this framework, the most basic elements to be analyzed are called "data objects". The core idea of OODA is that *by analyzing data objects directly we avoid loss of information that occurs when data objects are transformed into numerical summary statistics* [11]. An additional advantage of this approach is that the arbitrary choices necessary to translate complex objects into feature vectors are avoided.

OODA has been first applied to tree-structured objects [24], and then has become particularly successful in the field of Functional Data Analysis [16, 17, 13]. Several types of data objects have been explicitly analyzed within this framework, e.g. trees [2, 3, 19], graphs [11, 8], persistence diagrams [4, 14], shapes [7], manifolds (see [7] for references) and even sounds [23].

Despite the wide variety of applications, so far contributions within the OODA framework have been focusing only on single-type data objects. Among other consequences of this, many of the techniques used to tackle data objects are domain-specific and do not favour cross-pollination between different fields. Attempting to fill this gap, we introduce Energy Trees, a model for classification and regression using complex variables that perfectly fits in the OODA framework, with the additional advantage of accommodating variables of mixed type. We believe that this

possibility is an important innovation within the OODA framework, widening and enhancing its applicability.

Since classification and regression are not the only tasks one may want to perform on data objects, in this work we focus on how Energy Trees can be used in order to achieve unsupervised classification, i.e. clustering. We call the resulting model *Unsupervised Energy Trees*.

3 Energy Trees

The building blocks upon which Energy Trees are founded are Conditional Trees and Energy Statistics. For this reason, before passing onto describing the Energy Trees model, each of them will be shortly introduced.

Conditional Trees [9] are a special class of recursive binary partitioning models where a constant model is fitted in each region of the resulting partition. Conditional Trees address two well-known shortcomings of traditional trees, namely overfitting and a selection bias towards covariates with many possible splits, embedding a class of conditional inference statistical tests known as *permutation tests* [20] to perform the splits. The conditional distribution of statistics measuring the association between the response and the covariates is used to solve the selection bias problem. Moreover, multiple test procedures are performed to establish whether there is significant association between any of the covariates and the response, and, if not, the recursion stops. In other words, the overfitting problem is addressed by construction, without necessitating post-pruning techniques. Therefore, Conditional Trees do not suffer from the problems of other tree-like models, nonetheless it has been shown [9] that they can be implemented without comparative loss of prediction accuracy.

Energy Statistics are defined as functions of distances between statistical observations in metric spaces [21]. In this framework, Energy dependence coefficients are characterized by the important feature of measuring all types of dependence; e.g., the distance correlation coefficient equals zero if and only if the variables are independent [21]. In our context, it is worth to underline the implications of defining Energy Statistics as functions of *distances* between statistical observations. Indeed, based on this idea, when the variables (i.e. data objects) are complex, it is possible to use their real-valued nonnegative distances for inference. In other words, the power of this kind of statistics is that they focus on a single variable at a time, defining the distances between observations based on that variable, regardless of its nature. Once this is done for every variable, the resulting distances are compared, making the variables themselves comparable even if they are not of the same type.

Energy Trees may be seen as Conditional Trees where data objects of various types are made comparable using Energy Statistics. In particular, the statistical tests of association that characterize Conditional Trees are here performed using Energy tests of independence, that are based on Energy dependence coefficients. Subsequently, the algorithm of Energy Trees may be seen as an adaption of that of Conditional Trees, which is in turn the following:

1. test the global null hypothesis of independence between the response and all the covariates using a permutation test: if the null hypothesis is not rejected, stop;
2. select the covariate that shows the strongest association with the response;
3. search the best split point for that covariate using a permutation test;
4. partition the data;
5. repeat steps 1, 2, 3 and 4 for both of the new partitions.

where the global test in step 1 is performed separately testing the independence of the response with each covariate, and then the global null hypothesis is not rejected only if all the single null hypothesis are not rejected. To take into account this multiple testing, p-values are adjusted using Bonferroni correction.

In Energy Trees, the tests in steps 1 and 3 are implemented using Energy tests of independence, i.e. after evaluating the observations in terms of Energy Statistics, and in particular using distance correlation. However, the use of distance correlation is not straightforward, since it requires the definition of an appropriate distance for each type of complex variable. In addition to this, the search for the split point is not trivial for complex data objects. In the model, we include the possibility to choose between two alternative procedures to perform the split after selecting the most associated covariate. The first one is the translation of data objects into feature vectors, when possible; then, the feature vector that is more associated with the response is chosen for splitting, and the split point is searched in a traditional way with respect to that feature vector. The second one is clustering, where at each split two medoids are selected, and then data are partitioned minimizing the distances from the medoids.

Energy Trees are implemented in the R package called `etree`. Current version covers functional data, graphs and persistence diagrams, as well as numerical or nominal variables, as covariates.

4 Unsupervised Energy Trees

Energy Trees is a tree-structured model with a sound statistical foundation where data objects are complex and possibly mixed. Although it was initially tailor-made only for performing supervised classification and regression, it can be used also for unsupervised classification purposes. To achieve this goal, we follow and adapt the scheme of Unsupervised Random Forests (URF) [18].

URF are based on a simple but clever intuition: if the data are characterized by any structure, it should be recognizable from a randomly generated version of itself [18]. As brilliantly explained by [1], following this idea

> a synthetic dataset is randomly generated from the original dataset, and together they form a two-class classification problem that is then modeled using classical (supervised) RF. If the subsequent analysis results in a meaningful classification model then the interpretation of a RF model, using a proximity matrix, is what gives it the ability of being used as an unsupervised learning method. This proximity matrix assesses the number of instances in which two cases (i.e. [...] observations) are adopted into the same child node of a RF tree.

These instances are then averaged across the number of trees, producing a proximity matrix where only original observations are considered. These proximity scores are then used to perform a powerful unsupervised classification analysis.

Unsupervised Energy Trees (UET) are a model that exploits the basic principles used by URF in order to perform unsupervised classification using Energy Trees. However, since Energy Trees are structurally different from CART learners, the scheme must be adapted in an appropriate way.

The main difficulty is that in Energy Trees the covariate used for splitting is selected using an independence test between the response and each covariate. On the other hand, in the URF scheme the response variable is artificially attached to the dataset, resulting in no association at all with any covariate. Thus, another solution must be found.

The core idea of Unsupervised Energy Trees is to exploit the spirit of the URF scheme, where classification is made possible since in the synthetic dataset any relationship between original variables is removed [1]. Therefore, in UET, variable selection is carried out performing a distance correlation test of independence between every two covariates, using only the observations from the original dataset; then, the couple of covariates with the strongest association is selected for splitting.

Consequently, the split point search is performed in a similar manner to traditional Energy Trees, i.e. using clustering. However, clustering is performed on the complete dataset formed by the original and the synthetic datasets, and for each of the two variables selected. Then, the two resulting partitions are compared in terms of node impurity with respect to the response variable, and the best partition in this sense is selected as the actual one.

The stop criterion is the same as in Conditional Trees and Energy Trees. Once it is met, observations in terminal nodes are classified using the majority voting rule. Finally, a proximity matrix is calculated using the classification predictions provided by trees in an ensemble method such as bagging or Random Energy Forest (i.e. a Random Forest of Energy Trees).

5 Conclusion

In this contribution we showed how Unsupervised Energy Trees can be obtained starting from Energy Trees. Energy Trees are a model which perfectly fits in and possibly enhances the Object Oriented Data Analysis framework. Up to now, Energy Trees were mainly used to perform supervised classification and regression with complex and mixed-type covariates. However, it is also possible to apply them in clustering problems where the data objects may be both traditional, i.e. numeric or nominal, and complex, such as functions and graphs. This is obtained at the cost of suitably adapting the scheme of Unsupervised Random Forests to Energy Trees. The resulting model, Unsupervised Energy Trees, may be applied in a number of cases where other classical clustering techniques cannot be used, as it may be the case when data objects are not only traditional.

Using anchoring vignettes to adjust self-reported life satisfaction: a nonparametric approach leading to a Semantic Differential scale

Le anchoring vignettes nell'analisi della soddisfazione per la propria vita: un approccio non parametrico che conduce ad una scala sul Differenziale Semantico

Sara Garbin, Serena Berretta, Maria Iannario and Omar Paccagnella

Abstract Anchoring vignettes were introduced in the literature as a way to adjust self-evaluations from the Differential Item Functioning (DIF) problem, that leads incomparability of the individual answers based on an ordinal scale. In this article we introduce a new nonparametric approach to rescale and correct for DIF the original ratings using data collected by anchoring vignettes. Self-assessments based on the original Likert scale can be rescaled in a new variable based on a Semantic Differential scale, showing a larger number of ordinal values. An empirical study on life satisfaction in an old population (data are carried out from the Survey of Health, Ageing and Retirement in Europe) illustrates the importance of accounting for differences in the use of ordinal scales, by showing how our inferences about interpersonal comparisons may change as a function of the assumptions we consider.
Abstract *Le anchoring vignettes sono uno strumento introdotto in letteratura per correggere le valutazioni soggettive dal problema del Differential Item Functioning (DIF), che rende incomparabili le risposte degli individui derivanti da una scala ordinale. Questo articolo introduce un approccio non parametrico per riscalare e correggere dal DIF le valutazioni originarie sfruttando i dati raccolti per mezzo delle anchoring vignettes. In questo modo, le auto-valutazioni basate su una scala Likert possono essere riscalate in una nuova variabile costruita come una scala del Dif-*

ferenziale Semantico, che presenta un numero maggiore di valori ordinali rispetto alla variabile originaria. Un'applicazione empirica sulla soddisfazione verso la propria vita in una popolazione anziana, con dati raccolti attraverso l'indagine SHARE, illustra l'importanza di tener conto delle differenze nell'utilizzo di scale ordinali e mostra come i confronti interpersonali possano cambiare a seconda delle assunzioni adottate.

Key words: Anchoring vignettes, Ordinal data, Life satisfaction, Response scales.

1 Introduction

Life satisfaction is now widely used to evaluate people well-being [4]. Life satisfaction and other subjective psychological domains are usually measured by rating scales. However, whenever people are asked to rate themselves, the presence of individual heterogeneity leads respondents to interpret, understand or use the response categories for the same questions differently. This phenomenon is called *Differential Item Functioning* (DIF) by the psychometric literature [6].

[7] introduced the approach of the anchoring vignettes for adjusting self-evaluations by DIF and enhancing comparability across countries or groups. Anchoring vignettes are additional questions in the domain under investigation, where a hypothetical individual, manifesting just the trait of the concept of interest, is described. The same question is addressed to all respondents, but usually more anchoring vignettes are proposed, changing the level of severity, condition or context of the depicted scenario.

Anchoring vignette data may be analysed by means of a parametric and a nonparametric approach [8]. In particular, the idea of the nonparametric solution is to recode self-ratings relative to the answers collected in the corresponding set of anchoring vignettes. According to this nonparametric approach, our work aims at providing a novel mixture model to fit data coming from multi-ratings, recoding a variable based on a Likert scale to a new, DIF-free, variable based on a Semantic Differential (SD) scale [10]. This work is organised as follow: Section 2 introduces the new nonparametric solution dealing with anchoring vignettes. Section 3 briefly explains data used in the analysis proposed in Section 4.

2 The new adjusted measure

In the original nonparametric approach, self-evaluation is adjusted according to its relative position with respect to the set of the anchoring vignettes: self-rating is judged as better, equal or worse than the anchoring vignette ratings, regardless of the value of such evaluations. However, this solution implies the validity of the so-called *global ordering* assumption: the majority of the individuals belonging to each

group in the sample (i.e. people living in the same country) defines the same ranking of the anchoring vignettes as the one thought by the vignette designers according to the content of the vignettes (that is, the severity of the problem described in each scenario).

Our proposal for a DIF-free measure relies on the comparison of the self-evaluation with only one anchoring vignette. Assuming this vignette as the individual benchmark for the own response scale, the difference of the ratings between self-evaluation and the related anchoring vignette is computed. Self-assessments based on the original Likert scale can be rescaled in a new variable based on a Semantic Differential scale [10]. Indeed, the rescaled variable rates on a bipolar scale, where the position marked as "0" can be labelled as *neutral* (individual evaluates herself in the same way of the scenario depicted in the anchoring vignette). In addition to the standard nonparametric approach, our solution allows to calculate how much self-assessment is close or not to the benchmark described by the scenario. This is a typical feature of the SD scale, because it is able to measure both directionality of the reaction (i.e. positive vs negative) and intensity (i.e. slight vs extreme).

Let m the number of answer categories in the original self-reported and vignette questions and let the original Likert scale vary from 1 to m. According to the difference, our adjusted variable will assume a total of $2m-1$ values, from $-m+1$ to $(m-1)$. In a conventional ordinal way, the rescaled G-variable may be defined as:

$$G = m + d \tag{1}$$

where d is the value of the new variable according to the SD scale (that is, the magnitude of the difference between self- and vignette ratings).

This approach has several advantages with respect to the original nonparametric solution. First, it can be applied whenever anchoring vignettes are collected in a survey, regardless their number. This could be very important in longitudinal studies, where it is likely to collect just one anchoring vignette to retrieve information on the individual response scales varying over time. Second, there is no longer need of the *global ordering* assumption. Third, our solution transforms a Likert in a SD scale increasing the number of categories to be used for modelling the responses (as an example, if the original scale has 5 answer categories, the G-scale is composed by 9 values). This allows to obtain more information from the collected data.

3 Data

Data come from the second wave of SHARE (Survey of Health, Ageing and Retirement in Europe), collected in 2006/2007 [2]. For methodological details, see [3]. SHARE is a panel survey that collects detailed cross-national information on health, socio-economic status and family networks of people aged 50 and over from a large set of European countries. The sample is composed by 7,654 respondents, living in 11 countries (Belgium, Czech Republic, Denmark, France, Germany, Greece,

Italy, the Netherlands, Poland, Spain and Sweden). It is mainly characterised by female respondents (55.4%), aged 64.3 years on average, low educated and retired; however, a large cross-country heterogeneity is present. However, other than standard demographic information a wide set of explanatory variables is available, from socio-economic status (job status, income, wealth and so on) to health (chronic diseases, limitations with activities, cognitive abilities and so on).

The proposed self-reported question on life satisfaction is: "*How satisfied are you with your life in general?*"; an example of anchoring vignette (on the same domain) is: "*Carry is 72 years old and a widow. Her total after tax income is about 1,100 per month. She owns the house she lives in and has a large circle of friends. She plays bridge twice a week and goes on vacation regularly with some friends. Lately, she has been suffering from arthritis, which makes working in the house and garden painful. How satisfied with her life do you think Carry is?*". For both questions, respondents answered according to a 5-point Likert scale: 'Very dissatisfied'; 'Dissatisfied'; 'Neither satisfied, nor dissatisfied'; 'Satisfied'; 'Very satisfied'.

4 Results

In the second wave of SHARE, two anchoring vignettes on life satisfaction were collected. For this work, the one reported in Section 3 (Carry) was exploited, which results to be the best in terms of fitting when regressed on the original self-rating (AIC=16047.13 with respect to AIC=16093.52 for the other anchoring vignette). The G-variable was then computed. Frequency distributions of the original and the rescaled items are displayed in Figure 1.

When the observed variable Y is an m-category ordinal response variable, one of the candidate models to analyse this rating is the cumulative link model [9]. Alternatively, researchers may use the CUP model: introduced by [11] to account for uncertainty in the response, it is a mixture (Combination) of a discrete Uniform random variable U and a Preference random variable Y which mimics the standard cumulative models.

In this analysis, a CUP model is fitted to the data. Here we assume that $Y_i^* = j$ when $\alpha_{j-1} < Y_i^* \leq \alpha_j$, with latent regression for the preference part.

The estimate of the uncertainty parameter on the G-variable is close to one ($\hat{\pi} = 0.99$). Taking into account that the subject propensity to adhere to a well-structured response behaviour, rather than to a random choice, is modelled by mixing the preference components via the uncertainty parameter π, results reveal no uncertainty in the response process. Our rescaling approach has removed DIF from the collected data and the rescaled rating is an entirely reasoned assessment. As a consequence, we continue with our analysis of the standard cumulative model with proportional assumption (POM) [1]. Results for the final estimated model on the G-variable are reported in Table 1.

The number of statistically significant country dummies is large: controlling for individual characteristics, cross-country variability in life satisfaction reporting is

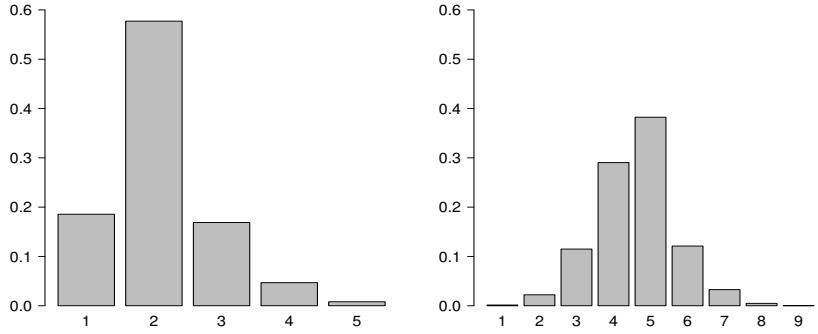

Fig. 1 Left: Frequency distribution of the original ordinal variable collected on a 5-point scale (1=Very satisfied; 5=Very dissatisfied). Right: Frequency distribution of the rescaled ordinal variable on a 9-point scale (1=High satisfaction; 9=High dissatisfaction).

Table 1 POM estimation of the rescaled life satisfaction variable ($k = 9$).

	Covariate	Satisfaction parameters	AIC
Thresholds	1|2	$\hat{\alpha}_1 = -7.959\,(0.359)$	21120.99
	2|3	$\hat{\alpha}_2 = -5.129\,(0.208)$	
	3|4	$\hat{\alpha}_3 = -3.232\,(0.196)$	
	4|5	$\hat{\alpha}_4 = -1.621\,(0.193)$	
	5|6	$\hat{\alpha}_5 = \ \ 0.326\,(0.193)$	
	6|7	$\hat{\alpha}_6 = \ \ 1.943\,(0.199)$	
	7|8	$\hat{\alpha}_7 = \ \ 4.015\,(0.251)$	
	8|9	$\hat{\alpha}_8 = \ \ 6.940\,(0.732)$	
Main model	DE	$\hat{\gamma}_1 = -0.317\,(0.065)$	
	SE	$\hat{\gamma}_2 = -0.745\,(0.093)$	
	NL	$\hat{\gamma}_3 = -0.823\,(0.089)$	
	FR	$\hat{\gamma}_4 = -0.544\,(0.104)$	
	DK	$\hat{\gamma}_5 = -0.228\,(0.070)$	
	CZ	$\hat{\gamma}_6 = \ \ 0.358\,(0.074)$	
	Age	$\hat{\gamma}_7 = -0.014\,(0.003)$	
	Single	$\hat{\gamma}_8 = \ \ 0.377\ \ (0.055)$	
	Retired	$\hat{\gamma}_9 = -0.295\,(0.064)$	
	Employed	$\hat{\gamma}_{10} = -0.348\,(0.067)$	
	Income	$\hat{\gamma}_{11} = -0.176\,(0.062)$	
	Wealth	$\hat{\gamma}_{12} = -0.029\,(0.007)$	

Note: (s.e. in parenthesis)

still important. As expected, life satisfaction is positively and significantly correlated with the socio-economic status. On the other hand, it is surprising the lack of any health covariates, given the well-known negative relationship between health status and satisfaction with one's own life [5]. However, this finding can provide an interesting interpretation of such relationship: the *G*-variable is a DIF-free measure of individual life satisfaction. Health variables may strongly affect the individual

response scales. Correcting for DIF, we are able to report all self-evaluation on a common scale, health status may have a role weaker than the socio-economic one.

Variable selection for robust model-based learning from contaminated data

Selezione di variabili nella stima robusta di modelli per dati contaminati

Andrea Cappozzo, Francesca Greselin, and Thomas Brendan Murphy

Abstract Several contributions to the recent literature have shown that supervised learning is greatly enhanced when only the most relevant features are selected for building the discrimination rule. Unfortunately, outliers and wrongly labelled units may undermine the determination of relevant predictors, and almost no dedicated methodologies have been developed to face this issue. In the present paper, we introduce a new robust variable selection approach, that embeds a classifier within a greedy-forward procedure. An experiment on synthetic data is provided, to underline the benefits of the proposed method in comparison with non-robust solutions.

Abstract *Recenti risultati in letteratura hanno dimostrato che l'apprendimento supervisionato migliora notevolmente quando si scelgono le variabili più rilevanti per la costruzione della regola discriminante. La presenza di valori anomali e di unità erroneamente classificate nel learning set può severamente minare la determinazione dei predittori rilevanti e sfortunatamente quasi nessuna metodologia affronta questo problema. Il presente contributo propone un nuovo approccio robusto, che incorpora un classificatore all'interno di un metodo incrementale di selezione delle variabili. Risultati simulativi mostrano i vantaggi del nuovo metodo, in comparazione con soluzioni non robuste.*

1 Introduction

Nowadays, hundreds or thousands of variables on each sample are available in fields like chemometrics, computer vision, engineering and genetics, and many other scientific domains. Feature selection techniques have been introduced in data analysis, mainly aiming at building simpler models, easier to interpret by researchers/users, with shorter training times. Models based on the right selection of variables allow to avoid the *curse of dimensionality*, reduce overfitting, and prevent identifiability problems that may arise in high dimensional spaces. This has been known for a long time, as demonstrated by the specific literature reviews on the topic in the fields of machine learning, data mining, bioinformatics, genomic, and statistics. Surprisingly, the impact that outliers and wrongly labelled units cause on the determination of relevant predictors has received far less attention. Indeed, contaminated data can heavily damage a classifier performance [6], and most variable selection methods rely on the implicit assumption of dealing with an uncontaminated training set.

The present paper aims at filling this gap. We propose a new robust variable selection method for model-based classification, by embedding a robust classifier, recently introduced in the literature, in a greedy-forward stepwise procedure for model selection. Section 2 recalls the problem of variable selection in model-based discriminant analysis, and the Robust Eigenvalue Decomposition Discriminant Analysis (REDDA), and then introduce the robust variable selection technique. Section 3 presents the comparison of several feature selection procedures within a simulation study in an artificially contaminated scenario. A discussion of our results concludes the paper, outlying some remarks and future research directions.

2 Robust variable selection in model-based classification

Model-based discriminant analysis is a probabilistic framework for supervised classification, in which a classifier is built from a complete set of N learning observations (i.e., the training set):

$$(\mathbf{x},\mathbf{l}) = \left\{(\mathbf{x}_1,\mathbf{l}_1),\ldots,(\mathbf{x}_N,\mathbf{l}_N);\mathbf{x}_n \in \mathbb{R}^P,\, \mathbf{l}_n = \{l_{n1},\ldots,l_{nG}\}' \in \{0,1\}^G;\, n=1,\ldots,N\right\} \tag{1}$$

where $\mathbf{x}_n$ is a P-dimensional continuous predictor and $\mathbf{l}_n$ is its associated class label, such that $l_{ng}=1$ if observation n belongs to group g and 0 otherwise with, clearly, $\sum_{g=1}^{G} l_{ng} = 1\,\forall n = 1,\ldots,N$. We assume that the prior probability of class g is $\tau_g > 0$ and $\sum_{g=1}^{G}\tau_g = 1$. The gth class-conditional density is modeled with a P-dimensional Gaussian distribution with mean vector $\boldsymbol{\mu}_g \in \mathbb{R}^P$ and covariance matrix $\boldsymbol{\Sigma}_g \in PD(P)$: $\mathbf{x}_n|\mathbf{l}_n = g \sim N_P(\boldsymbol{\mu}_g,\boldsymbol{\Sigma}_g)$. Therefore, the joint density of $(\mathbf{x}_n,\mathbf{l}_n)$ is given by:

$$p(\mathbf{x}_n,\mathbf{l}_n;\boldsymbol{\theta}) = p(\mathbf{l}_n;\boldsymbol{\tau})p(\mathbf{x}_n|\mathbf{l}_n;\boldsymbol{\mu}_g,\boldsymbol{\Sigma}_g) = \prod_{g=1}^{G}\left[\tau_g\phi(\mathbf{x}_n;\boldsymbol{\mu}_g,\boldsymbol{\Sigma}_g)\right]^{l_{ng}} \tag{2}$$

where $\phi(\cdot;\boldsymbol{\mu}_g,\boldsymbol{\Sigma}_g)$ denotes the multivariate normal density and $\boldsymbol{\theta}$ represents the collection of parameters to be estimated, $\boldsymbol{\theta}=\{\tau_1,\ldots,\tau_G,\boldsymbol{\mu}_1,\ldots,\boldsymbol{\mu}_G,\boldsymbol{\Sigma}_1,\ldots,\boldsymbol{\Sigma}_G\}$. Eigenvalue Decomposition Discriminant Analysis (EDDA) is a family of classifiers developed from the probabilistic structure in (2), wherein different assumptions about the covariance matrices are considered. Particularly, EDDA is based on the following eigenvalue decomposition:

$$\boldsymbol{\Sigma}_g=\lambda_g\boldsymbol{D}_g\boldsymbol{A}_g\boldsymbol{D}_g^{'} \tag{3}$$

where $\boldsymbol{D}_g$ is an orthogonal matrix of eigenvectors, $\boldsymbol{A}_g$ is a diagonal matrix such that $|\boldsymbol{A}_g|=1$ and $\lambda_g=|\boldsymbol{\Sigma}_g|^{1/p}$. Allowing each parameter in (3) to be equal or different across groups a family of 14 patterned models arises. To protect parameter estimates against label noise and outliers, [1] introduced a robust version of EDDA, called REDDA, by means of the maximization of a *trimmed mixture log-likelihood* [4], in which an impartial trimming level γ is enforced in the estimation procedure.

The next step is therefore to include a robust variable selection procedure within REDDA. We proceed in a stepwise manner, by considering the inclusion of extra variables into the model, and also the removal of existing variables from the model, one at a time, conditioning on their discriminating power. We start from the empty set and then, in each step of the algorithm, we partition the learning observations $\mathbf{x}_n$, $n=1,\ldots,N$, into three parts $\mathbf{x}_n=(\mathbf{x}_n^c,x_n^p,\mathbf{x}_n^o)$, where:

- $\mathbf{x}_n^c$ indicates the set of variables currently included in the model
- x_n^p the variable proposed for inclusion
- $\mathbf{x}_n^o$ the remaining variables

To decide whether to include the proposed variable x_n^p, we compare the following two competing models:

- *Grouping* ($\mathscr{M}_{GR}$): $p(\mathbf{x}_n|\mathbf{l}_n)=p(\mathbf{x}_n^c,x_n^p,\mathbf{x}_n^o|\mathbf{l}_n)=p(\mathbf{x}_n^c,x_n^p|\mathbf{l}_n)p(\mathbf{x}_n^o|x_n^p,\mathbf{x}_n^c)$
- *No Grouping* ($\mathscr{M}_{NG}$): $p(\mathbf{x}_n|\mathbf{l}_n)=p(\mathbf{x}_n^c,x_n^p,\mathbf{x}_n^o|\mathbf{l}_n)=p(\mathbf{x}_n^c|\mathbf{l}_n)p(x_n^p|\mathbf{x}_n^r\subseteq\mathbf{x}_n^c)p(\mathbf{x}_n^o|x_n^p,\mathbf{x}_n^c)$

where $\mathbf{x}_n^r$ denotes a subset of the currently included variables $\mathbf{x}_n^c$. The Grouping model specifies that x_n^p provides extra grouping information beyond that provided by $\mathbf{x}_n^c$; whereas the No Grouping model specifies that x_n^p is conditionally independent of the group membership given $\mathbf{x}_n^r$. We consider $\mathbf{x}_n^r$ in the conditional distribution because x_n^p might be related to only a subset of the grouping variables $\mathbf{x}_n^c$ [3]. The differences between the two models are graphically illustrated in Figure 1. The model structure of $p(\mathbf{x}_n^o|x_n^p,\mathbf{x}_n^c)$ is assumed to be the same for both grouping and no grouping specification, and we let $p(\mathbf{x}_n^c,x_n^p|\mathbf{l}_n)$ and $p(\mathbf{x}_n^c|\mathbf{l}_n)$ be a normal density with parsimonious covariance structure. Additionally, we assume $p(x_n^p|\mathbf{x}_n^r\subseteq\mathbf{x}_n^c)$ to be a normal linear regression model, as a result from conditional multivariate normal means. The selection of which model to prefer is carried out employing a robust approximation to the Bayes Factor $\mathscr{B}_{GR,NG}$, given by the ratio between the integrated likelihood of the two competing models. Along the lines of [5], twice the logarithm of $\mathscr{B}_{GR,NG}$ can be approximated with

$$2\log(\mathscr{B}_{GR,NG})\approx BIC(Grouping)-BIC(No\ Grouping) \tag{4}$$

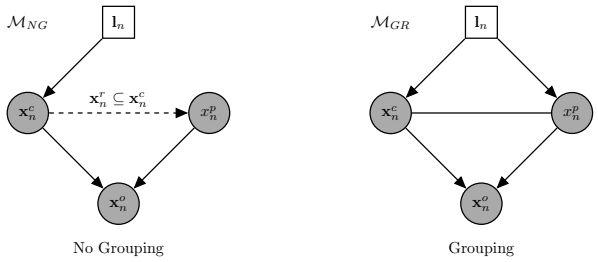

Fig. 1: Graphical representation of the Grouping and the No Grouping models

and a variable x_n^p with a positive difference in $BIC(Grouping) - BIC(No\ Grouping)$ is a candidate for being added to the model. A robust version of the BIC is employed here, for avoiding the detrimental effect that class and attribute noise might produce in the variable selection procedure. The Trimmed BIC (TBIC), firstly introduced in [4], is employed as a robust proxy for the quantities in (4). Let us define:

$$TBIC(Grouping) = \underbrace{2\sum_{n=1}^{N}\zeta(\mathbf{x}_n^c, x_n^p)\sum_{g=1}^{G} l_{ng}\log\left(\hat{\tau}_g^{cp}\phi(\mathbf{x}_n^c, x_n^p; \hat{\boldsymbol{\mu}}_g^{cp}, \hat{\boldsymbol{\Sigma}}_g^{cp})\right)}_{2\times\text{trimmed log maximized likelihood of } p(\mathbf{x}_n^c, x_n^p, \mathbf{l}_n)} + \\ - v^{cp} log(N^*) \tag{5}$$

$$TBIC(No\ Grouping) = \underbrace{2\sum_{n=1}^{N}\iota(\mathbf{x}_n^c, x_n^p)\sum_{g=1}^{G} l_{ng}\log\left(\hat{\tau}_g^{c}\phi(\mathbf{x}_n^c; \hat{\boldsymbol{\mu}}_g^{c}, \hat{\boldsymbol{\Sigma}}_g^{c})\right)}_{2\times\text{trimmed log maximized likelihood of } p(\mathbf{x}_n^c, \mathbf{l}_n)} - v^c log(N^*) + \\ \underbrace{+2\sum_{n=1}^{N}\iota(\mathbf{x}_n^c, x_n^p)\log\left[\phi\left(x_n^p; \hat{\alpha} + \hat{\boldsymbol{\beta}}' \mathbf{x}_n^r, \hat{\sigma}^2\right)\right]}_{2\times\text{trimmed log maximized likelihood of } p(x_n^p | \mathbf{x}_n^r \subseteq \mathbf{x}_n^c)} - v^p log(N^*). \tag{6}$$

The penalty terms v^{cp} and v^c indicate the number of parameters for a REDDA model respectively estimated on the set of variables $\mathbf{x}_n^c, x_n^p$ and $\mathbf{x}_n^c$; while v^p accounts for the number of parameters in the linear regression of x_n^p on $\mathbf{x}_n^r$. The 0-1 indicator functions $\zeta(\cdot)$ and $\iota(\cdot)$ identify the subset of observations that have null weight in the trimmed likelihood under the Grouping and No Grouping models, with $N^* = \sum_{n=1}^{N}\zeta(\mathbf{x}_n) = \sum_{n=1}^{N}\iota(\mathbf{x}_n)$. Accordingly, at each iteration of the procedure that leads to the final robust estimates, we discard the $\lfloor N\gamma \rfloor\%$ of the sample with the lowest contribution to the conditional likelihood, under the no grouping model. Once the Concentration step is enforced, the set of parameters $\{\alpha, \boldsymbol{\beta}, \sigma^2\}$ for the regression part is robustly estimated via ML on the untrimmed observations,

in which a stepwise method is employed for automatically choosing the subset of regressors $\mathbf{x}_n^r$.

After each addition stage, we make use of the same procedure described above to check whether an already chosen variable in $\mathbf{x}_n^c$ should be removed: in this case x_n^p takes the role of the variable to be dropped, and a positive difference in terms of TBIC implies the exclusion of x_n^p to the set of currently included variables. The procedure iterates between variable addition and removal stage until two consecutive steps have been rejected, then it stops. Notice that, whenever $\gamma = 0$, BIC and TBIC coincide and the entire approach reduces to the methodology described in [3].

3 Simulation study

The aim of this simulated example is to numerically assess the effectiveness of the new methodology, whilst investigating the effect that a (small) percentage of contamination has on standard variable selection procedures. We adopt the data generating process (DGP) in [3], and add some attribute and class noise to the original experiment. A total of $B = 100$ Monte Carlo (MC) experiments are conducted as follows. From the DGP outlined in [3], $N = 500$ units are generated and their group membership retained for constructing the training set; while $M = 5000$ unlabelled observations compose the test set. Subsequently, label noise is simulated by wrongly assigning 20 units coming from the fourth group to the third class. In addition, 5 uniformly distributed outliers, having squared Mahalanobis distances from $\boldsymbol{\mu}_g$ greater than $\chi^2_{3,0.975}$ $\forall g \in \{1,2,3,4\}$, are appended to the training set, with randomly assigned labels. These contaminations produce, in each MC replication, a total of 25 adulterated units, that account for slightly less than 5% of the entire learning set. We validate the performance of our novel method in correctly retrieving the relevant variables, the comparison being carried out considering the following methods:

- TBIC: new robust stepwise greedy-forward approach via TBIC
- SRUW: stepwise greedy-forward approach via BIC [3]
- SelvarMix: variable selection in model-based discriminant analysis with a regularization approach [2].

Once the important variables have been identified, the associated classifier (i.e., REDDA for the robust variable selection criteria, with trimming level $\gamma = 0.05$; and EDDA for the non-robust ones) is trained on the reduced set of predictors and the classification accuracy is computed on the test set. Lastly, for providing benchmark values on the relevance of feature selection, both EDDA and REDDA classifiers are also fitted on the original set with $P = 16$ variables. Table 1 and Figure 2 show that the misclassification error for TBIC is always lower than for non-robust procedures. As expected, the best prediction accuracy is obtained via the forward selection algorithm with TBIC selecting 3 variables. Interestingly, the EDDA classifier, coupled with (non-robust) variable selection via either SelvarMix or SRUW, shows on average a higher misclassification error than REDDA learned on the entire set of features. That is, the harmful effect of adulterated observations is increased

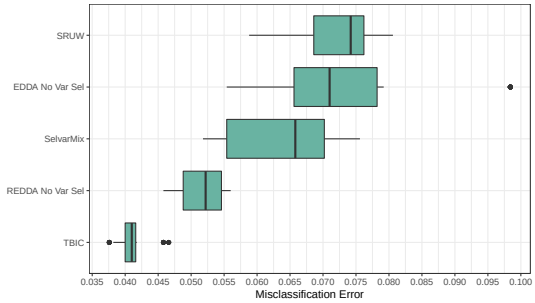

Fig. 2: Boxplots of the misclassification error, varying variable selection and model-based classification methods.

Table 1: Average misclassification errors, followed by their standard deviations.

Method	TBIC	REDDA NoVarSel	EDDA NoVarSel	SRUW	SelvarMix
Misc Error	0.0409	0.051	0.073	0.072	0.0639
	(0.0026)	(0.0026)	(0.0026)	(0.0037)	(0.0028)

by the presence of noisy variables, also shown by the poor performance of EDDA with no feature selection. Further research will be devoted to the development of a methodology that automatically assesses the contamination rate present in a sample, as the a-priori specification of the trimming level still remains an open issue in this field, particularly delicate for high-dimensional data.

Variable Selection in Text Regressions: Back to Lasso?

Selezione delle variabili nelle regressioni testuali: ritorno al Lasso?

Marzia Freo and Alessandra Luati

Abstract This study aims to explore the utility of text data as predictors in parametric regression models. Using the description of items on e-commerce platforms, we compare standard lasso, variable screening-based and randomization-based models in their ability to identify words really contributing to explain prices. Lasso models optimized for prediction attain high Predictive R^2, at the cost of using too many variables. The stability selection models provide an excellent trade-off between Predictive R^2 and the number of selected features. Sure Independence Screening and Lasso reach comparable results, when the number of features to select is set equal to the one of Stability Selection. Interestingly, Lasso behaves as well as computational intensive methods, when the number of selected variables is limited.

Abstract *Questo studio esplora l'utilità dei dati testuali nel ruolo di predittori in modelli di regressione parametrica. Usando la descrizione degli articoli nelle piattaforme di commercio online, vengono confrontati il lasso, i modelli basati sul variable screening e sulla randomizzazione, in termini di abilità di identificare le parole influenti per spiegare i prezzi. Il lasso ottimizzato per la previsione mostra un alto R^2 predittivo ma utilizza troppe variabili. Lo Stability Selection ha un eccellente trade-off tra R^2 predittivo e numero di parole selezionate. Sure Independent Screening e Lasso producono risultati confrontabili se il numero delle parole è fissato a priori pari allo Stability Selection. È interessante notare che il Lasso è competitivo con metodi computazionali intensivi quando il numero di parole selezionate è limitato.*

Key words: Text Mining, Lasso, Variable screening. Randomization methods, Online Prices.

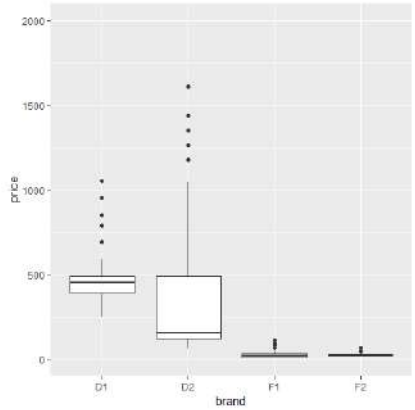
Problem and data

In the last decades, new technologies and the development of online social platforms have made available a large amount of text data. Consequently, several studies have been carried out with the aim of exploiting the informative content of text data, in favour of business and economic insights. Currently, texts are used as data in a variety of applications concerning authorship, sentiment, nowcasting, policy uncertainty, media slant, market definition, and other topics, and can be analysed by means of many different approaches (Gentzkow et al., 2019).

This study aims to explore the usefulness of text data as explanatory variables in parametric models. It investigates the analytics that allow one to exploit the content of unstructured text and its explanatory power. Are text data the new data for regression models? In what extent do they substitute the more often used, quantitative, data in economics? Which methodologies allow one to extract as much information as possible for text regressions?

We consider an application focused on the task of pricing fashion items available on producers' e-commerce platforms. The aim is to model regular prices, by avoiding prices on sale affected by markdown strategies which vary among brands. We use data scraped from UK e-commerce websites of four fashion producer brands. The brands are chosen to be heterogeneous with respect to the average price of items on sales (Figure 1): two of them are large fast-fashion chains selling at very low prices (F1 and F2), the remaining two (D1 and D2) found their business on design of enhanced fashion items. Fast fashion and enhanced design brands are discussed in Cachon and Swinney (2011). Each record collects information on price, category, brand and a field of description. The analysis is carried out for the knitwear category. Further categories have been analysed with coherent results, not shown here for sake of brevity. It is known that text is inherently high dimensional and sparse. Moreover, in this circumstance, it is reasonable to assume that only a small number of predictors contribute to the dependent variables. Before affording the issue of sparse modelling, we process some preliminary steps to map the raw text into a numerical matrix, the Document Term Matrix (DTM), whose cells indicate the count of the *j*-th word or token in the *i*-th document. Some text preparation operations are required in order to prepare data and to reduce meaningless dimensionality. First, we cancel out non-words elements (like numbers, punctuations, and proper names); then very common words are collected in a stop words list and deleted; finally, words are replaced by their roots through stemming. We respectively consider single words and single words plus bigrams, formed by all (unordered) pairs of words. In the end, the DTM contains 382 documents and 1245 features, of whom 229 are single words and 1016 are bigrams. Assuming that each single word or bigram represents a relevant feature for explaining the price of an item, our purpose is to identify a linear function relating prices to features. Note that, as prices are highly asymmetric it might be convenient to transform them (Box and Cox, 1964; Atkinson et al. 2019). However, we proceed with untransformed data as in our context "*approximate inference about the most meaningful parameters is clearly preferable to formally "exact" inference about parameters whose definition is in some way artificial*" (Box and Cox, 1964, pp. 214).

Figure 1. Distribution of prices by brand



Models and design of the study

Variable selection in regression analysis is an age-old problem in statistics, which currently encountered a renewed interest due to the increasing availability of high dimensional data. In this new setting, and in particular for text data, it is hard to disentangle the few meaningful variables that play a major role for interpretation purposes, from the redundant and noisy remaining variables. Among the large variety of variable selection techniques, the most applied method is certainly the Lasso (Tibshirani, 1996), both for its predictive performance and for its computational feasibility. Lasso does not come without limitations. For instance, it tends to select noisy variables if the tuning parameter is chosen to optimize prediction (Meinshausen and Bühlmann, 2006); it may exhibit poor variable selection results, if highly correlated predictors are present (Bach, 2008). Two main classes of methods have been proposed to overcome these limitations: variable screening and randomization. Variable screening aims to rank predictors by relevance; subsequently, the dimensionality will be reduced by selecting the highly ranked predictors and by running the standard variable selection Lasso (or its variants) over selected variables. A prominent method which belongs to this class is the Sure Independence Screening (from here in afterwards SIS, Fan and Lv, 2008). The rationale of randomization is to execute the Lasso, or another variable selection algorithm, over multiple training sets, generated by bootstrap or resampling, and to average over multiple results, so that the instability of running a selection algorithm only once can be overcome. Among the most significant randomization algorithms, we mention Bolasso (Bach, 2008), Stability selection (Meinshausen and Buhlmann, 2010), and Random Lasso (Wang et al., 2011).

The aim of this study is to identify which of these methods are more useful in finding the relevant variables to explain prices of items sold online. To this purpose, we compare some specifications of previously presented methods. To evaluate to

which extent true variables have been detected is a hard task, as the true model is unknown but in simulations. Hence, we generate 100 bootstrap replications from the original dataset. Each replicated dataset is divided into a training set and a hold-out sample. We define the selected variables as truly influential variables on the basis of 1) an a priori judgement, such as accepting features describing materials or decorations; 2) their explanatory power over the hold-out sample, measured in terms of Predictive R^2.

Main results and conclusions

For each bootstrap dataset, we first select variables over training data, using a pool of models, then we estimate a linear regression model by using previously selected variables as predictors, over the hold-out sample and finally we measure the Predictive R^2. The analyses have been carried out, for each generated dataset, by departing from the set of single words and bigrams, and the subset of only single words, respectively. Two variants of Lasso are presented: *lasso-min*, which is attained by minimizing the cross-validation error, and *lasso-1se*, which provides the most parsimonious model such that error is within one standard error of the error of *lasso-min*. To evaluate the performance of randomization, we choose the Stability Selection method, by imposing different thresholds of the selection probability. The results are very similar by changing the selection probability and here we present those attained with the thresholds 0.7, named *stabs*. As a screening method, we run the SIS algorithm and consider the performance produced by different number of selected predictors, from 1 to 15, labelled from *sis-k1* to *sisk15*. Finally, we evaluate the performance of the simple Lasso obtained by imposing different number of selected predictors, from 1 to 15, labelled from *lasso-k1* to *lasso-k15*. The main results, in terms of number of selected variables and Predictive R^2, are displayed in Fig.2 and 3.

We first observe that, in this type of application, the explanatory power of bigrams does not play a relevant role. Indeed, models based on bigrams perform only slightly better than corresponding models estimated over single words. Thus, we proceed by discussing results only for the analyses run over single words.

Lasso-min performs as expected: it always uses the highest number of predictors (in median around 55) to reach the highest Predictive R^2 (in median higher than 0.75). Lasso-1se is more parsimonious than lasso-min. It selects in median 15 predictors to explain 60% of price variability. Stability Selection produces in median a Predictive R^2 just lower than 0.5, lower than the ones of lasso, but using in median only 6 predictors. Focusing on the SIS method with the same median number of predictors, *P=6*, we note that it produces very similar results to the Stability Selection. The same pattern may be observed when the simple Lasso is used by fixing the number of selected variables to *P=6*.

Table 1 compares the six most frequently selected features over the one hundred bootstrap replications by the three methods, as well as the number of times in which they are selected. The column type indicates whether the feature may be classified as a “true” feature according to the a priori judgment. Both in term of persistence and

relevant variables Stability Selection outperforms the other methods, even if not heavily. In conclusion, in term of out-of-sample explanatory power, our findings show that both Stability Selection and SIS are able to improve the Lasso optimized through standard criteria finalized to prediction purposes. Moreover, it is worth noting that by limiting the number of selected variables, Lasso may attain comparable results.

Figure 2. Number of selected feature (left) and Predictive R^2, by method over bootstrap data – Single words (229 predictors)

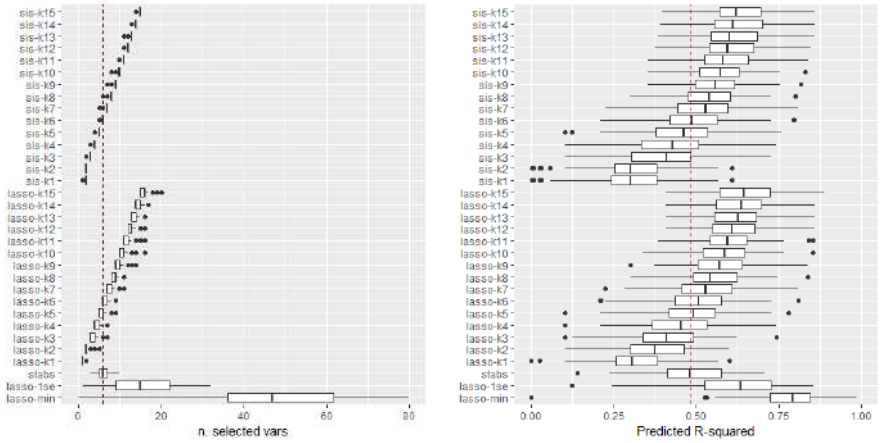


Figure 3. Number of selected feature (left) and Predictive R^2, by method over bootstrap data – Single words and bigrams (1245 predictors)

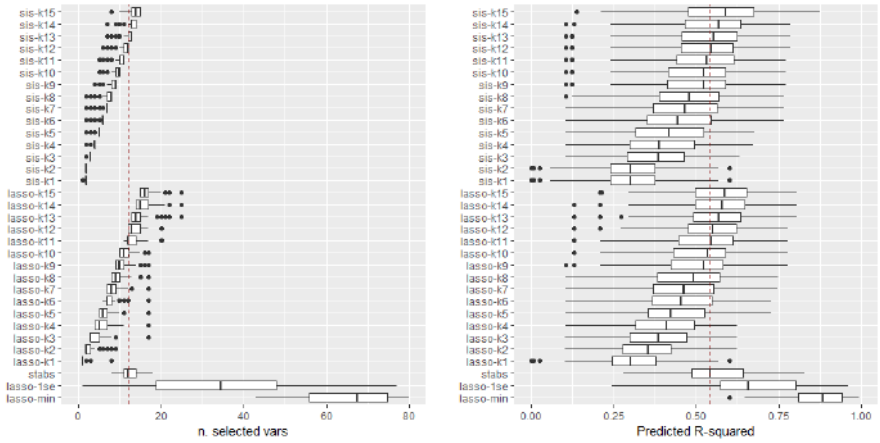

Concerning the ability to select relevant explanatory predictors, Stability Selection slightly outperforms other methods, which, notwithstanding, exhibit good performance. In our opinion, the most interesting finding is that Lasso behaves well when the number of selected variables is limited. So, our recommendation for future

works is to pose more emphasis on how to get better insights on stopping rules or Information Criteria.

Web Usage Mining and Website Effectiveness
Il Web Usage Mining e l'Efficacia dei Siti Web

Maria Francesca Cracolici and Furio Urso

Abstract Using usage mining techniques, the study explores the effectiveness of a tourism business website focussing on the differences between desk and mobile user browsing behaviour. Results indicate important direction for a rethink of the website design.
Abstract *Nel seguente articolo sono state utilizzate tecniche di Usage Mining al fine di valutare l'efficacia del website di un'azienda di ricettività turistica distinguendo tra comportamento di navigazione di utenti PC e utenti mobile. I risultati ottenuti hanno evidenziato problematiche relative alla progettazione del sito in questione.*

Key words: online browsing behaviour, tourism 2.0, web usage mining

1. Introduction

Nowadays, the effectiveness of a website is a key factor in the competitiveness of a company. A successful website should be easy to use, graphically appealing and match the mission of the company. In order to evaluate effectiveness we have to understand how users interact with the site by applying Web Usage Mining (WUM) techniques which analyse web generated Big Data.
In recent years, because of advances in mobile technologies, empirical studies have been carried out on the browsing behaviour of web users and how it may be influenced by the physical characteristics of the access device, such as the ability to conduct transactions at any time and place (Sumita and Yoshii, 2010); or the fact that the limited manageability of the touchscreen in some websites makes it difficult to use long-term channels for m-commerce (Ipsos, 2015). Furthermore, since the use of reduced screens requires a large number of scrolling movements, the type and amount of information that the user is able to manage is limited (Ghose et al., 2012).

Maria Francesca Cracolici, University of Palermo; email: mariafrancesca.cracolici@unipa.it
Furio Urso, University of Palermo; email: furio.urso@community.unipa.it

Moreover, PCs differ when it comes to consulting different sources of information at the same time (Chae and Kim, 2004).
By using Data from the website PalermoTravel[1], a Sicilian company operating in the tourism sector which offers rental apartments and auxiliary tourism services, our study explores whether the browsing behaviour of PC users differs from that of mobile device users. Tourism sector is an interesting case study because consumers in Tourism 2.0 (Sparks et al., 2013) obtain information anytime and anywhere to better plan their trips; hence travel services must be customizable and web site constantly improved.
The rest of the paper is structured as follows. Section 2 includes data description and WUM methods used to explore the surfing behaviour of users. Section 3 presents empirical results and some concluding remarks.

2 Data and Methods

As mentioned above, data on access to the website of PalermoTravel has been used to explore the browsing behaviour of its users. The website has 5 thematic areas: Attractions, Accommodation, Services, Experiences and Events. In addition, the site provides general information on the company and its staff, on partners and access to bloggers and user reviews.
The dataset consists of web server log data in *IIS-W3Cex Extended* format which was collected for the months of September to December 2017. It consists of 2,487,802 lines divided into 17 log fields.
Web Usage Mining enable us to identify and analyse user behaviour patterns in the flow of clickstreams (a sequential list of access requests). These patterns are generally represented by sets of pages, objects or resources that have been viewed and used by user groups with common needs and interests. In the Web Usage Mining process data is collected, cleaned and divided into sets of user transactions that represent the activity of the individual users during visits to the site (Liu e Kaselj, 2007). In Table 2.1., we can see an example of a section of a Path Matrix, where each row is a user session:

Table 2.1: *Path Matrix example*

Data is then processed in order to obtain the hidden patterns that reveal the behaviour of the users, and indices are calculated that are representative of users, sessions and site components; patterns and statistics are further processed and

[1] A pseudonym has been used, instead of using the real name of the company

aggregated to be used by Data Mining algorithms such as association rules and the Markov chain (Cooley, 2000).

Association rules analysis (Agrawal et al., 1993) in the context of WUM allows identification of groups of objects purchased or pages visited (more frequently in an observed period) providing a greater understanding of users' tastes.

Let $I = \{i_1, i_2, \ldots, i_m\}$ be a set of items and $T = \{t_1, t_2, \ldots, t_n\}$ a set of transactions where t_i is a set of items such that $t_i \subseteq I$. An association rule is an implication of the form:

$$X \rightarrow Y, where\ X \subset I, Y \subset I\ and\ X \cap Y = \emptyset$$

Using support and confidence measures, the effectiveness of the rule can be assessed. The support of a rule is the percentage of transactions in *T* that contains $X \cup Y$; while the confidence of a rule is a percentage value that measures how many of the transactions in *T* which contain *X* also contain *Y*, and consequently it determines the predictability of the rule. Additionally, the lift measure can be used to check whether the association rules are effective in predicting user behaviour. In our case, the lift is the ratio between the probability that users will display a page in a target category, conditional on having visited pages in other categories and the probability that a page of another target category will be displayed.

$$lift(X \rightarrow Y) = \frac{conf(X \rightarrow Y)}{P(Y)}$$

Lift values above (below) the unit indicate that the user's display of other page categories increases (decreases) the probability of moving on to the target category. An association rule mining algorithm, such as *apriori* algorithm (Agrawal and Srikant, 1994), determines the set of rules on the basis of minimum threshold values for confidence and support.

The Markov chain, however, enables us to explore the user navigation path within a website. This model is particularly suitable for modelling and predicting Data based on contiguous sequences of events; viz. each page-view can be seen as a precise state and the transition probability between two states can represent the probability that a user will move from one page to another during navigation. The Markov model allows one to predict the user probability of viewing a certain page given a certain route, to identify the most frequent navigation routes and to forecast subsequent visualizations conditional on the route.

A time homogeneous Markov chain of order *k* is a stochastic process $X^{(n)}$ that, at each time *n* takes state s_n from a finite set *S*, with probability that is independent of time *n* and that depends only on the states attained in the previous *k* times. This process can be described by transition matrices $P^{(k)}$, where the generic element $P_{i,j}^{(k)}$ is the probability of transitioning from state *i* at time $n-k$ to state *j* at time *n*.

Considering Usage Mining applications, the probability for a transition to either of the possible next states (pages) depends on user navigation behaviour, that can be

seen by considering the user's last *k* states (Moe 2003). Transition probability matrixes are estimated using Ching, Huang, Ng and Siu model (2013).

$$X^{(n+k+1)} = \sum_{i=1}^{k} \lambda_i Q_i X^{(n+k+1-i)} \;\; ; \;\; \sum_{i=1}^{k} \lambda_i = 1, \;\; \lambda_i \geq 0 \;\; \forall i$$

$$Q_i = \left[Pr_{j,h}^{(i)} \right]_{m \times m}$$

Where Q_i is an $m \times m$ lag-specific transition probability matrix and λ_i is the weight for lag i.

3 Results

Data was cleaned and pre-processed to obtain a suitable dataset consisting of 95,201 lines by IP address. 43,182 User Sessions were identified in order to follow the path of users within the site in the form of a sequence of pages viewed.

Table 3.1: *PC and Mobile access*

	Average page number	**Average page duration**	**Average session duration**
PC	6.488	60.129	182.606
Mobile	4.412	67.405	151.486

Table 3.1 shows that users accessing PCs view more pages on average and spend more time per session than users accessing via mobile. In contrast, mobile users spend more time on each page.
The association rules analysis, as regards PC access, reveals that many lift values are above 1 (Table 3.2). As for access via mobile device, we have only one significant lift value of 1.404, indicating an increase in the probability of viewing "Accommodation" after visiting the "Experience" area. Moreover, for access via mobile, we observe that few rules satisfy the threshold established for the support and confidence (Table 3.3.). Specifically, we applied the *apriori* algorithm by selecting the support threshold level at 5% and the confidence threshold level at 30%. We also considered the visualization of "Accommodation" as the rule *consequent*, distinguishing between PC and mobile users, using the R "arules" package.
It is noticeable that in case of PC access, viewing another area (except "Homepage" and "Attraction") increases the likelihood that the "Accommodation" area will be visited.
Users who access via mobile tend to view fewer areas, and joint visualizations decrease the probability of displaying a page of the "Accommodation" category. For both PC and Mobile access, the viewing the "Experiences" area seems to increase

the probability of exploring “Accommodation”, and indeed in the case of mobile access it is the only area that leads to viewing "Accommodation".

Table 3.2: *Association rules with Accommodation consequent for PC access data*

Rule	support	confidence	lift
{Events} => {Accommodation}	0.05	0.59	1.43
{Services} => {Accommodation}	0.06	0.556	1.337
{Info} => {Accommodation}	0.057	0.444	1.065
{Experiences} => {Accommodation}	0.097	0.596	1.433
{Homepage} => {Accommodation}	0.136	0.372	0.893
{Attractions} => {Accommodation}	0.187	0.392	0.94
{Experiences,Homepage} => {Accommodation}	0.06	0.851	2.044
{Attractions,Experiences} => {Accommodation}	0.065	0.758	1.82
{Attractions, Homepage} => {Accommodation}	0.092	0.67	1.61

Table 3.3: *Association rules with Accommodation consequent for Mobile access data*

Rule	support	confidence	lift
{Experiences} => {Accommodation}	0.051	0.531	1.404
{Homepage} => {Accommodation}	0.218	0.383	1.012
{Attractions, Homepage} => {Accommodation}	0.113	0.326	0.86

By applying the Markov chains, we tracked the paths of the users in probabilistic terms. The estimation of transition matrices performed on PC and mobile users did not show significant differences, so we clustered them all together.

Figure 3.1: *Transition probability matrixes: order 1 and 6*

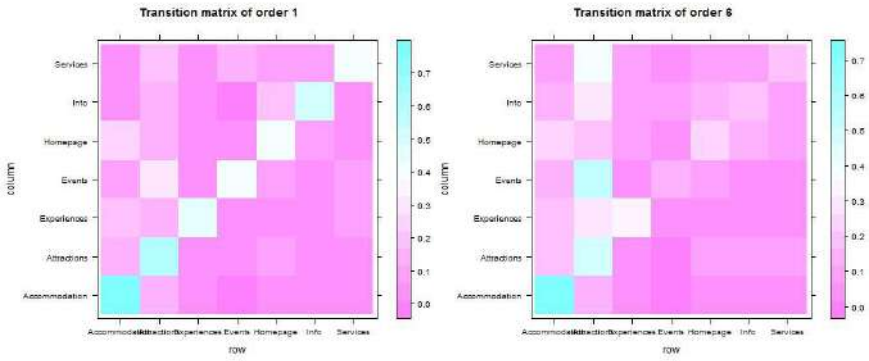

Figure 3.1 shows clearly that users tend to remain in the same subject area. Users who view a page in the "Accommodation" category have a 75% chance of moving to another page in the same category, a 12.9% probability of viewing the "Attractions" category and roughly a 6% probability for other areas.
Similar figures have been observed for users who view the "Attractions" category, while in the other categories the probability of moving to another page in the same area varies from between 38% and 54%.

The "Homepage" category is a little different. Those visiting the Homepage have a 23% chance of moving to "Accommodation " and a 16% probability of moving to "Attractions". The latter are the most visited areas coming from each of the categories. By increasing the order of transition matrices, for the "Accommodation" and "Attractions" categories, the situation remains almost the same.
Summing up, the association rules analysis showed that users seem to be more interested in obtaining general information about a holiday in Palermo rather than looking for accommodation. The obtained transition matrices have highlighted the monothematic nature of user paths; users tend to view pages sequentially in the same category.
Some critical considerations emerge. The homepage provides the user with a list of image links related to the "Attractions" area with the clear intent of stimulating curiosity. However, access to an attraction page leads to further attractions, as each page belonging to a thematic area contains image links limited to the same area. Since the core business of the company is its accommodation service, we suggest that the interest shown by users for the "Attractions" area pages be exploited to include image links of accommodation near the tourist attraction being described on each page.

Aberration for the analysis of two-way contingency tables

L'aberrazione per l'analisi di tabelle di contingenza a due vie

Roberto Fontana and Fabio Rapallo

Abstract The aberrations are quantities usually computed in the context of Factorial Experiments. In this work, we introduce the use of the aberrations in the framework of contingency table analysis, and we propose a test of independence for 2×2 tables based on the aberrations. With a simple simulation study, we compare its performance with the well known chi-square test and Fisher's exact test.

Abstract *Le aberrazioni sono quantità usualmente definite per i piani fattoriali. In questo lavoro introduciamo l'uso delle aberrazioni nell'ambito dell'analisi delle tabelle di contingenza e studiamo un test di indipendenza per tabelle* 2×2 *basato su queste. Mediante uno studio di simulazione ne valutiamo le performance confrontandole con quelle del test chi-quadro e del test esatto di Fisher.*

Key words: Factorial designs, Independence test, Replicates, Aberration

1 Introduction

When two binary random variables X and Y are observed on a sample of size n, the collected data are summarized in a 2×2 contingency table. If we denote with -1 and $+1$ the levels of both X and Y, the joint counts are $n_{-1,-1}$, $n_{-1,1}$, $n_{1,-1}$, and $n_{1,1}$. Moreover, we denote with $n_{-1,+}$ and $n_{1,+}$ the marginal counts of the variable X, and similarly with $n_{+,-1}$ and $n_{+,-1}$ the marginal counts of the variable Y. In the literature there are several techniques to test the independence of the two variable, or to measure the extent of the connection. For a review on 2×2 tables, see [1].

In this work we consider the chi-square test of independence and the Fisher's exact test. The chi-square test of independence is based on the test statistic

$$C = \sum_{(i,j)\in\{-1,1\}^2} \frac{(n_{i,j}-\hat{n}_{i,j})^2}{\hat{n}_{i,j}} = \sum_{(i,j)\in\{-1,1\}^2} \frac{(n_{i,j}-\frac{n_{i,+}n_{+,j}}{n})^2}{\frac{n_{i,+}n_{+,j}}{n}} \tag{1}$$

which is compared with the chi-square distribution with 1 degree of freedom. When the sample size is small, the Fisher's exact test should be preferred. In such a test, the exact hypergeometric probability of all tables with the same marginal counts as those of the observed table are computed. Given the value $n_{-1,-1}$ of the cell in position $(-1,-1)$, the value of $n_{-1,-1}$ together with the margins completely determine all the counts, and the corresponding hypergeometric probability is

$$\begin{aligned} &p(n_{-1,-1};n,n_{-1,+},n_{+,-1}) = \\ &= \frac{n_{-1,+}!n_{1,+}!n_{+,-1}!n_{+,1}!}{n!n_{-1,-1}!(n_{-1,+}-n_{-1,-1})!(n_{+,-1}-n_{-1,-1})!(n_{+,1}-n_{-1,+}+n_{-1,-1})!}. \end{aligned} \tag{2}$$

Then, the p-value of the test is obtained by summing up all the probabilities of the tables more extreme than the observed one, i.e., with hypergeometric probability less than or equal to the probability of the observed table. Note that the Fisher exact test can be used in both the one-sided and in the two-sided setting. The idea behind the Fisher's exact has been extended to multi-way tables in the framework of Algebraic Statistics, see e.g. [6]. Another common measure of association is the log-odds-ratio $\ell = \log\left(\frac{n_{1,1}n_{-1,-1}}{n_{-1,1}n_{1,-1}}\right)$ which is related to independence because under independence one has $\ell = 0$.

In this work we use aberrations to analyse two-way binary contingency tables. Aberrations are usually computed for Fractional factorial designs, which are commonly used in Design of Experiments. More specifically, un the case of binary designs, an important object associated to a design is its Word-Length Pattern (WLP). The WLP is used to discriminate among different designs through the Minimum Aberration (MA) criterion, which is based on the sequential minimization of the WLP. The MA criterion was introduced in [4] for binary designs and then extended with the name of Generalized Minimum Aberration to non-regular multilevel designs in [7]. The WLP is computed using the aberrations of all the main effects and interactions.

In general a $I \times J$ contingency table can be interpreted as a factorial design with two factors with I and J levels respectively. With a slight abuse of notation, we denote the two factors again with X and Y. In this context the values $n_{i,j}$ in the table, represent the number of replicates of the point (i,j) in the design, $i = 1,\ldots,I$ and $j = 1,\ldots,J$.

In our study, given a 2×2 contingency table we use the aberrations computed for the corresponding factorial design to build a statistic that measures the departure from independence, i.e., the distance of the observed table to the table that would have been obtained under the hypothesis of independence.

2 The case of 2×2 contingency tables

Let us consider a 2×2 contingency table

$$\begin{pmatrix} n_{-1,-1} & n_{-1,1} \\ n_{1,-1} & n_{1,1} \end{pmatrix}$$

where the entries $n_{i,j}$ are non-negative integers, $i, j \in \{-1, 1\}$. There is a natural 2^2 factorial design corresponding to this table

X	Y	n
1	1	n_{11}
1	2	n_{12}
2	1	n_{21}
2	2	n_{22}

In the context of the design above, $n_{i,j}$ represents the number of replicates corresponding to the points (i, j), $i, j \in \{-1, 1\}$. A commonly used measure associated to factorial design are *aberrations*. Using Prop. 1 in [2], we can compute the aberrations of the design in the previous table. We obtain:

$$a_X = a_{10} = \frac{(n_{1,+} - n_{-1,+})^2}{n^2}, \quad a_Y = a_{01} = \frac{(n_{+,1} - n_{+,-1})^2}{n^2},$$
$$a_{XY} = a_{11} = \frac{(n_{-1,-1} + n_{1,1} - n_{-1,1} - n_{1,-1})^2}{n^2}.$$

In [2] it was proved that under independence the difference δ between the second-order aberration a_{11} and the product of the first-order aberrations $a_{10} \cdot a_{01}$, $\delta = a_{11} - a_{10} \cdot a_{01}$ is zero.

We use δ as a measure of the distance of the observed table to table would have been obtained under independence.

More specifically we consider the case in which all the margins $n_{-1,+}$, $n_{1,+}$, $n_{+,-1}$, and $n_{+,1}$, are supposed to be fixed. For example this situation occurs when a fixed number of participants for two categories ($n_{-1,+}$, and $n_{1,+}$) are observed until a predefined number $n_{+,-1}$, of events are observed.

In this case, under the null hypothesis of independence, $n_{-1,-1}$ follows an hypergeometric distribution, $n_{-1,-1} \sim \text{Hypergeometric}(n, n_{-1,+}, n_{+,1})$. Then the probability mass function underlying the Fisher's exact test is given in Eq. (2) mentioned in the previous section.

The two-sided p-value for the Fisher's exact test, p_F is computed as

$$p_F = P(|n_{-1,-1} - n_I| \geq |n^{\text{obs}}_{-1,-1} - n_I|)$$

where $n^{\text{obs}}_{-1,-1}$ is the observed value of $n_{-1,-1}$, n_I is the expected value of $n_{-1,-1}$ under independence, $n_I = \frac{n_{-1,+} n_{+,-1}}{n}$ and $n_{-1,-1} \sim \text{Hypergeometric}(n, n_{-1,+}, n_{+,-1})$.

In a similar way, using the statistic δ we define the corresponding p-value p_δ as

$$p_\delta = P(|\delta - \mu_0| \geq |\delta^{\text{obs}} - \mu_0|)$$

where δ^{obs} is the observed value of δ and μ_0 is the mean of δ under the null hypothesis of independence. We notice that δ is a function of $n_{-1,-1}$ and then its density f_δ can be written as

$$f_\delta(d;n,n_{-1,+},n_{+,-1}) = \sum_{n_{-1,-1}:\delta(n_{-1,-1})=d} p(n_{-1,-1};n,n_{-1,+},n_{+,-1})$$

where $p(n_{-1,-1};n,n_{-1,+},n_{+,-1})$ is again the hypergeometric probability defined in Eq. (2). We obtain that the mean of δ under the null hypothesis of independence is

$$\mu_0 = \sum_{a=\max(0,n_{-1,+}+n_{+,-1}-n)}^{\min(n_{-1,+},n_{+,-1})} \delta(a)p(a;n,n_{-1,+},n_{+,-1}).$$

We compare the behaviour of these two tests and the chi-square test through a simulation study. We consider 2×2 tables with sample size $n = 20$. In the first scenario we consider the independence model. We choose the marginal probabilities as $p_{-1,+} = 0.5$ and $p_{+,-1} = 0.4$. It follows $p_{1,+} = 0.5$ and $p_{+,1} = 0.6$. We compute the cell probabilities $p_{i,j}$ as $p_{i,+}p_{+,j}$ with $i,j \in \{-1,+1\}$. In the second scenario, using the same marginal probabilities we consider a model close to the lower Fréchet-Hoeffding bound of the Fréchet class of the bivariate Bernoulli with means equal to 0.5 and 0.6:

$$p_{-1,-1} = \varepsilon, p_{-1,1} = 0.5 - \varepsilon, p_{1,-1} = 0.4 - \varepsilon, p_{1,1} = 0.1 + \varepsilon$$

where ε is chosen equal to 0.001. In the third scenario we define an intermediate situation defining the cell probabilities as a the average of the cell probabilities defined in scenario 1 and 2. We obtain

$$p_{-1,-1} = 0.1 + \varepsilon/2, p_{-1,1} = 0.4 - \varepsilon/2, p_{1,-1} = 0.3 - \varepsilon/2, p_{1,1} = 0.2 + \varepsilon$$

For all scenarios we run $1,000$ simulations. In each simulation we randomly generate a contingency table as a sample from a multinomial distribution with parameters $n = 20$ and $p_{-1,-1}, p_{-1,1}, p_{1,-1}, p_{1,1}$ defined as described above. We use the `RandMultinomial` function of SAS/IML [5]. Then for each simulation we compute the p-values corresponding to the two-sided Fisher's exact test (p_F), to the chi-square test (p_χ), and to the δ statistic (p_δ).

For each scenario and for each test, varying the significance level α between 0.010 and 0.200 we determine the corresponding *observed significance level* α^{obs} as the ratio between the number of simulations where the p-value is less than or equal to α and the total number of simulations ($1,000$ for each scenario):

$$\alpha^{\text{obs}} = \frac{\#(p\text{-value} \geq \alpha)}{1,000}$$

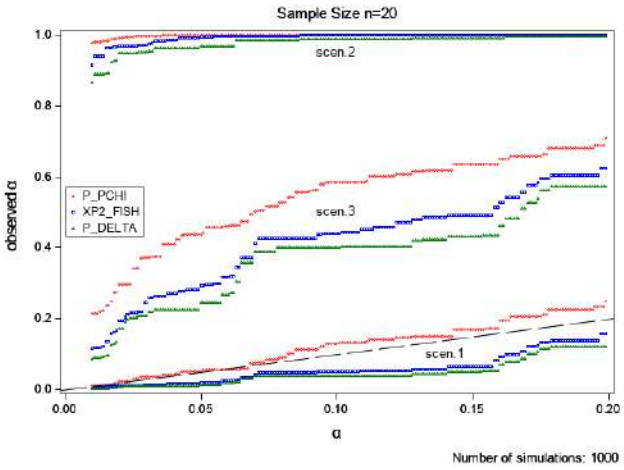

Fig. 1 Comparison between the significance level and the observed significance level. Sample size $n = 20$.

The results are summarized in Figure 1 . The scenario 1 (independence) shows that the Fisher's exact test and the delta-based test behaves similarly and they both look conservative. The chi-square test performs quite well if the significance level is chosen to be less than 7% approximately. The scenario 2 (absence of independence) exhibits a very good power for all the tests even if the delta-based test and the Fisher's exact test performs less well than the chi-square test. The scenario 3 shows an intermediate behaviour as expected.

The simulation study has been repeated reducing the total sample size to $n = 12$. The results are summarized in Figure 2. The overall performance decreases as expected but the observations made for the case $n = 20$ remain the same.

3 Extensions and future work

The use of aberrations in the context of contingency tables is new and looks promising. Nevertheless the simulation study shows that further research should be done to improve the performance of the test based on the δ statistic. Exploiting the results in [3], the results for the 2×2 case can be extended to the 3×3 case. In fact, the aberrations can be easily derived and straightforward computations show that, under independence, all aberrations of order two are equal to the product of the

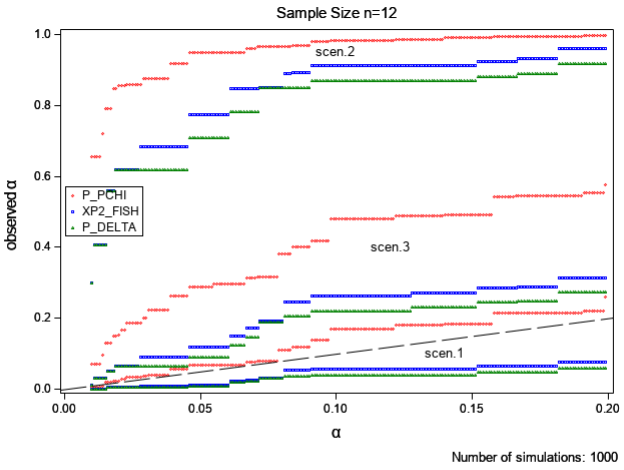

Fig. 2 Comparison between the significance level and the observed significance level. Sample size $n = 20$.

corresponding aberrations of order one. For instance: $a_{X^2Y} = a_{X^2} a_Y$. The procedure proposed here could be extended to the case of binary multi-way tables, where the aberrations are easy to compute and the patterns of dependence or independence among the variables can be difficult to detect. For larger tables, or for rectangular tables, the algebraic expressions of the aberrations become more complicated. One can overcome this difficulty by considering mean aberrations instead of aberrations, as suggested in [3], but this analysis is beyond the scope of the present work.

An investigation of the paradoxical behaviour of κ-type inter-rater agreement coefficients for nominal data

Studio sul comportamento paradossale dei coefficienti Kappa di accordo inter-valutatore per dati nominali

Amalia Vanacore[1] and Maria Sole Pellegrino[2]

Abstract A main criticism arising in agreement studies is the lack of robustness for some κ-type coefficients, that is their dependency on the frequency distribution of the ratings over classification categories. In order to investigate the statistical behaviour of three well-known κ-type coefficients, an extensive Monte Carlo simulation study has been conducted. The simulation study analyzed several scenarios, differing for sample size, rating scale dimension, number of raters, frequency distribution of ratings and pattern of agreement across raters.

Abstract *Una criticita' tipica degli studi di accordo riguarda la mancanza di robustezza di alcuni coefficienti Kappa, che deriva dalla dipendenza dei coefficienti dalle distribuzioni marginali di frequenza delle valutazioni fornite. Uno studio in simulazione Monte Carlo e' stato condotto per analizzare la robustezza di tre noti coefficienti Kappa. Lo studio in simulazione ha investigato la robustezza degli indici in scenari diversi tra loro per dimensione campionaria, numero di livelli della scala di valutazione, numero di valutatori, distribuzione di frequenza delle valutazioni e grado di accordo tra i valutatori.*

Key words: Inter-rater agreement, κ-type coefficients, Paradoxical behaviour

1 Introduction

In many fields, researchers and practitioners measure characteristics of interest by having two or more raters (e.g. clinicians, judges, psychologists, field experts) assigning scores to observed subjects, objects, or events. In these cases, a common issue is the reliability of the subjective classification process.

[1]Dept. of Industrial Engineering, University of Naples "Federico II", p.le Tecchio 80, 80125 Naples; email: amalia.vanacore@unina.it

[2]Dept. of Industrial Engineering, University of Naples "Federico II", p.le Tecchio 80, 80125 Naples; e-mail: mariasole.pellegrino@unina.it

To deal with this issue, a number of approaches have been proposed over the years and several coefficients have been introduced [15, 20, 22, 23]. For example, just to cite a few of them, the Intraclass Correlation Coefficient (ICC); the Kendall's W, a measure of rank correlation that is a generalization of Spearman's ρ correlation coefficient [16]; the Goodman and Kruskal's γ, based on the notion of concordance [10]; and the Krippendorff's α reliability coefficient [17].

A widespread approach relates the quality of subjective measurement procedures to the concept of inter-rater agreement, that is the agreement observed among two or more independent raters. The easiest way of measuring inter-rater agreement is to calculate the overall percentage of agreement; nevertheless, this measure does not take into account the agreement that would be expected by chance alone. A common solution is to adopt a coefficient belonging to the well-known family of the κ-type agreement coefficients, rescaled measures of the probability of observed agreement corrected with the probability of agreement expected by chance alone. As a matter of fact, different κ-type agreement coefficients have been proposed in the literature over the years changing for scale (nominal, ordinal and interval) and number of raters (two or more).

Despite their popularity, some κ-type agreement coefficients suffer from *paradoxical behaviour* due to two criticisms coming from the dependency on the marginal frequency distributions of the ratings over classification categories [6, 12]. The first paradox is the strong dependency on the *trait prevalence in the item population* which affects the observed marginal distribution of items across rating categories and thus the calculation of the chance agreement term. Specifically, fixing the observed agreement component, "unbalanced marginal totals produce higher values of κ than more balanced marginal totals" [8].
The second paradox is the dependency on the *marginal distribution of ratings over categories*: fixing the observed agreement component, the chance agreement obtained with symmetric marginal distribution is higher than the value obtained with asymmetric distribution and this makes the κ value considerably decrease [8]. These criticisms were firstly observed by Brennan and Prediger in 1981 [2] although they are widely known as *kappa paradoxes* as referred to by Feinstein and Cicchetti [4, 8].

The literature discussions on the paradoxical behaviour of κ-type agreement coefficients are limited to the simplest case of two raters and dichotomous (or at least nominal) data [3, 5, 11, 12, 21] whereas few research efforts have been devoted to κ-type agreement coefficients for inter-rater agreement [7, 13, 18, 19].

To the best of our knowledge, the most recent work is the study conducted by Quarfoot and Levine [19] who defined the robustness of an agreement coefficient as its "ability of giving roughly the same result for a fixed level of agreement irrespective of the frequency distribution used when correcting for chance agreement". Their simulation study aimed at investigating the robustness of five inter-rater agreement indices under a specific experimental condition (i.e. 8 raters classifying 100 items on a k-point ($4 \leq k \leq 11$) ordinal rating scale). In order to get more insight on this topic, this paper exploits the approach proposed in [19] to investigate and compare the robustness of three κ-type coefficients for inter-rater agreement with nominal data,

that is Fleiss' kappa K_F [9], *BP* coefficient [2] and Gwet's AC_1 [13]. Our simulation study analyzes several scenarios differing for sample size, rating scale dimension, number of raters, frequency distribution of ratings and pattern of agreement across raters.

The paper is organized as follows: in Section 2 the κ-type agreement coefficients are introduced; in Section 3 the simulation design is described and the main results are discussed; finally, conclusions are summarized in Section 4.

2 κ-type coefficients for inter-rater agreement

The κ-type agreement coefficients are rescaled measures of the observed proportion of agreement (p_a) corrected with the proportion of agreement expected by chance alone ($p_{a|c}$). All κ-type agreement coefficients, differing in scale type and number of raters, are formulated as follows:

$$\kappa = \frac{p_a - p_{a|c}}{1 - p_{a|c}} \tag{1}$$

The κ-type agreement coefficients range from -1 to +1: they are null when p_a equals $p_{a|c}$; when p_a is greater than $p_{a|c}$ the coefficients are positive; vice-versa, the coefficients are negative and can be interpreted as disagreement.
Different κ-type agreement coefficients have been proposed in the literature, sharing the same formulation of observed agreement but differing from each other in the notion of chance agreement and thus in the formulation of the $p_{a|c}$ term.

Let us consider the case of R raters classifying the same set of n items on a nominal k-point rating scale, with $k > 2$. Being r_{li} the number of raters classifying item l into category i, the proportion of observed agreement among multiple raters [14] is computed as follows:

$$p_a = \frac{1}{n} \sum_{l=1}^{n} \sum_{i=1}^{k} \frac{r_{li}\,(r_{li} - 1)}{R(R-1)} \tag{2}$$

The inter-rater agreement coefficient proposed by Fleiss [9] in 1971 (K_F) formulates the agreement expected by chance assuming that the items are classified into categories independently to each other:

$$p_{a|c}^{K_F} = \sum_{i=1}^{k} r_i^2 \tag{3}$$

where $r_i = 1/n \cdot \left[\sum_{i=1}^{k} r_{li}/R\right]$ is the propensity of classifying an item into category i. The $p_{a|c}^{K_F}$ depends on the propensity of classifying an item into each category so that the categories are not all equally probable but those with higher marginals are preferred over the others.

A solution to the above drawback is to assume that the probability of chance classification is uniform across categories:

$$p_{a|c}^{BP} = 1/k \tag{4}$$

The obtained coefficient is commonly known as Brennan-Prediger coefficient, hereafter *BP*, although it has been firstly suggested by Bennett et al. [1] when assessing the degree of inter-rater agreement on binary classifications.

The Agreement Coefficient (AC_1), proposed by Gwet in 2008 [13] formulates $p_{a|c}$ as the probability of the simultaneous occurrence of random rating in one replication (R) and agreement across replications (G):

$$p_{a|c}^{AC_1} = P(G \cap R) = P(G|R) \cdot P(R) = \frac{1}{k} \cdot \frac{\sum_{i=1}^{k} r_i(1-r_i)}{(k-1)/k} = \frac{1}{k-1} \sum_{i=1}^{k} r_i(1-r_i) \tag{5}$$

The conditional probability, $P(G|R)$, that the raters agree given that at least one of them has performed random ratings is formulated under the assumption of uniform distribution for chance measurements.

3 Simulation study

The simulated data sets are the classifications simultaneously provided by R raters on the same set of n items adopting a k-point nominal scale, considering that the generic i^{th} rater provides her/his classifications according to a given Frequency Distribution (FD) of ratings over classification categories and all the other $R-1$ raters agree with her/him according to a given pattern of agreement among raters (i.e. Agreement Distribution, AD).

The simulation study has been designed taking into account five multi-level factors: k, n, R, FD and AD. The factor k has 3 levels: $k = 3,4,5$ classification categories, the factor n has 3 levels: $n = 10,30,100$ items, the factor R has 3 levels: $R = 2,5,9$ raters, whereas the factors FD and AD have 6 and 1 level, respectively. FDs are all special cases of the beta-binomial distribution with different values of the shape parameters (a,b): FD 1 (0.25, 0.25), FD 2 (1, 1), FD 3 (2, 2), FD 4 (50, 50), FD 5 (25, 50), FD 6 (5, 50). The AD is a binomial distribution scaled on k and centred on R_i. For each combination of k, n, R, FD and AD, $r = 2000$ Monte Carlo data sets have been generated, for a total of $3 \cdot 3 \cdot 3 \cdot 6 \cdot 1 = 162$ simulated scenarios for each coefficient. The robustness of the κ-type agreement coefficients under study has been evaluated in terms of the mean agreement range $\overline{\text{AR}}$ over the 6 different FDs. The simulation algorithm has been implemented using Mathematica (Version 11.0, Wolfram Research, Inc., Champaign, IL, USA).

Simulation results, obtained for every combination of rating scale dimension, number of raters, sample size and agreement coefficient, are represented in Figure 1.

The simulation results show that, for each scenario (i.e. combination of rating scale size, number of rater and sample size), the robustness of the three κ-type coefficients against changes in the FD is generally comparable; the only exception is for $n = 10$ and $R = 2$, when K_F is slightly less robust than AC_1 and BP. Moreover, increasing the group dimension and the sample size makes the robustness improve; instead, with as few as $k = 5$ or less rating categories, the dimension less impacting on robustness seems to be the rating scale dimension.

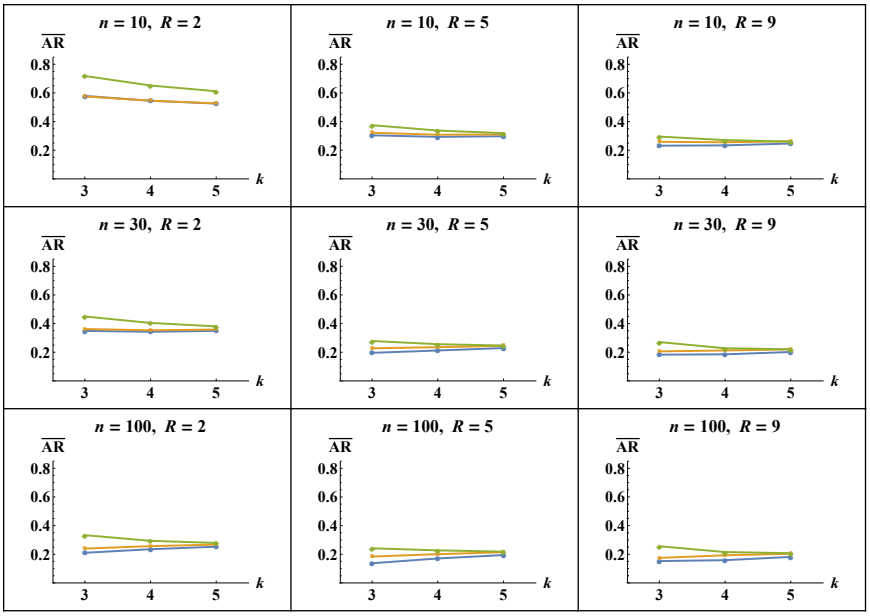

Fig. 1 Mean Agreement Range obtained for K_F (in green), BP (in blue) and AC_1 (in orange) as FD varies

4 Conclusions

The robustness of three κ-type inter-rater agreement coefficients for nominal data has been investigated via Monte Carlo simulation. Our findings suggest that the most robust κ-type coefficient is BP, assuming uniform chance agreement, followed by AC_1, formulating chance agreement assuming that at least one rater provides random ratings. Moreover, our results reveal that, beyond the approach adopted to correct for chance agreement, the statistical behaviour of inter-rater agreement coefficients is affected by the sample size of rated items and by the number of raters involved in the experiment.

A further development of forthcoming research aims at investigating the robustness of an inferential benchmarking procedure for the characterization of the extent

of agreement: whether and how the lack of robustness of the κ-type coefficients under study could affect the final agreement characterization.

Analyzing faking-good response data: Combination of a Replacement and a Binomial (CRB) distribution approach

Analisi di dati soggetti a processi tipo faking-good mediante approcci di mistura

Luigi Lombardi, Antonio Calcagnì

Abstract In this short paper, we describe a novel approach to model and analyse ordinal data in the presence of faking behavior, namely the tendency of survey's participants to falsify their responses in order to achieve a particular purpose. The proposal relies on the use of two statistical approaches commonly used to analyse faking and preference data: the Sampling Generation by Replacement (SGR) and Combination of Uniform and Binomial distributions (CUBE). By combining both SGR and CUBE, we propose CRB (Combination of Replacement and Binomial distributions), where the response ordinal measure is modeled as a convex combination of the shifted-Binomial distribution and the Replacement distribution. Thus, the first component aims to represent the response measure unaffected by faking behavior whereas the second element of the linear model represents the result of a faking strategy. As for the CUBE models, CRB parameters are estimated via Maximum likelihood by means of the EM algorithm. Finally, an application to ordinal data is proposed to show how the CRB model can be used to analyse self-reported data potentially affected by faking behavior.

Abstract *Abstract in Italian*. Questo lavoro presenta alcuni risultati preliminari per la definizione di un modello di analisi dei dati in presenza di *faking* o *malingering*. Dato un campione di misure ordinali - come quelle ottenute nel contesto delle *surveys* o questionari *self-report* - si definisce *faking* quel processo per il quale parte (o la totalità) dei rispondenti modifica la propria risposta in modo deliberato con l'obiettivo di ottenerne un vantaggio. Per l'analisi di tale tipologia di dati, si propone un nuovo approccio, denominato CRB (*Combination of a Replacement and Binomial distributions*), derivante dall'integrazione di due approcci statistici indipendenti, ossia SGR (*Sample Generation by Replacement*) and CUBE (Combination of Uniform and Binomial distributions). CRB modella la risposta ordinale mediante una combinazione lineare convessa di due componenti, una distribuzione Binomiale traslata per la componente ordinale della risposta ed una distribuzione di *Replace-*

ment per la componente faking. Come per i modelli CUBE, la stima dei parametri del modello è effettuata per massima verosimiglianza. Infine, un breve caso studio è utilizzato per mostrare il funzionamento del modello CRB per l'analisi e valutazione di dati soggetti potenzialmente a faking.

Key words: Fake-good data, CRB approach, Ordinal data, Generalized Mixture distribution, CUBE approach

1 Introduction

Faking behavior in self-report measures, a type of response set, is a tendency to falsify item responses in order to meet strategic goals (e.g., avoiding being charged with a crime, see [1]). This behavior may be observed in some sensitive contexts such as, for example, risky sexual behaviors and drug addictions (e.g., [2, 3]) where individuals may react by hiding their real opinions or honest responses.

SGR (Sample Generation by Replacement) is a probabilistic resampling procedure [4, 5] that can be used to study and evaluate uncertainty in inferences based on possible fake responses as well as to study the implications of fake data for empirical results. In general, a SGR analysis takes an interpretation perspective which incorporates in a global model all the available information (empirical or hypothetical) about the process of faking and the underlying true model representation. In particular, SGR has a statistical descriptive nature which tries to capture the phenomenological effect of faking according to an informational, data-oriented perspective based on a data replacement (information replacement) paradigm. SGR has been normally used as a methodology to study, using Monte Carlo simulation designs, the impact of fake data on parameter estimations and model fit evaluations.

Unlike SGR, CUBE models (Combination of a Uniform and a Binomial distribution) is a class of statistical models that is grounded on the data generating process of the discrete response choice [6, 7] which allows the modeling of rating data expressing preferences and evaluations. The CUBE approach considers the final discrete response as the combination of two components: *feeling* and *uncertainty*. The shifted Binomial component regards the expression of feeling and takes into account for the fraction of responses associated with a precise opinion on the rating. By contrast, the uniform component concerns to uncertainty in rating and mimics aspects not directly associated to the content of the item. This representation allows finer model specifications which include refuge options, response styles and possible overdispersion. Moreover, unlike SGR models, CUBE models are also supported by Maximum likelihood (ML) estimation procedures based on EM algorithms.

In this contribution, we introduce a novel model representation, called CRB (Combination of a Replacement and a Binomial distribution), which combines the two approaches by integrating into a common framework some nice features of the two perspectives to provide an effective data analysis strategy for faking behavior

in self-report measures. In particular, the new representation substitutes the second component (*uncertainty*) of CUBE with a replacement distribution mimicking the faking process in self-report measures.

2 Model

In this section, we will first highlight some connections between the two approaches according to a general probabilistic representation. Next, we will formally describe our proposal.

2.1 CUBE and SGR: similarities and differences

Let Y be a discrete (observed) random variable with a finite support $\{1,2,\ldots,m\}$ (e.g., a rating-type variable). In its general terms, the CUBE representation can be defined as follows:

$$P(Y=y) = \pi P(Z=y) + (1-\pi)P(V=y) \tag{1}$$

here Z and V are two hidden variables with the same support of Y. Note that, Eq. 1 constitutes a mixture representation for the observed variable Y. In particular, let $C \in \{0,1\}$ be a Bernoulli variable with parameter $\pi \in]0,1]$, then Eq. 1 can be rewritten as follows:

$$P(Y=y|C=1) = P(Z=y) \quad \text{and} \quad P(Y=y|C=0) = P(V=y) \tag{2}$$

Therefore, the mixture distribution reduces to a two step process where we first draw a coin C (with probability π of observing the target event), and next we sample the value of Y according to the previous dichotomous result observed on C. Note that, Eq. 1 implies a hidden joint distribution $P(C,Z,V)$ which in its general form *does not require* to satisfy the independence condition for the pair (Z,V). Therefore, $P(Y)$ represents the probability distribution of the transformed random variable

$$Y = CZ + (1-C)V. \tag{3}$$

Unlike CUBE, the SGR representation is defined as follows:

$$P(W=w) = \sum_x P(W=w|X=x)P(X=x) \tag{4}$$

where W and X are hidden variables with the same support of Y. In this context, the conditional distribution $P(W|X)$ is called the *replacement distribution*, whereas $P(X)$ is named the *prior distribution* for the true variable. In the SGR perspective, the random variable W is called the fake response, whereas X represents the true

hidden (and unknown) response. Note that $P(X)$ identifies the prior distribution of the true value X before any direct inspection of the observed data.

Now, we are in the position to link CUBE and SGR by setting the new transformed variable:

$$Y = CZ + (1-C)W \tag{5}$$

where, in this context, W denotes the fake random variable defined in Eq. 4. Note that a similar representation has been adopted in a recent SGR contribution called *mixture* SGR (see Eq. 11 in [8]). Recollecting all the terms we finally have:

$$P(Y = y) = \pi P(Z = y) + (1-\pi)P(W = y) \tag{6}$$

which, at a general level, directly connects SGR with the CUBE representation.

2.2 The CRB model

We now define the model instances for the CRB distribution. The first component is

$$b_y(\xi) = P(Z = y) = \binom{m-1}{y-1}(1-\xi)^{y-1}\xi^{m-y}, \qquad y = 1,2,\ldots,m, \tag{7}$$

the so-called shifted Binomial distribution with parameter $\xi \in [0,1]$. The second component of the CRB distribution is

$$p_y = P(W = y) = \frac{1}{m}\sum_{x=1}^{m} p_{y|x}, \qquad y = 1,2,\ldots,m, \tag{8}$$

with replacement distribution

$$p_{y|x} = \begin{cases} 1, & x = y = m \\ \frac{1}{m-x}, & 1 \le x < y \le m \\ 0, & 1 \le y \le \min\{x, m-1\} \end{cases} \tag{9}$$

The latter component corresponds to a fake good distribution (e.g., see Table 1 and Figure 1). Here we assume an uninformative prior for $P(X)$, that is to say, $P(X = x) = \frac{1}{m}$ for all $x = 1,2,\ldots,m$. Therefore, the CRB distribution takes the following form:

$$g_y \equiv P(Y = y) = \pi b_y(\xi) + (1-\pi)p_y. \tag{10}$$

Clearly, the distribution in Eq. 10 is a discrete one with a well defined two-dimensional parameter space $\Omega = \{(\pi,\xi) : 0 < \pi \le 1, 0 \le \xi \le 1\}$. Let $\mathbf{y} = (y_1, y_2, \ldots, y_n)$ be a random sample of n i.i.d. rating responses on the finite support $\{1,2,\ldots,m\}$. Then, the CRB log-likelihood function is expressed by:

$$L(\theta) = \sum_{i=1}^{n} \log\{\pi b_{y_i}(\xi) + (1-\pi) p_{y_i}\}. \tag{11}$$

Note that Maximum likelihood (ML) estimates can be obtained by EM algorithm according to the procedure outlined, for instance, by [9] for standard CUBE models.

3 Application

In this application we analyzed an hypothetical set of ordinal data about illicit drug use (cannabis consumption) among young people (see Table 1). In particular, the response variable uses a four-point ordinal scale ranging from 1 = *never* to 4 = *often*, with intermediate levels being 2 = *once* and 3 = *sometimes*. The observed frequencies for the four values were 27, 8, 5, and 3, respectively. To apply the faking-good model, as defined in Eq. 10, we reversed the rating scale. We finally ran the CRB model to the data sample with $n = 43$ independent rating observations. The estimated parameters were as follows:

$$\widehat{\pi} = 0.12090; \qquad \widehat{\xi} = 0.83336;$$

with a log-likelihood function $L(\widehat{\theta}) = -44.76983$ and a very low dissimilarity index $\delta = 0.01139$, which was calculated as the normalized difference between observed relative frequencies, $\widehat{p}_h$, and fitted probabilities, $\widehat{g}_h$:

$$\delta = \sum_{h=1}^{m} |\widehat{p}_h - \widehat{g}_h|.$$

The results suggested the prominent role of the replacement distribution component p_{y_i}, which modeled the faking-good style of response, in modulating the response process as reflected by the mixture parameter $(1-\pi)$.

Table 1 Replacement distribution $p_{y|x}$ and its marginal representation p_y. This corresponds to a fake good scenario such that $Y > X$ with a discrete uniform kernel.

	$X = x$					
$y\|x$	1	2	3	4	5	p_y
1	0.0	0.0	0.0	0.0	0.0	0.0

4 Results and conclusion

In this short contribution we described a new model to analyse self-reported measures which could potentially be affected by faking behavior. Indeed, as many research have previously shown (e.g., see [2]), the latter plays an important role in social research and surveys based on self-reported questionnaires. We proposed a *combination of Replacement and Binomial* (CRB) distributions approach which takes the advantages of two statistical methodologies, namely SGR [4] and CUBE [7] that were independently proposed to analyse faking and preference data respectively. The new CRB approach uses a statistical rationale based on a mixture distributions approach where ordinal measures are represented as convex linear combination of a shifted-Binomial distribution, modeling the component unaffected by faking, and a Replacement distribution, which models instead the faking component. Model parameters were estimated via Maximum likelihood as offered by the EM algorithm in the general CUBE framework [9]. We showed the novel CRB approach on a simple application involving ordinal data from a hypothetical case study. Results suggested how faking response styles should deserve more attention, especially in those research involving analyses based on self-reported surveys and questionnaires.

BOD – min range: A Robustness Analysis Method for Composite Indicators

Intervallo BOD – minimo: un metodo per l'analisi di robustezza degli indicatori compositi

Emiliano Seri, Leonardo Salvatore Alaimo, Vittoria Carolina Malpassuti

Abstract Composite indicators are a useful instrument to represent in a synthetic and easy to read way a phenomenon or a specific reality. However, synthesizing indicators using aggregative approaches inevitably involves a loss of information due to the reduction in size of the original matrix. So, in composite indicators construction, the robustness analysis phase is very important to validate the synthetic construct and to attempt to recover some of the lost information. This paper aims to present an interval, useful for the robustness analysis of composite indicators, between the best and the worst performance obtainable from the synthetic construct. The two margins of the range are obtained: for the upper bound, using the Benefit Of The Doubt approach, that is an application for composite indicators construction of the linear programming technique, Data Envelopment Analysis; and, for the lower bound, it has been used the minimum between the considered elementary indicators. The obtained range will comprehend almost every other synthetic measure that can be calculated with other aggregative methods for the considered matrix of indicators, so, our methodological proposal is useful to see the distance from the best and the worst obtainable cases.

Abstract *Gli indicatori compositi sono uno strumento utile per rappresentare in modo sintetico e di facile lettura un fenomeno o una realtà specifica. Tuttavia, la sintesi di indicatori mediante approcci aggregativi comporta inevitabilmente una perdita di informazioni a causa della riduzione delle dimensioni della matrice originale. Pertanto, nella costruzione di indicatori compositi, la fase di analisi della robustezza è molto importante per validare il costrutto sintetico e tentare di recuperare alcune delle informazioni perse. In questo articolo presentiamo un intervallo utile per l'analisi di robustezza degli indicatori compositi, compreso tra la performance*

migliore e quella peggiore ottenibili dal costrutto sintetico. L'estremo superiore del range è calcolato usando l'approccio del Benefit Of The Doubt, che è un applicazione per la costruzione di indicatori compositi della tecnica di programmazione lineare Data Envelopment Analysis. Per l'estremo inferiore è stato usato il minimo tra gli indicatori elementari considerati. Il range ottenuto comprenderà quasi ogni altra misura sintetica che che può essere calcolata con altri metodi aggregativi per la matrice di indicatori. Di conseguenza, questa proposta metodologica permette di osservare la distanza dal caso migliore e peggiore.

Key words: Composite indicators, Robustness analysis, BOD, Performance interval

1 Introduction

Constructing a composite indicator involves different subjective choices [4]. Subjectivity is an indispensable element in any measurement process; its presence does not make the process arbitrary [1]. But, different choices lead to different results; furthermore, a synthetic measure is useful to give an easy-to-read information about the phenomenon, but implicitly involves a loss of information due to the transition from a multi-dimensional to a uni-dimensional representation. For those reasons, the robustness analysis is a very important step in the composites construction. Its aim is to verify how the synthetic construct reacts to the different choices made to measure it. So, it is an instrument to validate the results and a way to find out some of the information loss during the previous phases of construction [5].

In this paper, we propose a new method for the robustness analysis of composite indicators based on the Benefit of the Doubt (BOD) approach. This method generates an upper bound and a lower bound to find the best and the worst performance that could be obtained aggregating a system of indicators. The space between the two bounds, it is going to include almost all the other constructs made with other mean-based aggregative methods, like: minimum, harmonic mean, geometric mean, arithmetic mean, quadratic mean, cubic mean and maximum. Thus, the proposed method could be useful to compare each of the cited techniques, observing their distance from the best and the worst performances. It is also useful to shrink the range of variation of the construct to observe the position of each unit in a real range of variation, in which each position can be reached by each unit.

2 Data envelopment analysis

DEA is a linear programming technique, useful to measure the relative efficiency of decision making units (DMU) on the basis of multiple inputs and outputs [7]. The efficiency of a set of variables can be adapted to construct a synthetic indicator using

an input-oriented DEA.[3]. The model assumes N inputs and M outputs for each of the I units. For the i^{th} unit, the inputs are represented by an array x_i and the outputs are represented by an array q_i. A first problem's formulation is the following: for each unit i the ratio of all the outputs over all the inputs is defined as

$$f(\mathbf{u},\mathbf{v}) = \frac{\mathbf{u}^{'}\mathbf{q}_i}{\mathbf{v}^{'}\mathbf{x}_i} \tag{1}$$

where $\mathbf{u}$ is an array of output weights and $\mathbf{v}$ is an array of input weights. The model seeks to maximize f, which represents the efficiency of the unit i^{th}, under the constraints that all the efficiency measures must be less than or equal to 1 and that the weights must be positive. This linear program is solved by assigning to each unit the most favourable weight. However, this formulation has infinite solutions of the form $(\delta\mathbf{u}, \delta\mathbf{v})$ for $\delta > 0$. To avoid it, the following constraint is introduced:

$$\mathbf{v}^{'}\mathbf{x}_i = 1$$

Thus the problem can be written as:

$$\begin{aligned} &\max_{\mathbf{u},\mathbf{v}} \mathbf{u}^{'}\mathbf{q}_i \\ &\text{s.t. } \mathbf{v}^{'}\mathbf{x}_i = 1 \\ &\quad \mathbf{u}^{'}\mathbf{q}_1 - \mathbf{v}^{'}\mathbf{x}_1 \leq 0 \\ &\qquad \vdots \\ &\quad \mathbf{u}^{'}\mathbf{q}_\mathrm{I} - \mathbf{v}^{'}\mathbf{x}_\mathrm{I} \leq 0 \\ &\quad \mathbf{u},\mathbf{v} \geq 0 \end{aligned} \tag{2}$$

Lastly we call the model DEA with no input if, for the array $\mathbf{x}_i$, we have $\mathbf{x}_i = (1,...,1)^{'}$. The model computes the weights so that the unit under investigation is valued as best as possible. The weights can differ from unit to unit and range between 0 and 1.

3 Benefit of doubt approach

The BOD method is an application of DEA that can be used to composite indicators construction[2][6]. The synthetic measure is expressed as the weighted sum of the elementary indicators relatively to a benchmark; more precisely, is defined as the performance of the single unit divided for the performance of the benchmark:

$$CI_c = \frac{\sum_{q=1}^{Q} I_{cq} w_{cq}}{I_{cq}^{*}} \tag{3}$$

where I_{cq} is the normalized score of the q$^{\text{th}}$ basic indicator ($q = 1, \ldots, Q$) for the unit c$^{\text{th}}$ ($c = 1, \ldots, C$) and w_{cq} is the corresponding weight. The benchmark I^*_{cq} is defined as:

$$I^*_{cq} = \max_{I_{c\in[1\ldots C]}} \sum_{q=1}^{Q} I_{cq} w_{cq} \tag{4}$$

The optimal set of weights (if exist) guarantees that each unit is associated to the best possible position compared to all the others. The optimal weights are obtained by solving equation 3 where the weights are non-negative. The result will be between zero and 1.

4 BOD – min range of performance: a robustness analysis method for composite indicators

In this paper, we propose a new interval of performance for composite indicators using the BOD approach for the upper bound and the minimum for the lower bound. With the obtained range, it is possible to compare the performance of the synthetic construct, calculated using most of the mean-based aggregative methods, for each considered unit, with the best and the worst obtainable performance. The proposed interval can be calculated on a set of indicators standardized using the Min-Max method, that bring each indicator on a range between 0 and 1. Our interval, shrink this range to lead to a real *photograph* of the units for the considered phenomenon and solve the common problem in composite indicators construction, that the results of each unit can have an evaluative function only relatively to those of the others.

We have chosen the BOD approach to make the upper bound because, as explained in Section 3, with this method it is possible to calculate the best reachable performance, associating to each variable the optimal weight for each unit. The lower bound corresponds to the minimum, because it is not reasonable that a unit should want to drop below its worst level.

Let's see now an application on a set of seven variables about the quality of work in the Italian regions in 2017 (Table 1). The selected indicators are:

- share of employed persons with temporary jobs for at least 5 years (V1);
- share of employees with below 2/3 of median hourly earnings (V2);
- share of employed people aged 15-64 years working over 60 hours per week (V3);
- share of employed persons not in regular occupation (V4);
- involuntary part-time (V5);
- share of employed persons who feel satisfied with their work (V6);
- Share of employed persons who feel their work insecure (V7).

Reg.	$V1$	$V2$	$V3$	$V4$	$V5$	$V6$	$V7$	Min	BOD

SARDEGNA	11.3	12.5	20.7	15.2	8.9	7.4	8.9	0.13	1.00

Table 1 Application of BOD – min range of performance: quality of work indicators; lower bound (Min); upper bound (BOD); Italian regions; year 2017.

First, we standardized the basic indicators and changed the polarity to those with present *negative polarity*[1]. The normalization method must be the relative indices with respect to the variation range, commonly called Min-Max:

$$r_{ij} = \frac{x_{ij} - \min\limits_{i}\left\{x_{ij}\right\}}{\max\limits_{i}\left\{x_{ij}\right\} - \min\limits_{i}\left\{x_{ij}\right\}} \tag{5}$$

Where x_{ij} is the value of ith unit for the jth indicator. We calculated the upper bound with the BOD approach (see equation 3); the lower bound was set equal to the minimum of each basic indicator normalized. The bounds obtained are reported in Table 1. We aggregated the standardized indicators r_{ij} using harmonic mean, geometric mean, arithmetic mean, quadratic mean, cubic mean; we report all the results in Figure 1[2].

[1] Polarity is the sign of the relation between the indicator itself and the phenomenon. All the indicators must have positive polarity, i.e. an increase in the normalized indicators corresponds to an increase in the composite index. To invert polarity, we use a linear transformation [1].

[2] Note that in geometric mean, 0 values have been changed with 0,001 in order to have explanatory results of the considered phenomena.

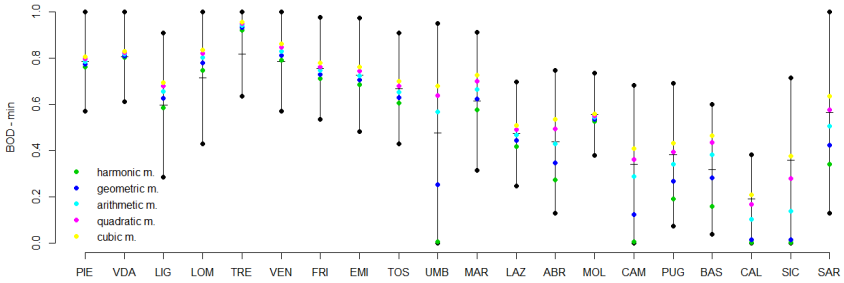

Fig. 1 BOD–min range of performance

5 Conclusions

Looking at Figure 1, it is clear that using the proposed method the range of variation of each unit has been widely narrowed or anyway made more truthful of the reality. It is also easier to compare the results obtained from different aggregation methods and to highlight where each of them is collocated in respect of the obtainable minimum and maximum.

Comparing classifiers for ordinal variables

Confronti tra classificatori per variabili ordinali

Silvia Golia and Maurizio Carpita

Abstract To choose a single category of a qualitative variable using its predicted probability distribution is the final task to solve a classification problem. In this study, five predictive criteria are proposed and compared with the modal one, which is the standard criterion. The predictive performances are evaluated considering a set of indicators built from the resulting 3×3 confusion matrix. The data used are the decimal betting odds on the matches, transformed in probabilities of loss, draw and win of the home team, coming from the Kaggle European Soccer database, for seasons from 2008/2009 to 2015/2016 of the Italian League Serie A.

Abstract *Il compito finale per risolvere un problema di classificazione è la scelta di una sola categoria di una variabile qualitativa utilizzando la sua distribuzione di probabilità. In questo studio, si propongono cinque criteri predittivi che vengono confrontati con il criterio usuale che impiega la moda. Le prestazioni predittive sono valutate attraverso un insieme di indicatori costruiti sulla matrice di confusione 3×3. I dati utilizzati sono le quote decimali delle scommesse effettuate sulle partite, trasformate in probabilità di perdita, pareggio e vittoria della squadra di casa, provenienti dal database Kaggle European Soccer, per le stagioni dal 2008/2009 al 2015/2016 giocate in Serie A.*

Key words: Classification, Bipolar Mean, Decimal betting odds, Prediction of the result

1 Some classification criteria for ordinal variables

To choose a single category of a qualitative variable using its predicted probability distribution is the final task to solve a classification problem. Once the predicted probability distribution is obtained by applying a statistical model or other methods, the classification depends on the criterion used. The standard classification criterion is the simple majority rule, that means to choose the mode (the category with higher predicted probability), but it is not the only one that can be applied. In particular, for an ordinal variable A with $k > 2$ categories, $a_1, a_2, \ldots, a_k$, one can take advantage of the ordered categories and use other measures of center such as the median or, after a numerical coding step, the expected value.

In this paper six classification criteria, reported in Table 1, have been considered. M1 is the standard Mode criterion, whereas M2 involves the median. M3 evaluates the difference between the predicted probabilities pr_i of the k categories of the variable A and the corresponding frequencies fr_i computed from previous data, and takes the category corresponding to the maximum difference, that is

Table 1: The proposed classifiers

Classifiers	Criterion
M1	Mode
M2	Median
M3	Maximum Distance
M4	Bipolar Mean + Maximum Distance
M5	Expected Value
M6	Mode + Expected Value

$$\arg \max_{i \in (a_1, a_2, \ldots, a_k)} (pr_i - fr_i). \tag{1}$$

The fourth method M4 involves the computation of the Bipolar Mean (BM) and the criterion M3. The BM for ordinal variables, proposed by [4], is a "synthetic" variable with no more than two adjacent categories with non zero frequencies. The BM is obtained using the Expected Value (EV) of the considered variable, where EV is the arithmetic mean of the numerical recoded categories, weighted with its frequencies, as follows:

1. if EV is an integer number $i \in (1,2,,k)$, then BM has one category a_i with frequency 1 and the others categories with zero frequency;
2. if EV is a non-integer number between i and $i+1$ with factional part equal to $frac(EV)$, then BM has two categories a_i and a_{i+1} with frequency $1 - frac(EV)$ and $frac(EV)$ respectively, and the others categories with zero frequency.

Some applications of the BM are described in [1, 3]. M4 is computed applying the equation (1) where pr_i and fr_i are substituted by the BM distributions pr_i^{BM} and fr_i^{BM}.

The criteria M5 and M6 request to code the categories of the variable A as $a_1 = 1, a_2 = 2, \ldots, a_k = k$. M5 takes the expected value of the recoded variable, whereas M6 resorts to the expected value only if the mode has a frequency less than a given threshold, otherwise it coincides with M1. In general the expected value is not exactly equal to one of the coded categories, so it necessary to apply a rounding procedure following the ceiling (c), round (r) or floor (f) rule.

The predictive performance of a classifier can be evaluated using some indicators computed from the confusion matrix, with generic frequency n_{OP} corresponding to the number of units belonging to the observed category O and predicted to belong to category P.

The first indicator is the *Sensitivity* for category C, that is

$$Sens_C = \frac{n_{CC}}{n_{C\bullet}},$$

which expresses how well the classifier recognizes a unit belonging to the category C. It can be of interest to compare the sensitivities of the categories computing their difference in absolute value; a useful indicator from these differences is the maximum (*Maximum Distance Between Sensitivities* - MDBS), that is:

$$MDBS = \max_{i \neq j} |Sens_{C_i} - Sens_{C_j}|.$$

The lower the MDBS, the better the classification.

Considering only the cases of correct classification for category C, it is possible to compute the *Precision* for the classifier as

$$Prec = \frac{\sum_C n_{CC}}{n},$$

where n is the sample size.

Rearranging the confusion matrix as a 2×2 matrix with reference of each category, it is possible to compute the Accuracy for the category C as

$$ACC_C = \frac{n_{CC} + n_{\overline{C}\,\overline{C}}}{n},$$

where $\overline{C}$ is the complement of category C, and then their average obtaining the *Average Accuracy* (AA), which is the average per-category effectiveness of a classifier.

2 An application to the Italian Soccer League Serie A

The applicative fields of the theory described in Section 1 are various, and include the prediction of the results of the soccer matches. In fact, in this context, the variable *result* with its three categories, loss (L), draw (D) and win (W) of the home team, has an ordinal nature (loss $\prec$ draw $\prec$ win). Moreover, it can be codified as 1-2-3 and considered as a numerical variable with the predicted probabilities as its frequency distribution.

The classification criteria described in the previous section were applied to the decimal betting odds on the matches coming from the Kaggle European Soccer database (KES) [2]. The interest was focused on the matches played in the Italian League Serie A during the seasons from 2008/2009 to 2015/2016. The KES database reports, for each match, the decimal betting odds provided by 10 betting companies and the final result. These odds were averaged and transformed into probabilities of L, D and W [5, 6].

From the set of the resulting 3014 triplets of probabilities, 1000 samples of 1500 matches were randomly sampled without replacement; the remaining 1514 triplets were used to estimate fr_i and fr_i^{BM} for the M3 and M4 criteria.

Criterion M6 was implemented considering four thresholds, that is 0.4 (M6.1), 0.5 (M6.2), 0.6 (M6.3) and 0.7 (M6.4). Moreover, for both M5 and M6 the three rounding rules were applied.

For each of these samples the results of the matches were predicted applying the six criteria under study and evaluated thanks to the indicators introduced in the previous section. Moreover, due to the peculiarity of this application, an extra indicator of performance has been considered. It was called *Mean Weighted Win* (MWW), and it is the average win that a gambler obtains betting on a result of the match. It is computed attributing a win of 3 to the right prediction, a null win if the prediction is win (loss) and the actual result is loss (win) and a win of 1 otherwise. MWW is a weighted average of the previous three scores, $S_j = 3,1,0$, that is

$$MWW = \sum_{j=1}^{3} S_j \cdot V_j,$$

with weights respectively equal to:

$$\begin{aligned} V_1 &= (n_{LL} + n_{DD} + n_{WW})/n \\ V_2 &= (n_{DW} + n_{WD} + n_{DL} + n_{LD})/n \\ V_3 &= (n_{LW} + n_{WL})/n. \end{aligned}$$

The higher the MWW, the better the classification.

Table 2 reports the mean values of all the predictive performance indices with standard errors in parenthesis.

M1 has the highest precision, even if is not different from the one of other classifiers such as M6.1, a high average accuracy but also a high MDBS due to the fact

Table 2: Mean values of the predictive performance indices of the classifiers based on the prediction of 1500 matches results randomly sampled 1,000 times (standard errors in parenthesis)

Classifier	$Sens_L$	$Sens_D$	$Sens_W$	MDBS	*Prec*	AA	MWW

M6.1.c	0.373 (0.02)	0.092 (0.01)	0.857 (0.01)	0.765 (0.01)	0.524	0.683	1.874
M6.1.f	0.482 (0.02)	0.153 (0.01)	0.745 (0.01)	0.593 (0.02)	0.518	0.679	1.873
M6.1.r	0.373 (0.02)	0.221 (0.02)	0.745 (0.01)	0.525 (0.02)	0.507	0.671	1.875
M6.2.c	0.190 (0.01)	0.209 (0.01)	0.860 (0.01)	0.672 (0.02)	0.508	0.672	1.867
M6.2.f	0.483 (0.02)	0.432 (0.02)	0.497 (0.01)	0.069 (0.02)	0.476	0.651	1.844
M6.2.r	0.190 (0.01)	0.624 (0.02)	0.497 (0.01)	0.434 (0.02)	0.448	0.632	1.841
M6.3.c	0.068 (0.01)	0.253 (0.02)	0.860 (0.01)	0.793 (0.01)	0.486	0.657	1.832
M6.3.f	0.485 (0.02)	0.596 (0.02)	0.274 (0.01)	0.322 (0.02)	0.416	0.611	1.750
M6.3.r	0.068 (0.01)	0.841 (0.01)	0.274 (0.01)	0.773 (0.02)	0.368	0.578	1.715
M6.4.c	0.015 (0.00)	0.261 (0.02)	0.860 (0.01)	0.846 (0.01)	0.474	0.649	1.810
M6.4.f	0.485 (0.02)	0.692 (0.02)	0.114 (0.01)	0.577 (0.02)	0.367	0.578	1.667
M6.4.r	0.048 (0.01)	0.874 (0.01)	0.216 (0.01)	0.826 (0.01)	0.344	0.563	1.674

The standard errors of *Prec* and *AA* and *MWW* are respectively equal to 0.01, 0.01 and 0.02 for all the criteria
Rounding rules for classifiers M5 and M6: ceiling (c), floor (f), round (r)

that mainly it is not able to correctly predict D. M2 is able to correctly predict a higher number of draws ($Sen_D = 0.623$) but it loses the capability to correctly predict the other two results; this finding translates into a reduction of the precision. M4 improves the performances of M3, it has the highest MWW and a more balance ability in correctly predicting all the three results. Considering the classifiers M5 and M6, it has to be noted the role played by the rounding procedure. As an example, for the classifier M5, applying the ceiling or round roundings, L is rarely correctly predicted, whereas, if the floor rounding is used, one loses the possibility to correctly predict W.

Discovering Interaction Effects Between Subject-Specific Covariates: A New Probabilistic Approach For Preference Data

La Scoperta Di Effetti Interazione Tra Variabili: Un Nuovo Approccio Probabilistico per i dati di preferenza

A. Baldassarre, C. Conversano, A. D'Ambrosio, M. De Rooij, E. Dusseldorp

Abstract This research presents a new probabilistic approach for the analysis of preference data when dealing with paired comparisons. The combination of the extended log-linear Bradley-Terry model with the regression trunk methodology generates a new model that allows finding interaction effects between subject-specific covariates. By fitting Poisson regressions to find the best split points and applying the final pruning procedure, the result is a small regression tree (so-called regression trunk). It represents a compromise between an easier interpretation of higher-order interaction effects and an efficient partition of individuals according to their preference scales.

Abstract *Questa ricerca mette in luce un nuovo approccio probabilistico per l'analisi dei dati di preferenza espressi con comparazioni a coppie. La combinazione del modello Bradley-Terry log-lineare con il metodo regression trunk consente la generazione di un albero di regressione. Attraverso una serie di regressioni Poisson è possibile ricercare i migliori punti di split e trovare le principali interazioni tra variabili. Il risultato finale è un albero di regressione di piccole dimensioni, che costituisce il giusto compromesso tra interpretabilità dei risultati ed efficienza di ripartizione degli individui in base alle preferenze espresse*

Key words: Preferences, Bradley-Terry Model, Regression Trunk, Decision tree

1 Introduction

Recently, several scientific fields, such as behavioral, political, and computational sciences, are showing a growing interest in preference data analysis. Generally, a number m of judges express their preferences for n objects by assigning values to each of them or by ordering the items from the most preferred to the least one. In the first case, they are called rankings; in the second one, we talk about orderings (Marden, 1995).

In literature, there are several statistical models and methodologies to analyze these data. Among these, there are methods based on badness-of-fit adaptation (Carrol, 1972; Coombs, 1950; Heiser and De Leeuw, 1981; D'Ambrosio and Heiser, 2016) and probabilistic models (Marden, 1995; Heiser and D'Ambrosio, 2013).

In some circumstances, different groups of judges may express different preferences scales given their different characteristics. The heterogeneity can be addressed by introducing subject-specific covariates (Dittrich, Hatzinger and Katzenbeisser, 1998; Strobl, Wickelmaier and Zeileis, 2011).

This paper presents a model that follows a probabilistic approach and generates a regression tree into which the individuals are divided according to their preferences and characteristics. It overcomes the problems related to additive models that become complex when there are interactions. Furthermore, it solves the typical difficulty of tree-based models, namely capturing linear effects between variables. One of the strengths of the regression trunk is that it is not necessary to have a priori information about the interactions between the covariates to build the regression tree. Through the extended log-linear Bradley-Terry model, we apply the regression trunk methodology for the analysis of preference data when subject-specific covariates are observable within a dataset.

In section 2, we introduce the Bradley-Terry model and its log-linear extended version. In section 3, our methodology is explained with a brief reference to the regression trunk model.

2 The log-linear Bradley-Terry model

The model that we propose works with preferences expressed through paired comparisons. In literature, the Bradley-Terry model (Bradley and Terry, 1952), is one of the most widely used methods for these kinds of data. It is a logistic model for paired preference data, and it has been applied in psychology and several other disciplines.

For example, when the number of objects is n, then $\frac{n\times(n-1)}{2}$ comparisons can be calculated. For example, if $n = 3$ and the items are A B C, the paired comparisons will be A-B, A-C, and B-C.

Let $\Pi_{(ij)i}$ denote the probability that the item i is preferred in comparison with j. The probability that j is preferred is $\Pi_{(ij)j} = 1 - \Pi_{(ij)i}$ (ties cannot occur). The Bradley-Terry model has item parameters β_i such that (Agresti, 2007, p. 286)

$$logit(\Pi_{(ij)i}) = \log\left(\frac{\Pi_{(ij)i}}{\Pi_{(ij)j}}\right) = \beta_i - \beta_j. \tag{1}$$

The Bradley-Terry model can also be fitted as a log-linear model (Fienberg and Larntz, 1976; Sinclair, 1982; Dittrich, Hatzinger, and Katzenbeisser, 1998), in which the number of preferences for i in comparison with j is assumed to follow a Poisson distribution. Let $e_{(ij)i}$ be the expected number of comparisons in which i is preferred to j. Then $e_{(ij)i} = n_{ij}\Pi_{(ij)i}$ has a log-linear representation

$$\begin{aligned} \ln(e_{(ij)i}) &= \mu_{(ij)i} + \lambda_i^O - \lambda_j^O \\ \ln(e_{(ij)j}) &= \mu_{(ij)j} - \lambda_i^O + \lambda_j^O, \end{aligned} \tag{2}$$

where μ is a nuisance parameter representing the items involved in the comparison, and λ_i^O is the item i related term such that $\lambda_i^O = \frac{1}{2}\log(\pi_i)$, with π_i equal to the probability of preferring the item i. Note that the superscript O refers to the position of the object (object-specific parameter) without considering the characteristics of the judges. It will be removed for easier reading from the equations that follow.

The Bradley-Terry model can be extended to incorporate categorical (e.g., gender) or numerical covariates (e.g., age). The model building becomes more complicated when dealing with continuous subject-specific covariates than when dealing with categorical ones. In fact, in the first case, it has to be extended for each subject and each value of the covariates. The log-linear Bradley-terry model equations for subject m and comparison ij with continuous subject-specific covariates are

$$ln(e(y_{ij;m})) = \mu_{ij;m} + y_{ij;m}(\lambda_{i;m} - \lambda_{j;m}), \tag{3}$$

where $y_{ij;m} \in \{-1, 1\}$ indicates whether the judge m expresses ($y_{ij,m} = 1$) or not ($y_{ij,m} = -1$) a preference in the comparison between i and j. If it is preceded by the letter e, then we deal with the expected value of y.

The parameter $\lambda_{i;m}$ can be expressed through a linear relation

$$\lambda_{i;m} = \lambda_i + \sum_{p=1}^{P} \beta_{ip} x_{p;m}, \tag{4}$$

where $x_{p;m}$ is the pth covariate ($p = 1...P$) associated to judge m. The parameters β express the effect of the subject-specific covariates on item i. λ_i is an intercept and indicates the location of object i in the overall preference scale.

3 The regression trunk applied to preference data

The extension of the log-linear Bradley-Terry model with subject-specific covariates allows the application of a regression model to paired comparisons. Here, we fol-

low the regression trunk methodology, which combines a multiple regression model and a regression tree (Dusseldorp and Meulman, 2004). In specific, it makes predictions by considering linear main effects and interaction effects for the same set of covariates.

The idea underlying the regression trunk is that, in some cases, it is not necessary building a large tree to capture the interactions between variables. The final result of the model is a small regression tree (so-called regression trunk) that represents a compromise between the interpretability of interaction effects and the ability to summarize the available information about the individuals' characteristics. The basic regression trunk is defined by a single linear model

$$\hat{Y} = \hat{\beta}_0 + \sum_{p=1}^{P} \hat{\beta}_p X_p + \sum_{t=1}^{T-1} \hat{\beta}_{P+t} I\{(X_1, ..., X_P) \in t\}, \tag{5}$$

where T is the total number of terminal nodes, and $T-1$ represents the total number of indicator variables, where the region not included works as reference group. $\hat{\beta}_0$ indicates the estimated intercept for the reference group, while for the node t the estimated intercept is represented by $\hat{\beta}_0 + \hat{\beta}_{P+t}$. The first part of the equation represents the linear part of the model estimated using all the observations and covariates for the main effects. The second part indicates the interaction effects obtained by partitioning the m observations.

In this research, we adapt the extended Bradley-Terry model with subject-specific covariates to the regression trunk methodology for the analysis of preference data.

The tree is built by fitting Poisson regressions and combining a regression model with main effects and a small number of higher-order interaction effects. This model allows observing the preference scale in each node of the tree and quantifying the probability of preferring certain items for different groups of individuals.

Usually, the building process of a generic regression tree is composed of different steps: the definition of a splitting criterion, the definition of a stopping rule, and a pruning procedure.

Similarly, the regression trunk for preference data uses as splitting criterion the deviance between one Poisson regression and the subsequent. Given the subject-specific covariate X_p, we consider all the values as a possible split point. Each of these values represents the rule to discretize the candidate variable X_p and to create the associated dichotomous variable Z. This variable is added to the model, and the deviance is calculated and stored. The process is repeated in each node, for each variable, and each value, calculating in total (number of nodes) $\times$ (number of variables) $\times$ (number of judges) different regressions. After that, the split point that minimizes the deviance in node t is chosen as the best split point. This value is used as a rule to create a new dichotomous variable Z_i^*, which gives information about the judges' partition. The building procedure is allowed by using Z_i^* for the subsequent regressions.

The definition of a stopping rule represents a choice that is declined to the users and their aims. The option that we propose is to split a parent node with m observations only if the child node includes a number greater than $\sqrt{m}$. Another option

would be to repeat the process until a predefined number of T terminal nodes is reached.

To apply the final pruning, the V-fold cross-validation is computed for each step of the process in the same way as it is used in CART and STIMA (Dusseldorp, Conversano and Van Os, 2010). The Poisson regression is fitted on the training set, and the predicted values $\hat{Y}_i$ are calculated on the test set to compute the cross-validation deviance. We choose as pruning rule to cut the nodes that induce a deviance increase, also considering the standard error through the $c \times SE$ rule.

Generally, the pruning procedure restitutes a small regression trunk (e.g., $T = 5$) given that the cross-validation deviance usually decreases and, after a certain split, it starts to increase.

Hybrid random forests for ordinal data

Un approccio ibrido alle foreste random per dati ordinali

Rosaria Simone and Gerhard Tutz

Abstract Prediction of ordinal outcomes is a compelling statistical task for which no definitive method is universally acknowledged. A semi-parametric approach to random forests is proposed that exploits the efficiency of ordinal regression models to gain information on the impact of explanatory variables on ordered response categories. In contrast to other proposals, scoring of categories is avoided, and both the partitioning process and the assignment rule use their ordering only. The proposed hybrid approach between model-based structuring and classification trees is illustrated on ratings on probability to vote for German Parties.

Abstract Il contributo propone un approccio semi-parametrico alle foreste random per dati ordinali basato sull'uso di modelli di regressione. Il metodo non richiede la scelta di codifiche numeriche per le categorie né per l'algoritmo di partizionamento ricorsivo né per le regole di assegnazione a fini previsionali. L'approccio è illustrato sulla base di valutazioni ordinali della probabilità di voto per i partiti Tedeschi.

Key words: Decision trees, ordinal data models, random forests

1 The State of the Art

The present study fits in research efforts devoted to developing trustworthy methods for predicting ordinal outcomes. For these data, tree methods mostly rely on the assignment of numeric scores to ordered categories, which is a questionable practice (see, for instance, both the packages rpartOrdinal [1] and its improved version rpartScore [5]). Numeric scoring of categories underlies also some proposals of ran-

dom forests for ordinal responses [8, 10], as well as conditional inference trees [9]. Since the latter approach allows to grow unbiased trees, hereafter it will be considered as benchmark.

A hybrid approach between model-based structuring and classification trees for ordinal outcomes to grow random forests [3] is introduced. The concept resorts to well-suited regression models for ordinal responses in the partitioning process only. Prediction accuracy of alternative base-learner for hybrid random forests will be checked in terms of the well-known Rank Probability Score (RPS, [7]). On this basis, a new accuracy measure based on a majority of vote rule for the minimum RPS is advanced to identify the best suited base-learner for a given hybrid random forest. Hybrid random forests based on ordinal logit and adjacent category models [12] will be illustrated on ratings for the probability to vote for German parties (taken from the General German Social Survey in 2008, [6]).

2 Hybrid random forests

In the following, first the construction of hybrid model-based trees is introduced and then the concept is used to grow random forests.

Hybrid trees

Parametric ordinal models are efficient tools to evaluate which variables are influential when response categories are ordered and the order is to be exploited. Therefore, we use a baseline model $\mathscr{M}(Y;\boldsymbol{x},\boldsymbol{\theta})$, where Y is the ordered response, which takes values in m categories $c_1 \prec c_2 \prec \cdots \prec c_m$, $\boldsymbol{x}$ is a vector of predictors, and $\boldsymbol{\theta}$ is the estimable parameter vector. Simple and easy-to-fit models hereafter considered are:

- the cumulative model: $P(Y \leq r) = F(\beta_{0r} + \boldsymbol{x}^T\beta), \quad r = 1,\ldots,m,$
- the adjacent categories model: $P(Y_i = r | Y_i \in \{r-1, r\}) = F(\beta_{0r} + \boldsymbol{x}^T\beta), r = 2,\ldots,m$

where $F(\cdot)$ is a suitable link function. Thus, a tree is built by using fits of the baseline model to select the best variable to perform the split along with the split points. Specifically, an ordinal regression model is fitted with predictor $\eta_r = \beta_{0r} + x_{j,c}\beta$, where $x_{j,c} = I(x_j \geq c)$, and $I(.)$ denotes the indicator function ($I(a) = 1$ if a is true, and $I(a) = 0$, otherwise). The impact of variable x_j at split point c is investigated by testing the null hypothesis $H_0 : \beta = 0$. The resulting p-value is an indicator of the relevance of the split, with small values indicating high relevance. Therefore, at node k the model $\mathscr{M}(Y;x_{j,c},(\{\beta_{0r}\},\beta))$ is fitted to the observations in that node for each candidate splitting variable and possible split points. The combination of variable and split point (x_j, c) that yields the smallest p-value is selected to generate the descendant nodes. The procedure is iterated for each node until a stopping criterion is met or when the minimum p-value is above some threshold α, possibly

corrected for multiple testing. Since partitioning of the predictor space is obtained by evaluating splits in specific covariates, typically several splits are possible (especially for continuous ones), which are considered as equally important. In order to obtain unbiased trees in the spirit of [9], one could resort to permutation tests for the test statistics [2]. However, this issue will not be addressed in the following preliminary analysis since it is mitigated by the random selection of predictors run to grow trees in the forest. A first application of the concept of hybrid trees appears in a benchmark study carried out in [4] based on the model-based procedure of [13].

Random forests

Random forests as a combination of trees typically show much better performance in terms of prediction than single trees [3]. They belong to the class of ensemble methods, which means that various predictors are aggregated for prediction of the response. The problem of possibly correlated splits is overcome by choosing, for each tree and at each step, a random selection of candidate splitting variables. Assume that model $\mathscr{M}$ is considered in the partitioning process of each of the B hybrid trees in the forest, say $\mathscr{T}^1,\ldots,\mathscr{T}^b,\ldots,\mathscr{T}^B$. Then:

- each $\mathscr{T}^b$ is grown by using a learning sample $\mathscr{S}_L$ obtained by bootstrapping (with replacement) from the original data $\mathscr{S}$, with size n. For the b-th tree, the test set to evaluate its prediction accuracy will be composed of those *out-of-bag observations* in $\mathscr{S}$ that were not used to grow the tree (oob for short).
- Each tree is grown up to a large depth. Growing descendants from a node stops if the number of observations to attempt a split or if any of the sample sizes of the candidate children nodes is below some threshold.

For each replicate b, the same training set and test set will be used to grow a hybrid random forest when assuming different base learners for the partitioning process. For each tree, a random set of $\sqrt{K}$ splitting covariates among those that were not yet included are selected in each step of the splitting procedure, where K denotes the number of (binary) candidate variables of the predictor space. For these variables, tests are performed to find the next split. In order to reduce the computational time but also account for the varying number of splits in covariates, for continuous covariates a random split point can be selected (yet ensuring that a minimum number of observations fall in both groups).

Prediction accuracy of a random forest can be measured in terms of the rank probability score (RPS, [7]). For each $i=1,\ldots,n$ corresponding to an oob for tree $\mathscr{T}$, let $RPS_i^{(\mathscr{T})}$ be the (empirical) RPS of observation Y_i in the test set computed on the basis of the classification obtained by tree $\mathscr{T}$. If $(f_1^{(\mathscr{T})},\ldots,f_m^{(\mathscr{T})})$ is the relative frequency distribution at the terminal node of $\mathscr{T}$ corresponding to the profile $\boldsymbol{x}_i$ of Y_i, then one computes

$$RPS_i^{(\mathscr{T})} = \frac{1}{m-1}\sum_{j=1}^{m}\left(\sum_{s=1}^{j} f_s^{(\mathscr{T})} - I(Y_i \le j)\right)^2 \tag{1}$$

with lower values indicating a higher accuracy for prediction of Y_i ($I(Y_i \leq j)$ denotes the indicator function of the event $(Y_i \leq j)$). The predicted distribution resulting from a random forest is composed of the predictions from the single trees. Specifically:

- let $\mathscr{F}^{(i)}$ be the set of trees in the forest for which Y_i is an out-of-bag observation. For each $\mathscr{T} \in \mathscr{F}^{(i)}$, let $RPS_i^{(\mathscr{T})}$ be its RPS in the corresponding terminal node (established on the basis of its covariate profile $\boldsymbol{x}_i$).
- For Y_i, consider the average $\widehat{RPS}_i$ of the RPS values $RPS_i^{(\mathscr{T})}$, for $\mathscr{T} \in \mathscr{F}^{(i)}$.
- In the end, the performance of the hybrid random forest based on model $\mathscr{M}$ for the partitioning process will be measured by the index:

$$I = \sum_{i=1}^{n} \widehat{RPS}_i$$

- Lower values of the performance index I will denote higher prediction accuracy.

3 An application to voting probability for political parties

More and more often, opinion polling of voting intentions is accompanied by the collection of ratings for the probability to vote for each candidate in order to foster the understanding of the electoral behaviour. This is the case of some rating variables collected within the General German Social Survey: as shown in Figure 1, in several cases the distributions are U-shaped or J-shaped, and the modal value might not be meaningful when used to summarize the distribution and predict future observations. For illustrative purposes, a predictors matrix of $K = 12$ (binary)

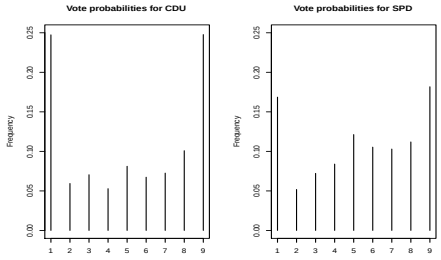

Fig. 1 Observed distribution of ratings for voting probabilities for the main German Parties

covariates is considered to grow a random forest. Table 1 reports some instances of the proposed *majority of vote* rule for prediction based on the distribution of median values. They are obtained in the following way:

- Given Y_i, consider the trees $\mathscr{T} \in \mathscr{F}^{(i)}$ for which Y_i is an out-of-bag observation;

- For each $\mathscr{T} \in \mathscr{F}^{(i)}$, let $(f_1, \ldots, f_m)$ be the frequency distribution in the terminal node corresponding to profile $\boldsymbol{x}_i$, and set

$$\hat{Y}_i^{(\mathscr{T})} = Median(f_1, \ldots, f_m).$$

  This choice corresponds to assigning, as a prediction for Y_i, the category with the minimum RPS value in the associated node. It is worth mentioning that predictions based on the modal value of the distribution of a terminal node would result mostly in the first and last response categories for the data under examine.
- Set $\hat{Y}_i$ the modal values of $\{\hat{Y}_i^{(\mathscr{T})} : \mathscr{T} \in \mathscr{F}^{(i)}\}$.

Observation	Prediction		
	Hybrid with Ordinal logit	Hybrid with adjacent	Ctree
1	3	3	3
9	8	8	8
6	4	3	3
8	8	7	8
6	6	6	6
7	6	6	6
8	6	7	6
2	3	3	3
5	6	7	8
4	5	5	5

Table 1 Some instances of observations and predicted outcomes established on the basis of the proposed *majority of vote* rule

For pointwise prediction, the overall accuracy (when using model $\mathscr{M}$ for the partitioning process of hybrid trees in a random forest) can be assessed in terms of the distance between the (minimum) RPS value associated to the predicted category, say $RPS_{\hat{Y}_i}^{(\mathscr{T})}$, and the RPS value $RPS_{Y_i}^{(\mathscr{T})}$ of the observed one, namely:

$$a^{(\mathscr{M},\mathscr{T})}(Y_i|\boldsymbol{x}_i) = |RPS_{\hat{Y}_i}^{(\mathscr{T})} - RPS_{Y_i}^{(\mathscr{T})}| \tag{2}$$

for each tree $(\mathscr{T})$ in $\mathscr{F}^{(i)}$. Then, the model $\mathscr{M}$ that attains the lowest distance in the sense of (2), after averaging over trees in the forest and over observations, can be considered as the best performing one. Table 2 reports the chosen performance indicators for the proposed hybrid random forests; for comparisons, random forests using the conditional inference approach as base learner (implemented within the R package `partykit`) have been considered.

	Accuracy as in (2)			RPS		
	Ordinal logit	Adjacent Category	Ctree	Ordinal logit	Adjacent Category	Ctree
CDU	0.092	0.091	0.092	620.04	618.46	613.27
SPD	0.098	0.098	0.098	578.48	579.14	578.96

Table 2 Prediction performances of hybrid random forests and forests with `ctree` as base learner

4 Ongoing research

The main contribution of the proposal is the introduction of a hybrid decision tree for ordinal data that exploits model fitting for the partitioning process and that does not need artificial numerical coding of ordered categories. Accordingly, hybrid random forests can be developed for prediction of rating outcomes. The rationale allows to introduce a new accuracy measure based on a majority of vote rule for the minimum RPS to identify the best base-learner for the hybrid random forests. The idea is illustrated on an original application to the understanding of the electoral behaviour. Further research will be addressed to variable importance measures for predictors, designed without the need of numerical scoring (which is considered in [10], for instance). Non-parametric trees tailored to provide flexible interpretation of response patterns yet respecting the ordinal nature of data, can be pursued via quantile trees, by basing the partitioning process on differences in multiple quantiles [11].

Model-based approach to biclustering ordinal data

Approccio di biclustering basato su modello per dati ordinali

Monia Ranalli and Francesca Martella

Abstract A finite mixture model to simultaneously cluster the rows and columns of two-mode ordinal data matrix is proposed. Due to the numerical intractability of the likelihood function, estimation of model parameters is based on composite likelihood (CL) methods and essentially reduces to a computationally efficient Expectation-Maximization type algorithm. The performance of the proposed approach is discussed on both simulated and real datasets. The results are encouraging and would deserve further discussion.

Abstract *Si propone una mistura finita per classificare sia le righe che le colonne di una matrice di dati ordinali. La stima dei parametri è ottenuta tramite un algoritmo di tipo EM definito sulla base di una verosimiglianza composita. La performance dell'approccio proposto è discussa sia su dati simulati che reali. I risultati ottenuti sono incoraggianti e meritano ulteriori approfondimenti.*

Key words: Mixture models, biclustering, ordinal data, latent variable models

1 Introduction

Cluster analysis has been mainly developed for continuous data. Only in the last decades, an increasing interest in clustering ordinal data has been observed. Such data are encountered very frequently in practice to measure, for example, attitudes, abilities or opinions. However, practitioners often apply on their ranks models and techniques developed for continuous data. To take into account the ordinal nature of

Monia Ranalli

Francesca Martella
Sapienza University of Rome, Piazzale Aldo Moro 5, Rome e-mail: francesca.martella@uniroma1.it

the data there exist two approaches developed mainly in the factor analysis framework: the Item Response Theory (IRT; [3, 1]) and the Underlying Response Variable (URV; [10, 11, 19]). In the former, the probabilities of the categories are assumed to be analytic functions of some latent variables having a particular cluster structure. The best known model is the Latent Class Analysis (LCA; [8]) where the latent variable is nominal. Examples where the latent variables are continuous are found in [4, 16, 7]. In the URV approach, the ordinal variables are seen as a discretization of continuous latent variables jointly distributed as a finite mixture model; examples can be found in [6, 13, 21]. In both approaches, the use of latent continuous variables makes the estimation rather complex because it requires the computation of many high dimensional integrals. The problem is usually solved by surrogating the likelihood function.

In some cases, the interest would be to provide a joint clustering of units and variables that is, to partition the data matrix into homogeneous blocks with respect to some observed features. The task, which may be thought of as a extension of standard clustering approaches to group both units (rows) and variables (columns) in a data matrix, is often referred to as biclustering, but it is also known under a broad range of different names, including double clustering, block clustering, bidimensional clustering, co-clustering, grid clustering, simultaneous clustering and block modelling. In case of ordinal data, such approach may be useful in many research fields, as for instance in marketing studies where finding a subset of customers that tends to evaluate similarly a subset of products or services may help the researchers to target some products or services according to customer profiles. A number of distance and model based biclustering methods exists. Among distance-based methods, we mention the double k-means method of [26] and [24], for example. Among model-based approaches, we found proposals developed for continuous data such as in [14], for binary or count data such as in [20].

Specifically looking at ordinal data, to the best of our knowledge, we found two proposals. One approach, proposed by [15], is a generalization of [20] in case of ordinal data. It relies on the proportional odds model and can be seen also as an extension of the one-mode clustering model given by [5]. The other proposal has been introduced by [9] and it relies on a recent distribution for ordinal data (BOS for Binary Ordinal Search model [2]).

The aim of this paper is to propose a new model for biclustering ordinal data. Following the URV approach, the observed variables are considered as a discretization of latent continuous variables distributed as a mixture of Gaussians. To introduce a partition of the P variables within the g-th component of the mixture, we adopt a factorial representation of the data following the modelling approach developed in [14], where a binary row stochastic matrix, representing variable membership, is used to cluster variables. In this way, we associate a component in the finite mixture to a cluster of variables and define a bicluster of units and variables. Notice that the number of clusters of variables (and therefore the partition of variables) may vary with clusters of units. More precisely, we consider the CMAP criteria [22] to define unit clustering, whereas a binary and row stochastic matrix for representing the variable partition.

However, the model specification involves multidimensional integrals that make the maximum likelihood estimation rather cumbersome and in some cases infeasible. To overcome this issue, the model is estimated within the EM framework maximizing a composite likelihood based on m-dimensional marginals. In the current work, we present the model estimation considering $m = 2$, i.e. a pairwise likelihood, that is the product of all possible likelihoods based on the bivariate marginals (see e.g. [21] and references therein). However, as long as sparsity is not a problem and computations are feasible, it is possible to use a higher m, as shown in the simulation study and real data applications. Under some regularity conditions [18], the estimators are consistent, asymptotically unbiased and normally distributed. In general, they are relatively less efficient [12, 25] compared to full maximum likelihood estimators, but much more efficient in terms of computational complexity.

2 Model

Let $x_1,\ldots,x_P$ be ordinal variables and $c_i = 1,\ldots,C_i$ the associated categories for $i = 1,\ldots,P$. There are $R = \prod_{i=1}^{P} C_i$ possible response patterns $\mathbf{x}_r = (x_1 = c_1,\ldots,x_P = c_P)$, with $r = 1,\ldots,R$. The ordinal variables are generated by thresholding $\mathbf{y}$, which is a latent multivariate continuous random variable distributed as a mixture of G Gaussian densities $\phi(\cdot)$ with means $\boldsymbol{\mu}_g$, covariance matrices $\boldsymbol{\Sigma}_g$ and mixture weights p_g $(g = 1,\ldots,G)$. The link between $\mathbf{x}$ and $\mathbf{y}$ is expressed by a threshold model defined as $x_i = c_i \Leftrightarrow \gamma_{c_i-1}^{(i)} \leq y_i < \gamma_{c_i}^{(i)}$. where $-\infty = \gamma_0^{(i)} < \gamma_1^{(i)} < \ldots < \gamma_{C_i-1}^{(i)} < \gamma_{C_i}^{(i)} = +\infty$ are the thresholds defining the C_i categories. Let $\boldsymbol{\psi} = \{p_1,\ldots,p_{G-1},\boldsymbol{\mu}_1,\ldots,\boldsymbol{\mu}_G,\boldsymbol{\Sigma}_1,\ldots,\boldsymbol{\Sigma}_G,\boldsymbol{\Gamma}\}$ be the set of model parameters, where $\boldsymbol{\Gamma}$ is the set of vectors $\boldsymbol{\gamma}^{(i)}$ $(i = 1,\ldots,P)$. The probability of response pattern $\mathbf{x}_r$ can be expressed as follows

$$\Pr(\mathbf{x}_r;\boldsymbol{\psi}) = \sum_{g=1}^{G} p_g \int_{\gamma_{c_1-1}^{(1)}}^{\gamma_{c_1}^{(1)}} \cdots \int_{\gamma_{c_P-1}^{(P)}}^{\gamma_{c_P}^{(P)}} \phi(\mathbf{y};\boldsymbol{\mu}_g,\boldsymbol{\Sigma}_g)d\mathbf{y} = \sum_{g=1}^{G} p_g \pi_r(\boldsymbol{\mu}_g,\boldsymbol{\Sigma}_g,\boldsymbol{\Gamma}) \qquad (1)$$

where $\pi_r(\boldsymbol{\mu}_g,\boldsymbol{\Sigma}_g,\boldsymbol{\Gamma})$ is the probability of response pattern $\mathbf{x}_r$ in cluster g. Thus, for a random i.i.d. sample of size N, the log-likelihood has the following form

$$\ell(\boldsymbol{\psi};\mathbf{X}) = \sum_{r=1}^{R} n_r \log\left[\sum_{g=1}^{G} p_g \pi_r\left(\boldsymbol{\mu}_g,\boldsymbol{\Sigma}_g,\boldsymbol{\Gamma}\right)\right], \qquad (2)$$

where n_r is the observed sample frequency of response pattern $\mathbf{x}_r$ and $\sum_{r=1}^{R} n_r = N$. According to [14], in order to cluster not only the units but also the variables of the data matrix, we suggest a factorial representation of component-specific covariance structure of the latent variable $\mathbf{y}$ involving the binary row stochastic matrix $\mathbf{A}_g = \{a_{giq}\}$ with $i = 1,\ldots,P$; $q = 1,\ldots,Q_g$ $(g = 1,\ldots,G)$ representing variable membership. Specifically, $a_{giq} = 1$ if and only if the $i-$th variable belongs to the

$q-$th cluster in the g-th component, and 0 otherwise. In detail, conditional on the $g-$th component of the mixture with probability p_g $(g = 1,\ldots,G)$, $\mathbf{y}_r$ is specified as follows

$$\mathbf{y}_{rg} = \boldsymbol{\eta}_g + \mathbf{A}_g\mathbf{f}_{rg} + \boldsymbol{\varepsilon}_{rg} \tag{3}$$

where $\boldsymbol{\eta}_g$ is a component-specific mean vector, $\mathbf{f}_{rg}$ is a Q_g-dimensional ($Q_g < P$) vector of component-specific latent variables (factors), which is assumed to be i.i.d. Gaussian variate with vector mean $\mathbf{0}$ and covariance matrix $\mathbf{I}_{Q_g}$, where $\mathbf{I}_{Q_g}$ denotes the $Q_g \times Q_g$ identity matrix. Furthermore, $\boldsymbol{\varepsilon}_{rg}$ are i.i.d. Gaussian component-specific random variables with mean $\mathbf{0}$ and covariance matrix $\mathbf{D}_g = \text{diag}(\sigma^2_{1g},\ldots,\sigma^2_{Pg})$. According to this assumption, a unit in the g-component follows a multivariate density with mean $\boldsymbol{\eta}_g$ and covariance $\mathbf{A}_g\mathbf{A}'_g + \mathbf{D}_g$, that is

$$\mathbf{y}_{rg} \sim N(\boldsymbol{\eta}_g, \mathbf{A}_g\mathbf{A}'_g + \mathbf{D}_g). \tag{4}$$

Note that, the covariance specification implies: (i) a block diagonal correlation structure; (ii) the correlation between variables depends on the variances only. It is worth to note that, the proposed model may assume different specifications whether the $\mathbf{D}_g$ and $\mathbf{A}_g$ matrix are constrained to be equal across row clusters.

2.1 Estimation

The maximization of (2) is quite time consuming and becomes infeasible when P increases due to the presence of multidimensional integrals. For this reason, model parameters are estimated through an EM framework maximizing the pairwise log-likelihood, i.e. the sum of all possible log-likelihoods based on the bivariate marginals. The estimators obtained have been proven to be consistent, asymptotically unbiased and normally distributed. In general, they are less efficient than the full maximum likelihood estimators, but in many cases the loss in efficiency is very small or almost null [25].
The pairwise log-likelihood is

$$\begin{aligned} p\ell(\boldsymbol{\psi};\mathbf{x}) &= \sum_{i=1}^{P-1}\sum_{j=i+1}^{P} \ell(\boldsymbol{\psi};(x_i,x_j)) \\ &= \sum_{i=1}^{P-1}\sum_{j=i+1}^{P}\sum_{c_i=1}^{C_i}\sum_{c_j=1}^{C_j} n^{(ij)}_{c_ic_j} \log\left[\sum_{g=1}^{G} p_g \pi^{(ij)}_{c_ic_j}(\boldsymbol{\eta}_g, \mathbf{A}_g\mathbf{A}'_g + \mathbf{D}_g, \boldsymbol{\gamma})\right], \end{aligned} \tag{5}$$

where now, after the reparameterization, the set of models parameters is $\boldsymbol{\psi} = \left\{p_1,\ldots,p_{G-1},\boldsymbol{\eta}_{11},\ldots,\boldsymbol{\eta}_{1Q_1},\ldots,\boldsymbol{\eta}_{G1},\ldots,\boldsymbol{\eta}_{GQ_G},\mathbf{A}_1,\ldots,\mathbf{A}_G,\mathbf{D}_1,\ldots,\mathbf{D}_G,\boldsymbol{\Gamma}\right\}$. Furthermore, $n^{(ij)}_{c_ic_j}$ is the observed frequency of a response in category c_i and c_j for variables x_i and x_j respectively, while $\pi^{(ij)}_{c_ic_j}(\boldsymbol{\eta}_g, \mathbf{A}_g\mathbf{A}'_g + \mathbf{D}_g, \boldsymbol{\gamma})$ is the corresponding probability under the model obtained by integrating on dimensions i and j the density of a normal distribution with parameters $\left(\boldsymbol{\eta}_g, \mathbf{A}_g\mathbf{A}'_g + \mathbf{D}_g\right)$ between the corresponding threshold parameters γ. It is clear that the pairwise approach is feasible as it requires

the evaluation of integrals of bivariate normal distributions, regardless of the number of observed or latent variables. The computation of parameter estimates is carried out using a EM-type algorithm.

2.2 Classification, model selection and identifiability

The CMAP criteria [22] is used to define unit clustering, whereas a binary and row stochastic matrix for representing the variable partition. One of the features of model-based clustering methods is that they provide quite a rigorous theoretical basis to choose the number of unit and variable clusters; in this perspective, the choice of G and Q_g $(g = 1, \ldots, G)$ involves several comparisons between different potential models. The best model is chosen by minimizing the composite version of penalized likelihood selection criteria like BIC or CLC (see [23] and references therein). A further important point of the proposed model that is worth to be discussed is parameter identifiability. Adopting a pairwise likelihood estimation approach, the number of essential parameters equals the number of parameters of a log linear model with only two factor interaction terms. Thus it means that we can estimate a lower number of parameters compared to a full maximum likelihood approach. Furthermore, to estimate both thresholds and component parameters if all the observed variables have three categories at least and when groups are know, we set the first two thresholds to 0 and 1, respectively [17]. Finally, the factorial reparameterization of component-specific covariance of the latent variable involving $\mathbf{A}_g$ is unique since the matrix $\mathbf{A}_g$ does not suffer from the identifiability issues, apart from clusters labels permutations, differently from the factor loadings matrix in the factor analysis model.
Further details will be given in the extended version of the paper along with simulation and real data results to show the effectiveness of the proposal.

New algorithms and goodness-of-fit diagnostics for ranked data modelling with the Extended Plackett-Luce distribution

Nuovi algoritmi e diagnostiche di bontà di adattamento per la modellizzazione dei dati di ranking con la distribuzione di Plackett-Luce estesa

Cristina Mollica and Luca Tardella

Abstract The *forward order* assumption postulates that the ranking process of the items is carried out by assigning the positions from the top (most-liked) to the bottom (least-liked) alternative. This assumption has been recently relaxed in the *Extended Plackett-Luce model* (EPL) through the introduction of the discrete *reference order* parameter, describing the rank attribution path. By starting from two formal properties of the EPL, we derive novel diagnostic tools for testing appropriateness of the EPL assumption. We also show how one of the two statistics can be exploited to construct a heuristic method, that surrogates the maximum likelihood approach for inferring the underlying reference order. The performance of the proposals was compared with more conventional approaches through an extensive simulation study.

Abstract *L'ipotesi di ordinamento in avanti postula che il processo di ranking venga eseguito assegnando le posizioni dalla prima all'ultima. Questa ipotesi è stata recentemente rilassata nel modello di Plackett-Luce esteso (EPL) attraverso l'introduzione del parametro discreto detto ordine di riferimento, che descrive il percorso di attribuzione del rango. Partendo da due proprietà formali dell'EPL, deriviamo nuovi strumenti diagnostici per testare l'adeguatezza del modello EPL. Mostriamo anche come una delle due statistiche possa essere impiegata per costruire un metodo euristico, che surroga l'approccio di massima verosimiglianza per l'inferenza sull'ordine di riferimento. La performance delle proposte è stata confrontata con approcci più convenzionali attraverso un ampio studio di simulazione.*

Key words: ranking data, Plackett-Luce model, model specification, goodness-of-fit assessment, bootstrap, heuristic methods

1 Introduction

Let us consider an experiment in which a sample of N judges is asked to rank a set $I = \{1,\dots,K\}$ of K labeled alternatives, namely *items*, according to a certain criterion. A *ranking* is a vector $\pi = (\pi(1),\dots,\pi(K))$ collecting the ranks assigned to each item, specifically the entry $\pi(i)$ indicates the position attributed to the i-th alternative. Equivalently, data can be recorded in the *ordering* format $\pi^{-1} = (\pi^{-1}(1),\dots,\pi^{-1}(K))$, where the generic component $\pi^{-1}(j)$ indicates the item ranked in the j-th position. Therefore, ranking data are multivariate ordinal data taking values in the set of permutations $\mathscr{S}_K$ of the first K integers.

This work concentrates on the parametric family of stagewise ranking models, in particular on the *Extended Plackett-Luce model* (EPL) introduced by [1]. The EPL generalizes the *Plackett-Luce model* (PL) [2, 3] by relaxing the implicit forward order assumption with the introduction of the *reference order parameter* $\rho = (\rho(1),...,\rho(K))$. It indicates the rank assignment order, i.e., $\rho(t)$ is the position attributed at the stage t. The probability of an ordering π^{-1} under the EPL is

$$\mathbf{P}_{\text{EPL}}(\pi^{-1}|\rho,\underline{p}) = \mathbf{P}_{\text{PL}}(\pi^{-1}\rho|\underline{p}) = \prod_{t=1}^{K} \frac{p_{\pi^{-1}(\rho(t))}}{\sum_{v=t}^{K} p_{\pi^{-1}(\rho(v))}} \qquad \pi^{-1} \in \mathscr{S}_K, \qquad (1)$$

where ρ is the discrete parameter, specifically a permutation of the first K integers, and the positive quantities p_i's are referred to as *support parameters*, proportional to the probabilities for each item to be ranked in the position indicated by the first entry of ρ. Hereinafter, we will shortly refer to (1) as EPL$(\rho,\underline{p})$. Inference on the EPL and its generalization into a finite mixture framework was originally addressed from the Maximum Likelihood Estimation (MLE) perspective in [1], via the hybrid Expectation-Maximization-Minorization (EMM) algorithm. Recently, [4] introduced the Bayesian version of the EPL, where a tuned joint Metropolis-within-Gibbs sampling was developed to conduct approximate posterior inference. The MCMC algorithm was also adapted to infer on the EPL with order constrains on ρ [6] and on the Bayesian EPL mixture [7].

2 Novel EPL diagnostics and comparative evaluation

Specific diagnostic tools to evaluate model adequacy of multistage ranking models are very limited in the ranking literature and their effectiveness has not been deeply explored. The present work aims at providing some contributions in this direction.

Let us suppose that we have some data simulated from an EPL$(\rho,\underline{p})$. We expect the marginal frequencies of the items at the first stage to be ranked according to the order of the corresponding support parameter component. On the other hand, we expect the marginal frequencies of the items at the last stage to be ranked according to the reverse order of the corresponding support parameter component. One can then derive that the ranking of the marginal frequencies of the items corresponding

to the first and last stage should sum up to $(K+1)$, no matter what their support is. Of course, this is less likely to happen when the sample size is small or when the support parameters are not so different of each other. In any case, one can define a test statistic by considering, for each couple of integers (j, j') candidate to represent the first and the last stage ranks, namely $\rho(1)$ and $\rho(K)$, a discrepancy measure $T_{jj'}(\pi)$ between $K+1$ and the sum of the observed ranks of the frequencies corresponding to the same item extracted in the first and in the last stage. Formally, let $\underline{r}_j^{[1]} = (r_{j1}^{[1]}, \ldots, r_{jK}^{[1]})$ and $\underline{r}_{j'}^{[K]} = (r_{j'1}^{[K]}, \ldots, r_{j'K}^{[K]})$ be the marginal item frequency distributions for the j-th and j'-th positions, to be assigned respectively at the first [1] and last [K] stage. In other words, the generic entry $r_{ji}^{[s]}$ is the number of times that item i is ranked j-th at the s-th stage. The proposed EPL diagnostic relies on the following discrepancy

$$T_{jj'}(\pi) = \sum_{i=1}^{K} |\text{rank}(\underline{r}_j^{[1]})_i + \text{rank}(\underline{r}_{j'}^{[K]})_i - (K+1)|, \tag{2}$$

implying that the smaller the value $T_{jj'}(\pi)$, the larger the plausibility that the two integers (j, j') represent the first and the last components of the reference order. In this sense, $T_{jj'}(\pi)$ is a measure of the closeness of the positions j and j' in ρ. To globally assess the conformity of the sample with the EPL, we consider the statistic

$$T_m(\pi) = \min_{j<j'} T_{jj'}(\pi). \tag{3}$$

With the aim at further enlarging the collection of diagnostics for the EPL class, we focus our attention also on another specific property of the EPL, knows as *Luce's choice axiom* or *independence of irrelevant alternatives* (IIA). The IIA hypothesis implies that the probability ratio of selecting item i over item i' is constant over the stages of the ranking process (constant ratio rule), as long as the two items are both still available. Formally, it implies that the expected paired comparison frequency at stage t of choosing item i over item i' is $\tau^*_{ii't} = T_{ii't} p_i/(p_i + p_{i'})$, given by the product between the total number $T_{ii't}$ of pairwise comparisons between i and i' at stage t and the theoretical pairwise comparison probability under the EPL. Hence, a chi-squared statistic for the IIA assumption can be defined as follows

$$X^2_{\text{IIA}} = \sum_{t=1}^{K-1} \sum_{i<i'} \frac{(\tau_{ii't} - \tau^*_{ii't})^2}{\tau^*_{ii't}},$$

where $\tau_{ii't}$ is the observed paired comparison frequency at stage t.

After introducing novel test statistics, one should enquire into their power, for instance through a bootstrap approach, and preferably compare it with that of some standard goodness-of-fit tools for ranking models. To this aim, we conducted a simulation study under alternative model specifications, involving in the comparison the chi-squared discrepancies based on the top frequencies, the pairwise comparisons and the first-order marginals, given respectively by

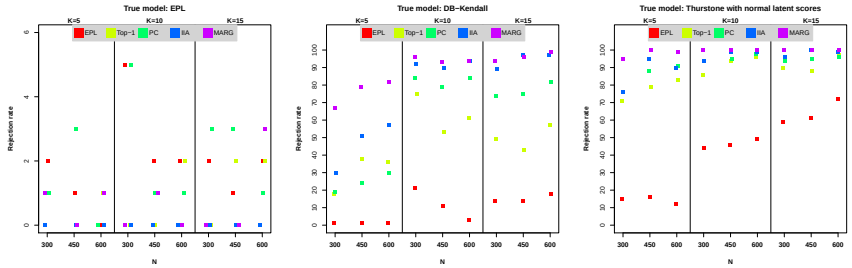

Fig. 1: Rejection rates of the EPL assumption for alternative goodness-of-fit diagnostics computed on simulated data from different model scenarios.

$$X^2_{\text{TOP}} = \sum_{i=1}^{K} \frac{(m_{1i} - m^*_{1i})^2}{m^*_{1i}} \qquad X^2_{\text{PC}} = \sum_{i<i'} \frac{(\tau_{ii'} - \tau^*_{ii'})^2}{\tau^*_{ii'}} \qquad X^2_{\text{M}} = \sum_{j=1}^{K} \sum_{i=1}^{K} \frac{(m_{ji} - m^*_{ji})^2}{m^*_{ji}}$$

where the expected frequencies are $m^*_{1i} = Np_i$ and $\tau^*_{ii'} = N\frac{p_i}{p_i + p_{i'}}$, whereas m^*_{ji} were estimated with a Monte Carlo simulation.

A comparative evaluation of the competing model specification tools was carried out by means of an extensive simulation study. For each possible combination (K,N), with values varying respectively in the grids $K \in \{5,10,15\}$ and $N \in \{300,450,600\}$, we drew 100 datasets with N orderings of K items from the following ranking distributions: i) EPL, ii) distance-based model (DB) with the Kendall metric (DB-Kend), iii) DB with the Hamming distance (DB-Ham) and iv) TH with normal latent scores (TH-norm). where the true parameter values were uniformly generated. To approximate the reference distribution of the test statistics under the EPL assumption, the bootstrap method was applied. Finally, for each model adequacy criterion, we estimated the mis- and correct rejection rates with the relative frequency of the times that the p-value was smaller than or equal to 0.05.

The simulation study revealed a satisfactory performance of all the considered diagnostics regarding the rates of mis-rejections, testified by estimated Type I error probabilities below 0.05 (Figure 1, left). On the other hand, noteworthy differences emerged in terms of the power. Firstly, measure (3) exhibited a consistent poor behavior of the estimated power under each considered model scenario, see for instance the plots in the middle and on the right of Figure 1. At least two motivations can be put forward to argue this evidence. The former is related to the formal definition of $T_m(\pi)$; in fact, (3) is a parameter-free measure based on the ranks of the expected marginal frequencies, rather than on the computation of the parameter-dependent first- and last-stage theoretical probabilities. This makes $T_m(\pi)$ by construction a rougher diagnostic in the comparison with the other statistics. Secondly, the remarkably low power of (3) under the DB with the Kendall metric (Figure 1, center) suggested that the monotonicity property of the first- and last-stage item probabilities is not specific of the EPL, but it is shared by other rankings models too. Another stable evidence highlighted by the comparative analysis concerns the

best-performing diagnostic, which turned to be the one relying on the marginal item distributions. However, it is no less apparent that, for higher values of K and N, the performance of the new IIA statistic is pretty much equivalent to that of the chi-squared based on the marginal distributions and, in general, always better than the remaining competing statistics typically used in the real-data applications.

3 Likelihood-free estimation of the reference order

Rather than from a model specification perspective, in this section we explored the utility of the statistic (3) from the inferential point of view.

Let $\mathbf{T}(\pi) = (T_{jj'}(\pi))$ be the $K \times K$ matrix with entries defined in (2). For each component $T_{jj'}(\pi)$, the inequality $T_{jj'}(\pi) \leq u_K$ holds, where the upper bound u_K corresponds to the constant value in the main diagonal of the matrix, i.e., $u_K = T_{jj}(\pi) = \sum_{l=1}^{K} |2l-(K+1)|$ depending on data only through K. Our heuristic method to estimate the unknown parameter ρ is composed of the following steps:

1. compute $\mathbf{D}(\pi) = |\mathbf{T}(\pi) - u_k \mathbf{J}_K|$, where $\mathbf{J}_K$ is $K \times K$ all-ones matrix, so that each component $D_{jj'}(\pi)$ can be interpreted as a measure of the distance between positions j and j' in the sequential rank assignment process;
2. use the matrix $\mathbf{D}(\pi)$ as the input of a Principal Component Analysis (PCA);
3. estimate ρ by taking the non-decreasing ordering of the scores $(s_1, \ldots, s_K)$ of the K positions on the first PC.

The inferential effectiveness of the proposal to recover the true discrete parameter was explored by means of a simulation study. For each possible combination (K,N), where $K \in \{5,10,15\}$ and $N \in \{50,200,1000,10000\}$, we drew 100 datasets $\underline{\pi}_{(R)}^{-1}$ with $R = 1, \ldots, 100$ from the EPL with uniformly generated parameters. For comparison purposes, we inferred the reference order of each simulated sample $\underline{\pi}_{(R)}^{-1}$ with the heuristic strategy described above, with the one replacing the PCA with the Multidimensional Scaling (MDS) and with the MLE approach [1], which is considered as the reference method for the present estimation task. Finally, the estimation performance of the competing strategies were compared in terms of: i) percentage of matching between $\dot{\rho}^{(R)}$ and $\hat{\rho}^{(R)}$ (% recoveries) and ii) average cograduation $\bar{r}_{\text{Spear}}(\dot{\rho}, \hat{\rho})$ between the estimated and the actual reference order computed with Spearman's rank correlation.

As apparent in Table 1, PCA and MDS exhibited essentially the same ability. Compared with the MLE, one can appreciate very good results for the heuristic methods. The percentage of matching consistently grows with N and, by checking also the cases where there is not an exact correspondence, on average an analogous trend is highlighted for the relative Spearman correlation. Additionally, if we look at a fixed N, the percentage of recoveries shows a worse tendency for larger values of K. In this regard, the cases $K \in \{10,15\}$ combined with a relatively very low ($N = 50$) and very high ($N = 10000$) sample size deserve some considerations to stress typical issues which can be encountered in a ranking data analysis. First, in a

Table 1: Inferential performance of the heuristic methods via PCA and MDS to estimate the reference order on simulated data compared to the MLE.

	% recoveries			$\bar{r}_{\text{Spear}}(\hat{\rho},\hat{\rho})$		
(K,N)	PCA	MDS	MLE	PCA	MDS	MLE
$(5,50)$	58	60	45	0.86	0.86	0.69
$(5,200)$	79	80	77	0.89	0.89	0.95
$(5,1000)$	91	90	100	0.92	0.93	1.00
$(5,10000)$	97	97		0.94	0.94	
$(10,50)$	3	5	3	0.90	0.89	0.87
$(10,200)$	14	16	23	0.93	0.93	0.98
$(10,1000)$	55	54	68	0.96	0.95	0.99
$(10,10000)$	79	78		0.96	0.96	
$(15,50)$	0	0	0	0.92	0.92	0.91
$(15,200)$	0	1	3	0.94	0.94	0.97
$(15,1000)$	13	15	26	0.97	0.97	0.99
$(15,10000)$	48	51		0.97	0.97	

sparse data situation, all of the estimation techniques exhibit a great uncertainty in recovering the actual ρ, testified by the negligible values of the recovery percentage. On the other hand, although a better behavior of the MLE is expected for $N = 10000$, this has not been implemented since, without a specialized program, fitting the EPL to a large sample can be deeply computational demanding if not actually unfeasible. Moreover, the computational burden is further aggravated by the multiple initialization needed to address the issue of local maxima. In the light of these remarks, the likelihood-free approach can be motivated as a straightforward method that can be combined with the MLE or with an MCMC method in the Bayesian framework. In fact, without computational costs, it can implemented as a preliminary step to obtain a promising initialization, that can guide the parameter space exploration towards the global optimum and substantially reduce the elaboration time.

Unfolding non-metrico basato sull'aumento di matrici: un approccio basato sulla funzione copula

Marta Nai Ruscone and Antonio D'Ambrosio

Abstract In this contribution an effective procedure to avoid degeneracies in multidimensional unfolding for preference rank data is proposed. We adopt the strategy of augmenting the data matrix, trying to build a complete dissimilarity matrix, by using copula-based association measures among rankings (individuals), and between rankings and objects (namely, a rank-order representation of the objects through tied rankings). Our proposal is able to both recover the order of the preferences and reproduce the position of both rankings and objects in a geometrical space. Application on real datasets show that our procedure returns non-degenerate unfolding solutions.

Abstract *In questo contributo viene proposta un'efficace procedura per evitare soluzioni degeneri nell'unfolding multidimensionale per dati di tipo rank. La strategia utilizzata é quella di aumentare la matrice dei dati, cercando di costruire una matrice di dissimilaritá completa, utilizzando misure di associazione basate su copule tra rank (individui) e tra rank e oggetti (ovvero, una rappresentazione dell'ordine dei rank e degli oggetti attraverso rank appaiati). La nostra proposta é quindi in grado di catturare sia l'ordine dei rank sia la posizione di rank e oggetti in uno spazio geometrico. Applicazioni su dataset reali mostrano che la nostra procedura restituisce soluzioni non degeneri.*

1 The copula function

Copula are functions that join multivariate distribution functions to their marginal distribution functions [8]. They describe the dependence structure existing across pairwise marginal random variables. In this way we can consider bivariate distributions with dependency structures different from the linear one that characterizes the multivariate normal distribution.

A bivariate copula $C : I^2 \to I$, with $I^2 = [0,1] \times [0,1]$ and $I = [0,1]$, is the cumulative bivariate distribution function of a random variable (U_1, U_2) with uniform marginal random variables in [0,1]

$$C(u_1, u_2; \theta) = P(U_1 \leq u_1, U_2 \leq u_2; \theta), \quad 0 \leq u_1 \leq 1 \quad 0 \leq u_2 \leq 1 \tag{1}$$

where θ is a parameter measuring the dependence between U_1 and U_2.

The following theorem by Sklar [8] explains the use of the copula in the characterization of a joint distribution. Let (Y_1, Y_2) be a bivariate random variable with marginal cdfs $F_{Y_1}(y_1)$ and $F_{Y_2}(y_2)$ and joint cdf $F_{Y_1,Y_2}(y_1, y_2; \theta)$, then there always exists a copula function $C(\cdot, \cdot; \theta)$ with $C : I^2 \to I$ such that

$$F_{Y_1,Y_2}(y_1, y_2; \theta) = C\big(F_{Y_1}(y_1), F_{Y_2}(y_2); \theta\big), \quad y_1, y_2 \in \mathbb{R}. \tag{2}$$

Conversely, if $C(\cdot, \cdot; \theta)$ is a copula function and $F_{Y_1}(y_1)$ and $F_{Y_2}(y_2)$ are marginal cdfs, then $F_{Y_1,Y_2}(y_1, y_2; \theta)$ is a joint cdf.
If $F_{Y_1}(y_1)$ and $F_{Y_2}(y_2)$ are continuous functions then the copula $C(\cdot, \cdot; \theta)$ is unique. Moreover, if $F_{Y_1}(y_1)$ and $F_{Y_2}(y_2)$ are continuous the copula can be found by the inverse of (2):

$$C(u_1, u_2) = F_{Y_1,Y_2}(F_{Y_1}^{-1}(u_1), F_{Y_2}^{-1}(u_2)) \tag{3}$$

with $u_1 = F_{Y_1}(y_1)$ and $u_2 = F_{Y_2}(y_2)$. This theorem states that each joint distribution can be expressed in term of two separate but related issues, the marginal distributions and the dependence structures between them. The dependence structure is explained by the copula function $C(\cdot, \cdot; \theta)$. Moreover the (2) provides a general mechanism to construct new multivariate models in a straightforward manner. By changing the copula function we can construct new bivariate distributions with different dependence structures, with the association parameter indicating the strength of the dependence, also different from the linear one that characterizes the normal distribution.

Each copula is related to the most important measures of dependency: the Pearson correlation coefficient and the Spearman grade correlation coefficient. The Spearman grade correlation coefficient (see [8] pp. 169-170 for the definition of the grade correlation coefficient for continuous random variables) measures the association between two variables and can be expressed as a function of the copula. More precisely, if two random variables are continuous and have copula C with parameter θ, then the Spearman grade correlation is

$$\rho_s(C) = 12 \int_{I^2} C_\theta(u_1, u_2) du_1 du_2 - 3. \quad (4)$$

For continuous random variables it is invariant with respect to the two marginal distributions, i.e. it can be expressed as a function of its copula. This property is also known as 'scale invariance'. Note that not all measures of association satisfy this property, e.g. Pearson's linear correlation coefficient [5].

2 Unfolding as a special case of multidimensional scaling on copula-based association between rankings

Unfolding, originally formulated by Coombs [3] for the analysis of the two-mode preference choice data, is a technique that allows the estimation of two configurations usually representing the coordinates for a set of m individuals and a set of n objects on the basis of proximity values between them, typically expressing preferences of each individual over each object.

Therefore unfolding applies multidimensional scaling [4] to an off-diagonal $n \times m$ matrix, usually representing the scores (or the rank) assigned to a set of m items by n individuals or judges [1]. Using of either scores or rankings traditionally discriminates between metric and non-metric unfolding.

The goal is to obtain two configuration of points representing the position of the judges (X) and the items (Y) in a reduced geometrical space. Each point representing the individuals is considered as an ideal point so that its distances to the object points correspond to the preference scores [3].

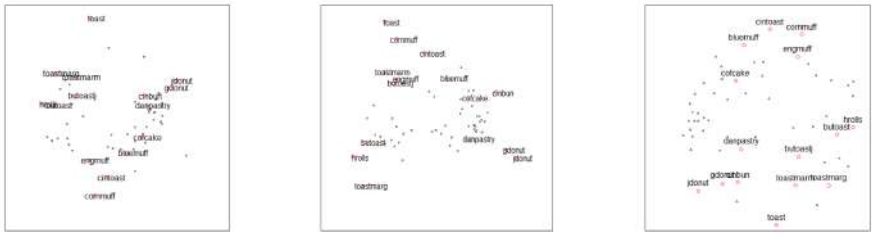
Unfolding can be seen as a special case of multidimensional scaling because the off-diagonal matrix is considered as a block of an ideal distance matrix in which both the within judges and the within items dissimilarities are missing. The presence of blocks of missing data causes the phenomenon of the so-called degenerate solutions, i.e., solutions that return excellent badness of fit measures but not graphically interpretable at all.

To tackle the problem of degenerate solutions, several proposals have been presented in the literature [1]. By following the approach introduced by [9], we adopt the strategy of augmenting the data matrix, trying to build a complete dissimilarity matrix, and then applying any MDS algorithms.

Let $\boldsymbol{\Gamma}$ be the original $m \times n$ original preference data matrix. In order to augment the data matrix we add to this n additional rows, one for each of the n objects, that correspond to tied rankings representing the jth item, $j = 1, \ldots, n$. As a result, a new $N \times n$ $\boldsymbol{\Gamma}^*$ matrix is obtained, with $N = n + m$. Then we use copula-based association measures among rankings (the individuals), and between rankings and objects (namely, a rank-order representation of the objects through tied rankings), obtaining in fact a $N \times N$ dissimilarity matrix to be analyzed with any MDS algorithm.

3 An application on a real data set

Fig. 1 shows a comparison between the Unfolding solutions of PRESCAL [2], which actually is the most used algorithm for Unfolding analysis, and our proposal by using the Spearman grade correlation coefficient via copula on the breakfast data set. Green and Rao [6] collected 42 rankings of 15 objects by asking 21 students and their wives to order 15 breakfast items in terms of their preference.



(a) Row-conditional Prefscal solution (b) Unconditional Prefscal solution (c) Spearman augmented unfolding

Fig. 1: Unfolding solutions for breakfast data. Breakfast items are labeled as follow: Toast pop-up; Buttered toast; English muffin and margarine; Jelly donut; Cinnamon toast; Blueberry muffin and margarine; Hard rolls and butter; Toast and marmalade; Buttered toast and jelly; Toast and margarine; Cinnamon bun; Danish pastry; Glazed donut; Coffee cake; Corn muffin and butter.

PREFSCAL works by setting two penalties on a modified loss function in such a way to guarantee non degenerate solutions. A possible drawback of this algorithm is that it is not always clear how set the penalty terms. In fact the user must make attempts in order to find the right solution.
The figure emphasizes that the solution of our procedure is not degenerate and it is comparable with the one of PREFSCAL, especially with its unconditional output. It is normal that our output looks like the unconditional PREFSCAL solution because we propose a solution that, depending on how we defined the dissimilarity matrix, is unconditional as well.

4 Concluding remarks

We propose an unfolding algorithm based on the augmentation of the data matrix and a copula-based association between rankings. The shown result highlights that our proposal produces non-degenerate unfolding solutions that are comparable with the ones obtained with PREFSCAL. With respect to PREFSCAL, any parameter

must be a priori chosen by the user. On the other hand PREFSCAL always guarantees non degenerate solutions. A robust simulation study will be discussed.

Ordinal probability effect measures for dyadic analysis in cumulative models

Misure di probabilità ordinali per l'analisi diadica in modelli cumulativi

Maria Iannario and Domenico Vistocco

Abstract Dyadic data analysis (DDA) is increasingly being used to better understand, analyze and model intra- and inter-personal mechanisms in various types of dyads such as husband-wife, caregiver-patient, doctor-patient, parent-child or athlete-coach as in our example. A key strength of the DDA is its flexibility to take the (non)independence available in the dyads into account. In this article, we illustrate the value of using DDA to examine how sports performance is perceived by an athlete and if it is consistent with the declared performance by his/her coach. A probability summary for ordered comparison of groups referred to a measure of stochastic superiority is used to indicate the consistency of perceived assessments.
Abstract *L'analisi dei dati diadici (DDA) è sempre più utilizzata per comprendere, analizzare e modellare i meccanismi intra e interpersonali in vari tipi di diade come marito-moglie, assistente-paziente, medico-paziente, genitore–bambino o atleta–allenatore. Quest'ultimo caso viene analizzato nel presente contributo. In particolare, la flessibilitá della DDA nel tener conto della (non)indipendenza presente nelle diadi viene qui considerata per esaminare in che modo un atleta percepisce la prestazione sportiva e se questa percezione è coerente con la valutazione della prestazione dichiarata dal suo allenatore. Al fine di considerare la coerenza delle valutazioni espresse dai due attori del processo considerato, si utilizza una misura di probabilità stocastica che permette il confronto ordinato dei gruppi.*

1 Introduction

The study deals with modelling the actor/partner interdependence in case of categorical dyadic data by presenting an alternative approach with respect to the current used methods [7]. The research aims at evaluating the consistency of perceived assessments on some topics related to the performance in sport dyads (athletes/coaches). The proposal may adjust the score perceived by the athletes in the definition of their performance by means of coach evaluation. The analysis is about a cross–sectional study on 100 couples of athlete-coach from Italian Swimming Federation–Campania region section, collected between November and December 2019. Satisfaction and other psychological domains were measured by rating scales on a $k = 7$ point scale. Frequency distribution of some items are displayed in Figure 1.

Figure 2 is about two items, *Challenging* and *Talent*, whose response distribution of the two groups of dyads is almost the same for the first item and very different for the second one, as remarked in the next analysis. The observer agreement plot ([4], [5]) provides a graphical representation of agreements of the assessment perceived by athletes and coaches. Each chart depicts a $n \times n$ square, where n denotes the total sample size and the black squares, each of size $n_{jj} \times n_{jj}$, $j = 1,2,\ldots,k$, denoting the observed agreement. The larger boxed rectangles depict the maximum possible agreement, since they are obtained starting from the observed marginals. Therefore, a visual impression of the strength of the agreement is obtained comparing the areas of dark squares with the area of white rectangles. A further information is provided by the lighter shaded rectangles, that depict the weighted contribution from off-diagonal cells. This allows to interpret the partial agreement among athletes and coaches comparing the areas of lighter shaded rectangles to the area of external rectangles. Finally, the positions of the dark squares with respect to the diagonal line provide information about "observer bias", i.e. the case where the observers consistently tend to classify the objects into higher or lower categories than the other.

Figure 3 depicts the path of the levels of the considered two items exploiting a correspondence analysis map [6], *Challenging* being on the left–side and *Talent* on the right–side. The two paths inside each plot represent the Athletes' levels (solid line) and the Coaches' levels (dotted line) of the two items. Multiple correspondence analysis has been carried out on the whole set of items, even if only the two illustrative items are represented for the sake of illustration. The plots confirm the different patterns of the two items, already suggested by the previous agreement plot.

2 Ordinal Superiority Measures for dyadic data analysis

When Y is a k-category ordinal response variable, one of the candidate model to analyse the rating is the cumulative link model [8]:

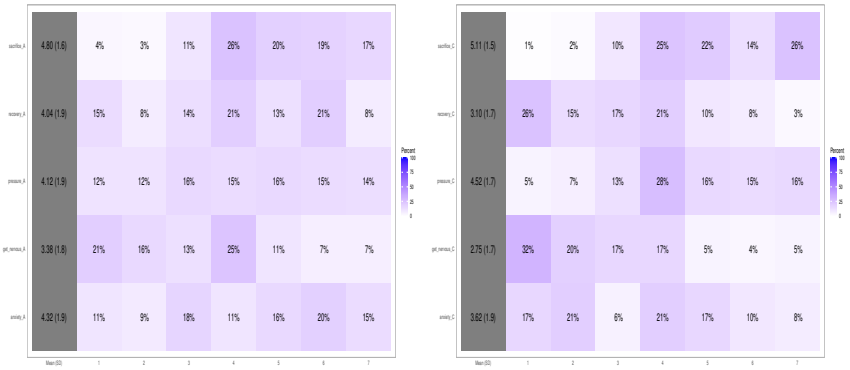

Fig. 1 Frequency distribution of subjective perceptions concerning 5 items collected on a 7 point scale (1=total disagreement; 7=total agreement). First column reports means and standard deviation. Left: Athletes' responses. Right: Coaches' responses

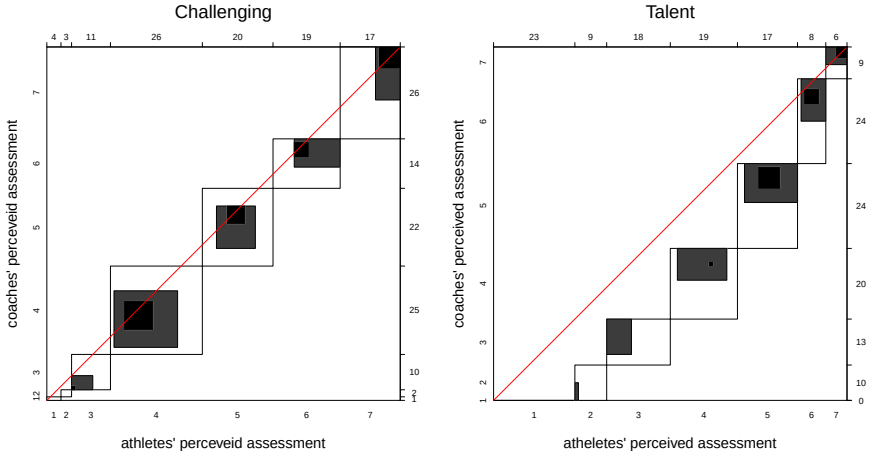

Fig. 2 Agreement plots of subjective perceptions concerning 2 items collected on a 7 point scale (1 = total disagreement; 7 = total agreement). First one is related to Athletes' challenging. Second one concerns Athletes' talent. The Athletes' responses are depicted on the horizontal axis, the Coaches' responses on the vertical axis.

$$P(Y_i = j \mid \boldsymbol{X}_i;\boldsymbol{\theta}) = P\left(\alpha_{j-1} < Y_i^* \leq \alpha_j | \boldsymbol{X}_i\right) = \\ = F_\varepsilon(\alpha_j - \boldsymbol{X}_i\boldsymbol{\beta}) - F_\varepsilon(\alpha_{j-1} - \boldsymbol{X}_i\boldsymbol{\beta}), \tag{1}$$

where

$$P(Y_i \leq j | \boldsymbol{X}_i;\boldsymbol{\theta}) = F_\varepsilon(\alpha_j - \boldsymbol{X}_i\boldsymbol{\beta}), \qquad i = 1,2,\ldots,n;\ j = 1,2,\ldots,k. \tag{2}$$

The parameter vector $\boldsymbol{\theta} = (\boldsymbol{\alpha}', \boldsymbol{\beta}')'$ contains the intercept values $\boldsymbol{\alpha} = (\alpha_1,\ldots,\alpha_{k-1})'$, where $-\infty = \alpha_0 < \alpha_1 < \ldots < \alpha_k = +\infty$ are the thresholds of the scale of a latent vari-

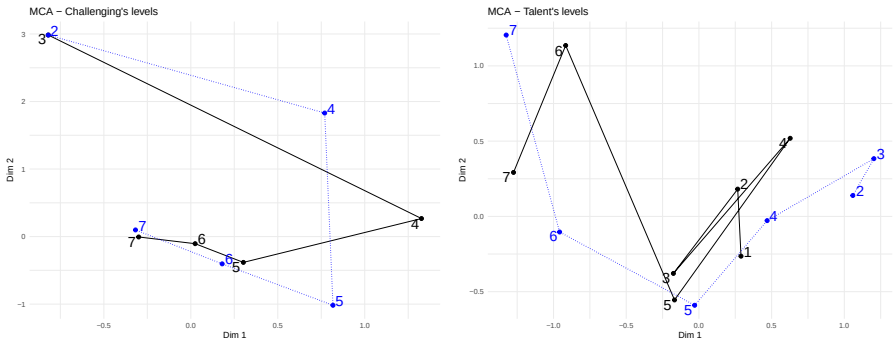

Fig. 3 Multiple correspondence maps of subjective perceptions concerning 2 items collected on a 7 point scale (1 = total disagreement; 7 = total agreement). The analysis is carried out on the whole set of items but only the levels of *Challenging* (left–side) and *Talent* (right–side) are represented. The two lines in each panel refer athletes' levels (solid black line) and coaches' levels (dotted blue line), respectively.

able Y^* surrounding the response Y, and the covariates coefficients $\boldsymbol{\beta} = (\beta_1, \ldots, \beta_p)'$. The vector $\boldsymbol{X}_i = (X_{i1}, \ldots, X_{ip})$ contains instead the covariates. Here, $\boldsymbol{\theta} \in \Omega(\boldsymbol{\theta})$, where $\Omega(\boldsymbol{\theta})$ is an open subset of $\mathbb{R}^{p+k-1}$.

Some common choices for $F_\varepsilon(.)$ are the Gaussian, the logistic or the standard Gumbel distribution and the related models are named probit, logit, and extreme value, respectively. The latter, related to log-log and the complementary log-log link function, is adopted when a skewed distribution is assumed. The ordinal superiority measures apply directly to the latent variable model (see [2, 3]). These measures represent our selected approach to compare groups by studying the probability that an observation from one group (=coaches) is scored above an independent observation from the alternative group (=athletes) of dyad.

We consider a dichotomous variable to identify the two clusters of coaches and athletes. Let Y_C^* and Y_A^* be independent underlying latent response variables at $\boldsymbol{X}$. Denoting by g_C (coaches) and g_A (athletes) two groups of statistical units related to the observed Y. An "*ordinal superiority measure*" or "*measure of stochastic superiority*" is

$$\gamma = P(Y_{g_C}^* > Y_{g_A}^*; \boldsymbol{X}) = P\left[\frac{(Y_{g_C}^* - Y_{g_A}^* - \beta)}{\sqrt{2}} > \frac{-\beta}{\sqrt{2}}\right],$$

regardless of $\boldsymbol{X}$ values, which for the probit, logit and complementary loglog link [2] is, respectively:

$$\gamma = \Phi(\hat{\beta}/\sqrt{(2)}), \qquad \gamma \approx \frac{exp(\hat{\beta}/\sqrt{2})}{1+exp(\hat{\beta}/\sqrt{2})}, \qquad \gamma = \frac{exp(\hat{\beta})}{1+exp(\hat{\beta})}.$$

In the three expressions β is the group parameter. From γ index is possible to obtain the other measure

$$\Delta = 2\gamma - 1.$$

Both γ and Δ indexes are normalized ($\gamma \in [0,1]$ and $\Delta \in [-1,1]$); when $\gamma > 1/2$ or $\Delta > 0$, the ratings from g_C tend to be larger than the ratings from g_A assessing an ordinal superiority of g_C over g_A.

For γ and Δ, simple confidence intervals result directly from ordinary confidence intervals for β for the corresponding ordinal cumulative link model.

3 Results

Results point out the role played by coach adjustment enhancing the feeling and the relationship of the dyads. Table 1 reports the ordinal superiority measures along with the corresponding 95% confidence intervals for the probit model. The same results for the logit model are shown in Table 2 and for the extreme value model (complementary log–log link function) in Table 3. The value of $\hat{\gamma}$ lower than $1/2$, with exception of *pressure*, *sacrifice*, *talent*, and *work out*, indicates an ordinal inferiority of the ratings of coaches with respect to athletes. It means that coaches are less critical than their athletes. Actually, for the items *improvement* and *challenging* in the case of logit and probit models, $\hat{\Delta} \simeq 0$ providing similar responses in the two groups. Results of the latter model for an underlying extreme value distribution, which is plausible for the evaluations expressed by coaches and athletes, are quite different from the logit or probit models but lead to the same conclusions.

The ordinal superiority measures extend directly to summary comparisons of multiple groups, based on more general models that have multiple indicator variables for the groups. Thus, a possible extension may consider a triad analysis where athletes who are in teams may be analysed. In this case captain's rating may be introduced in the analysis reporting the evaluation of a peer.

Simulated annealing for maximum rater agreement

Simulated annealing per il calcolo della massima concordanza

Fabio Rapallo and Maria Piera Rogantin

Abstract In this work we consider the weighted kappa as a measure of rater agreement for ordinal variables, and we use a simulated annealing algorithm to find the maximum agreement configuration. The proposed algorithm allow us to show, through some examples, that the maximum agreement depends strongly on the choice of the weighting scheme.

Abstract *In questo lavoro consideriamo l'indice kappa pesato come misura di rater agreement per variabili ordinali e utilizziamo un algoritmo di simulated annealing per determinare la massima concordanza. L'algoritmo permette di mostrare, tramite esempi, come la massima concordanza dipenda dalla scelta dei pesi.*

Key words: Algebraic Statistics, Markov bases, MCMC maximization

1 Introduction

Rater agreement analysis is one of the most active research areas in the field of categorical data analysis. Let us consider two (or more) raters which independently classify a set of N items based on a rating scale with m categories. For two raters, the data are therefore collected in a square $m \times m$ contingency table, where the diagonal cells correspond to agreement, while the off-diagonal cells correspond to disagreement. When multiple raters are involved and each of them classify all the N items, the data are collected in a multi-way contingency table.

Fabio Rapallo

Maria Piera Rogantin
Dipartimento di Matematica, Università di Genova, via Dodecaneso 35, 16146 Genova, e-mail: rogantin@dima.unige.it

For two raters, the Cohen's kappa introduced in [4] and the weighted Cohen's kappa introduced in [5] have become the most popular measures of agreement. For a discussion on the Cohen's kappas, its generalizations to the multi-observer case, and other related indices of agreement, refer to [7].

The un-weighted version of the Cohen's kappa only distinguishes between agreement cells and disagreement cells, and thus it is used in case of ratings on a nominal scale. When the rating scale is ordinal, or in general when there are some disagreements to be considered more serious than others, then the weighted kappa should be preferred. In this framework, the choice of the weights is a delicate issue, see for instance [10] and the references therein for a recent discussion on the use and interpretation of different weighting schemes.

Another classical issue concerning the Cohen's kappa is the normalization. The kappa belongs to the family of "chance corrected measures of agreement", and its expression can be summarized in

$$\kappa = \frac{O-E}{1-E} \tag{1}$$

where O is the proportion of observed agreement and E is the proportion of expected agreement under independence of the ratings. In Eq. (1), κ can be considered a normalized measure, since the maximum value of κ is 1. But the value $\kappa = 1$ can not be actually reached when the marginal distributions are different. This fact leads to some difficulties in the interpretation of the measured κ, and even to classical counterexamples, see for instance [9].

In this work, we introduce a MCMC algorithm (simulated annealing) based on the notion of Markov bases to find the maximum agreement. Due to space limitation, we introduce the algorithm only in the case of two raters, but it can be extended also to the multi-rater case. As an application, we also discuss some examples to show that different weighting schemes lead to different maximum agreement tables.

2 Cohen's kappa and weighted Cohen's kappa

In the two-rater setting, let us denote with p_{ij} the probability of the cell (i,j), and with p_{i+} and p_{+j} the marginal distributions ($i,j = 1,\dots,m$). The Cohen's kappa is:

$$\kappa = \frac{\sum_{i=1}^m p_{ii} - \sum_{i=1}^m p_{i+}p_{+i}}{1-\sum_{i=1}^m p_{i+}p_{+i}} = 1 - \frac{\sum_{(i,j)\in D} p_{ij}}{\sum_{(i,j)\in D} p_{i+}p_{+j}}, \tag{2}$$

where $D = \{(i,j) \ : \ i \neq j\}$ is the set of the disagreement cells. Given a matrix of (symmetric) weights of agreement $W = (w_{ij})$ with $0 \leq w_{ij} \leq 1$ for all (i,j) and $w_{ii} = 1$ for all i, the weighted kappa is:

$$\kappa_w = \frac{\sum_{i,j=1}^m w_{ij}p_{ij} - \sum_{i,j=1}^m w_{ij}p_{i+}p_{+j}}{1-\sum_{i,j=1}^m w_{ij}p_{i+}p_{+j}} = 1 - \frac{\sum_{(i,j)\in D} u_{ij}p_{ij}}{\sum_{(i,j)\in D} u_{i,j}p_{i+}p_{+j}}, \tag{3}$$

where in the second expression $u_{ij} = 1 - w_{ij}$. In practice, the u_{ij} are weights of disagreement, and it is easily seen that $u_{ij} = 0$ on the main diagonal. Note that when $w_{ij} = 0$ for $i \neq j$ in Eq. (3) one recovers the un-weighted kappa in Eq. (2). When a sample is available, the indices κ and κ_w are estimated through the sample proportions.

Among the most commonly used weights there are:

1. the quadratic weights (see [8]):

$$w_{ij} = 1 - \frac{(i-j)^2}{(m-1)^2}$$

2. the linear weights (see [3]):

$$w_{ij} = 1 - \frac{|i-j|}{m-1}$$

In order to illustrate the theory, we also consider a square-root version of the weights, namely:

$$w_{ij} = 1 - \frac{\sqrt{|i-j|}}{\sqrt{m-1}}$$

To avoid confusion, we denote with $\kappa_{w,2}$, $\kappa_{w,1}$, and $\kappa_{w,0.5}$ the weighted kappa computed with the quadratic, linear, and square-root weights, respectively.

Remark 1. Note that in the case of the quadratic weights, the disagreement weights u_{ij} do not define a distance on the set $\{1,\ldots,m\}$, since the triangular inequality is not satisfied.

3 The algorithm

While the computation of the maximum agreement is simple for the un-weighted kappa (at least in the two-rater setting), the problem is not trivial when the weighted kappa is considered. In order to determine the configuration with maximum agreement, we use here the simulated annealing within the context of Algebraic Statistics, and therefore we make use of a Markov basis in order to navigate the fiber (or reference set) of an observed contingency table. For an introduction to Markov bases and their use in MCMC techniques for categorical data see [2].

The fiber of an observed table n_{obs} with respect to a linear sufficient statistic $T : \mathbb{N}^{m\times m} \longrightarrow \mathbb{N}^s$ is the set

$$\mathscr{F}_T(n_{\text{obs}}) = \left\{ n \in \mathbb{N}^{m\times m} \ , \ T(n) = T(n_{\text{obs}}) \right\} . \tag{4}$$

To ease the notation we drop the dependence on n_{obs} and we write simply $\mathscr{F}_T$ instead of $\mathscr{F}_T(n_{\text{obs}})$ when there is no ambiguity.

In our case, the function T is the sufficient statistics corresponding to the margins, i.e., $T(n) = (n_{1+}, \ldots, n_{m+}, n_{+1}, \ldots, n_{+m})$. To define a connected Markov chain on the fiber $\mathscr{F}_T$, we use an approach based on the Markov moves and Markov bases.

A *Markov move* is any table f with integer entries that preserves the linear function T, i.e. $T(n \pm f) = T(n)$ for all $n \in \mathscr{F}_T$. A *Markov basis* for a fiber $\mathscr{F}_T$ is a finite set of moves $\mathscr{M} = \{f^{(1)}, \ldots, f^{(r)}\}$ such that for all n_1 and n_2 in $\mathscr{F}_T$, there exist a sequence of moves $f^{(i_1)}, \ldots, f^{(i_A)}$ such that

$$n_2 = n_1 + \sum_{a=1}^{A} f^{(i_a)} \tag{5}$$

and

$$n_1 + \sum_{j=1}^{a} f^{(i_j)} \geq 0 \quad \text{for all } \; a = 1, \ldots, A\,. \tag{6}$$

Eqs. (5) and (6) state that with a Markov basis it is possible to connect any two tables of $\mathscr{F}_T$ staying non-negative.

When T is the linear statistics preserving the margins, it is known that a Markov basis is formed by basic moves, i.e., moves of the form

$$\begin{array}{cc} -1 & +1 \\ +1 & -1 \end{array} \qquad \text{or} \qquad \begin{array}{cc} +1 & -1 \\ -1 & +1 \end{array}$$

on each 2×2 minor of the table. More formally (see [6] and [11]):

$$\mathscr{M} = \left\{ f \in \mathbb{Z}^{m \times m} \; : \; f_{i_1 j_1} = f_{i_2 j_2} = 1, f_{i_1 j_2} = f_{i_2 j_1} = -1, \text{ and 0 otherwise} \right\}.$$

For brevity, a move of $\mathscr{M}$ is denoted with $f_{i_1 i_2 j_1 j_2}$ where the pedices specify the row and column indices of the relevant 2×2 minor. With such a Markov basis we can use the simulated annealing to maximize the observed agreement (or equivalently to minimize the disagreement) among all tables with fixed margins. Define the observed disagreement of a table n as

$$D(n) = \frac{1}{N} \sum_{i,j=1}^{m} u_{ij} n_{ij}\,.$$

Using the Markov moves to define the neighbors, the MCMC simulated annealing starts from the observed table and runs at each step b ($b = 1, \ldots, B$) as follows:

1. Choose a move $f \in \mathscr{M}$ and define $n' = n + f$;
2. If n' is non-negative, then move the chain from n to n' with transition probability $\min\{\exp((D(n) - D(n'))/\tau_b), 1\}$, where τ_b is the temperature at time b.

The reader can refer to [12] for a general introduction to simulated annealing in the discrete case and for a discussion on the computational details of the algorithm, as for instance the choice of the temperature function τ_b.

4 Examples and discussion

In this section we use our algorithm to show, through two numerical examples, that the maximum agreement depends strongly on the choice of the weighting scheme and that the solution is not unique in the case of linear weights. The first example is based on artificial data, while the second one is a real-world example.

The first example concerns a 3×3 table. In Table 1 on the left, there is the table of the observed counts. For this table, we have $\kappa_{w,2} = 0.5087$ with quadratic weights, $\kappa_{w,1} = 0.4328$ with linear weights, and $\kappa_{w,0.5} = 0.3934$ with square-root weights. Then, we can compute the maximum values of the weighted kappa by means of the MCMC algorithm introduced above: using quadratic weights, we obtain a weighted kappa $\kappa_{w,2} = 0.7399$ (Table 1, center-left); using linear weights we have $\kappa_{w,1} = 0.6073$ (Table 1, center-right); using square-root weights, we have $\kappa_{w,0.5} = 0.6586$ (Table 1, right).

Table 1 A 3×3 example. The observed table (left), the table with maximum $\kappa_{w,2}$ with quadratic weights (center-left), a table with maximum $\kappa_{w,1}$ with linear weights (center-right), the table with maximum $\kappa_{w,0.5}$ with square-root weights (right).

	1	2	3	
1	6	1	4	11
2	0	8	0	8
3	0	0	6	6
	6	9	10	25

Remark 2. The configuration with maximum $\kappa_{w,1}$ is in general not unique. For instance, in the 3×3 example above, there are 5 different tables reaching the maximum value of $\kappa_{w,1} = 0.6073$. Among such tables, the value of $\kappa_{w,2}$ ranges from 0.5087 to 0.7399.

As a second example, we analyze the data from [1], page summarizing the diagnoses of multiple sclerosis for two neurologists on an ordinal scale. In Table 2 on the left, there is the table of the observed counts. For this table, we have $\kappa_{w,2} = 0.5246$ and $\kappa_{w,1} = 0.3797$. Here the $\kappa_{w,0.5}$ is not considered. In the configuration of maximum agreement using quadratic weights we have $\kappa_{w,2} = 0.7849$, while using linear weights we have $\kappa_{w,1} = 0.5715$.

Through the examples above we conclude that, in the weighted case, the solution of maximum agreement is not merely the table with the highest possible counts on the main diagonal, and this can be easily seen by comparing the solutions for the quadratic and the square-root weights. The differences between the optimal configurations under different weighting schemes decrease when the marginal distributions are nearly homogeneous.

Further work on this topic includes the extension to the multi-rater case, and an analytical study of the agreement in terms of the Markov moves. In fact, the

non-uniqueness of the optimal configuration with linear weights suggests that the combinatorial structure of the fiber $\mathscr{F}_T$ has a relevant role in the rater agreement analysis. Finally, a simulation study should complement the analysis, especially for large tables or multi-rater problems, where the curse of dimensionality may affect the performance of the MCMC algorithm.

Models and methods – Regression

A Clusterwise regression method for Distributional-valued Data

Un metodo di regressione cluster-wise per dati distribuzionali

Rosanna Verde, Francisco de A. T. de Carvalho, Antonio Balzanella

Abstract In this paper we propose a cluster-wise regression strategy for aggregated data represented by distributions. The basic idea is that the set of observed data are related by local causal relationships for different clusters. Some cluster-wise regression methods are based on K-means clustering algorithms, where the representatives of clusters are expressed by linear models and the assignment of an element to a cluster is performed according to the minimum distance to the model, in the sense of ordinary least squares (OLS). The proposed method extends this strategy to data expressed by empirical distributions or histograms. The present work refers to one of the regression models proposed in the analysis of the dependence of histogram type variables and to the k-means algorithm developed for such data. The metric used is the L_2 Wasserstein distance. An application on real distributional data corroborate the method.

Abstract *In questo lavoro si propone una strategia di regressione cluster-wise per dati in forma di distribuzioni. L'idea é che l'insieme dei dati osservati presentino una differente relazione di causualitá tra una variabile dipendente e un insieme di variabili indipendenti, per ciascuna classe. In letteratura diversi metodi di regressione cluster-wise si basano su un algoritmo di tipo K-means, dove i rappresentanti dei cluster sono espressi da modello di regressione lineare e l'assegnazione avviene sulla base della minima distanza dal modello, nel senso dei minimi quadrati. Il metodo proposto estende tale strategia a dati espressi da distribuzioni empiriche o istogrammi. Il presente lavoro fa riferimento ad uno dei modelli di regressione*

proposti nell'ambito dell'analisi della dipendenza di variabili di tipo istogramma e all'algoritmo k-means, esteso a tali dati. In particolare, la metrica utilizzata é la distanza L_2 di Wasserstein. Un'applicazione su distribuzioni di dati reali permette di validare la metodologia proposta.

Key words: Cluster-wise regression, Distributional data, Wasserstein distance

1 Introduction

In this paper we propose a cluster-wise regression strategy for distributional-valued data, in the framework of distributional data analysis [1], [8].

Cluster-wise linear regression (CLR) comprises a collection of methods developed to find the best fitting models according to the clustering of data [14], therefore, they aim at finding simultaneously the clusters and the models, by optimizing suitable criteria.

A pioneering paper in the search of local models and a clustering of data is the Typological Principal Component Analysis [7]. It is based on the simultaneous search, by alternating steps, of k subspaces of maximal inertia and on the assignment of the elements to the cluster according to the minimum distances to the local plane, until the convergence to a stable partition and K final sub-spaces. Then, Spath ([14], [15], [16]) focuses on the partitioning of a set of objects into K classes and establishing a regression model within each class. Thus, CLR can be characterized as a combination of cluster analysis (partitioning) and regression, where the representatives of the clusters are expressed by linear models and the assignment of an element to a cluster is performed according to the minimum distance to the model, in the sense of ordinary least squares. Preda et al. [13] proposed a clusterwise method based on PLS regression. Mixture-model formulations of CLR have been also proposed in [4], [12], [18] that assume the response variable estimations to be obtained from a mixture of K conditional density distributions.

In the framework of Symbolic Data Analysis [1], [3] presented a cluster-wise generalization for interval data based on a double regression on the centers and radii of the intervals, according to a suitable strategy in the analysis of this kind of multivalued data. Here, we propose a generalization of the K-means based cluster-wise regression for another type of symbolic data, the distributional-valued data, which are expressed by empirical distributions or histograms.

Distributional-valued data are a way to summarize large amounts of data, as they allow to treat information already in aggregate form. Recently many methods have been developed based on a suitable metric, the L_2 Wasserstein distance; they have allowed to extend classical data analysis methods to distribution-valued data. The cluster-wise regression method, here proposed, refers to one of the regression models for histogram type variables [8] and to the k-means algorithm developed for such data [9].

The main contribution of the proposed algorithm consists in analysing linear dependence structures for clusters of distributional data, which take into account the different characteristics (location, variability and shape) of the distributions in each cluster, also related to the decomposition property of the L_2 Wasserstein distance. An application on distribution of aggregated real data corroborates the procedure.

2 Distributional-valued data and L_2 Wasserstein metric

Let $Q = \{o_1, \ldots, o_N\}$ be a set of N objects described by $p+1$ distributional-valued variables. We assume that one of the $p+1$ distributional-valued variables is related to a dependence relationship by the other p ones. Then, we denote with Y the dependent variable and with X_j $(j = 1, \ldots, p)$ the independent variables, observed on the N individuals. Each i-th object o_i $(1 \leq i \leq N)$ is represented by $p+1$ distributions (or distributional-valued data): f_i^y, f_{ij}^x $(j = 1, \ldots, P)$.

Several distances to compare density or frequency distributions have been proposed in the literature. Among them, we consider the L_2 Wasserstein distance [17] due to its properties.

Given two *pdf*'s $f(x)$ and $g(x)$, with means $\bar{x}_f$ and $\bar{x}_g$ and finite standard deviations s_f and s_g. From the associated cumulate distribution functions $F(x)$ and $G(x)$ and the respective *quantile functions* $x_f(t) = F^{-1}(t)$ and $x_g(t) = G^{-1}(t)$, the L_2 Wasserstein distance [17] is defined as follows:

$$d_W(f,g) = \sqrt{\int_0^1 \left[x_f(t) - x_g(t)\right]^2 dt}. \tag{1}$$

In [2] it is shown that the squared L_2 Wasserstein distance can be rewritten as:

$$d_W^2(f,g) = \left(\bar{x}_f - \bar{x}_g\right)^2 + \int_0^1 \left[x_f^c(t) - x_g^c(t)\right]^2 dt. \tag{2}$$

Where $\bar{x}_f$ and $\bar{x}_g$ are the averages of the distributions and $x_f^c(t)$ and $x_g^c(t)$ are the respective centered quantiles functions.

3 Clusterwise Regression for Distributional-valued data (CRD)

The proposed method looks for a partitioning of the set Ω of distributional data into K homogeneous clusters and the best fitting regression equation for each cluster.

The regression model used to fit distributional data was introduced by [10], as follows:

$$y_i(t) = \beta_0 + \sum_{j=1}^{p} \beta_j \bar{x}_{ij} + \sum_{j=1}^{p} \gamma_j x_{ij}^c(t) + e_i(t), \quad \forall t \in [0,1] \tag{3}$$

where: β_o is the constant, β_j's are the coefficients associated to the vectors of the averages $\bar{x}_{ij}$ of the distributions f_{ij}, and γ_j are the coefficients of the centered quantile functions x_{ij} ($j = 1, \ldots, p$).

This model decomposition, due to the Wasserstein distance properties, allows to consider separately the two components related to the location and the variability-shape of the distributions. In order to estimate these parameters, we define the Sum of Square Errors function (SSE) like in the LS method, using the squared Wasserstein L_2 metric:

$$\begin{aligned} SSE(\beta_0, \beta_j, \gamma_j) &= \sum_{i=1}^{n} \int_0^1 e_i^2(t)dt = \\ &= \sum_{i=1}^{n} \int_0^1 \left[y_i(t) - \left(\beta_0 + \sum_{j=1}^{p} \beta_j \bar{x}_{ij} + \sum_{j=1}^{p} \gamma_j x_{ij}^c(t) \right) \right]^2 \end{aligned} \tag{4}$$

According to the aim of the cluster-wise regression model, fixed the number K of clusters, the better partition $P_k = C_1, \ldots, C_K$ and the best fitting models $\hat{y}^k$ for each cluster C_k, are achieved by minimising the $SSE(\beta_0^k, \beta_j^k, \gamma_j^k | P_k)$:

$$\begin{aligned} SSE(\beta_0^k, \beta_j^k, \gamma_j^k | P_k) &= \sum_{k=1}^{K} \sum_{i \in C_k} \int_0^1 e_{ik}^2(t)dt = \\ &= \sum_{k=1}^{K} \sum_{i \in C_k} \int_0^1 \left[y_i^k(t) - \left(\beta_0^k + \sum_{j=1}^{p} \beta_j^k \bar{x}_{ij} + \sum_{j=1}^{p} \gamma_j^k x_{ij}^c(t) \right) \right]^2 dt \end{aligned} \tag{5}$$

The assignment of the element o_i to a cluster C_k is performed according to the minimum error e_{ik}.

The convergence of the algorithm is guaranteed by the decreasing of the criterion relating to the improvement of the fitting of the regression models of clusters.

We consider two indexes to evaluate the goodness of fit of the cluster-wise regressions: the Ω index proposed by [6], and the $RMSE_W$ (Root Mean Square Error, according to the L_2 Wasserstein distance), computed for each cluster (here denoted as Ω^k and $RMSE_W(C_k)$), and globally ($RMSE_W(P_k)$) for the partition:

$$\Omega^k = \frac{\sum_{i \in C_k} d_W^2(\hat{y}_i^k(t), \bar{y}^k)}{\sum_{i \in C_k} d_W^2(y_i^k(t), \bar{y}^k)}; \; RMSE_W(C_k) = \sqrt{\frac{SSE(\beta_0^k, \beta_j^k, \gamma_j^k | C_k)}{n_k}} \tag{6}$$

$$RMSE_W(P_k) = \sqrt{\frac{\sum_{k=1}^{K} SSE(\beta_0^k, \beta_j^k, \gamma_j^k | C_k) \cdot n_k}{N}} \tag{7}$$

where: $\bar{y}^k$ (for $k = 1, \ldots, K$) and $\bar{y}$ are the averages of the distributional-values of the y_i's belonging to the cluster C_k, for each $C_k \in P_k$, and the average of the all

observed distributional-values y_i (for $i = 1, \ldots, N$), respectively; n_k is the cardinality of the cluster C_k (for $k = 1, \ldots, K$).

4 Application

The proposed method has been corroborated on the air quality dataset from the Clean Air Status and Trends Network (CASTNET), also used in [10]. The data are refereed to the Ozone concentration in 78 USA sites and to some related variables. Especially, we have selected Temperature (X_1) ($^\circ C$), Solar Radiation (X_2) (W/m^2) and of Wind Speed (X_3) (m/s), as explicative variables to study the linear effect on the Ozone concentration (Y) (ppb). The period of reference to summarize the hourly data is the summer season of 2010 and the central hours of the days (10 a.m. - 5 p.m.). For each one of the 78 site, Ozone concentration, Temperature, Solar Radiation and Wind Speed are expressed by their "summer-daylight hours" distributions (histograms). Setting the number of clusters to $K = 5$, the results of CDR are shown in Tab. 4 compared to the global Regression model of Distributional data (RD):

Method	N	Ω	$RMSE_W$
RD	78	0.81	4.54
	n_k	Ω^k	$RMSE_W(C_k)$
CRD(C_1)	18	0.93	2.71
CRD(C_2)	34	0.92	3.02
CRD(C_3)	4	0.90	4.76
CRD(C_4)	10	0.87	3.35
CRD(C_5)	12	0.86	3.47
			$RMSE_W(P_k)$
CRD			**3,15**

The clusterwise regression performs a better fitting of the regression models, for each cluster data, as shown by the higher values of the indexes Ω^k and $RMSE_W(C_k)$ compared with the $\Omega = 0.81$ and $RMSE_W = 4.54$ of the global model (RD). Only the $RMSE_W(C_3)$ is a little higher than the $RMSE_W$ compensate for the Ω^3 lower than Ω. Based on these results, we are confident that the CRD can better catch the linear dependence of the regressor from the exploratory distributional variables when data arise from different sub-populations or the relationship between Y and the X_j variables is not linear.

5 Conclusion

In this paper we have introduced a suitable clusterwise regression model for distributional data. The proposed model combines the K-means clustering algorithm with a regression model for distributional-valued data in order to identify both a partition of the data and the best fitting regression models (one for each cluster). The use of the L_2 Wasserstein distance has allowed to analyse the linear relationships of the independent variables on the response one, with respect to the averages of the distributions and the centred quantile functions which express the variability and shape characteristics of the distribution of data. The application of the proposed strategy on environmental data sets has shown the interest of this approach.

A nonparametric approach for nonlinear variable screening in high-dimensions

Un approccio non parametrico per la selezione di variabili non lineari in alta dimensionalità

Giordano Francesco, Milito Sara and Parrella Maria Lucia

Abstract We present a fully-nonparametric method for screening selection called Derivative Empirical Likelihood Independent Screening (D-ELSIS) for regression analysis in high-dimensions. Since our method is model-free, it is able to identify explanatory variables that contribute to the explanation of the response variable in nonparametric and non-additive contexts. The proposed method is a two-step approach that combines the estimation of marginal derivatives by local polynomials together with the empirical likelihood technique. In the first step D-ELSIS selects the relevant variables, while in the second step it identifies the nonlinear ones. The simulation results give evidence of a good performance for D-ELSIS.

Abstract *Presentiamo un metodo non parametrico per la selezione di variabili chiamato Derivative Empirical Likelihood Independent Screening (D-ELSIS) per la regressione in alta dimensionalità. Poichè il nostro metodo è model-free, è capace di identificare le variabili esplicative che contribuiscono alla spiegazione della variabile di risposta in constesti non parametrici e non additivi. Il nostro approccio prevede due step e combina la stima della derivata marginale effettuata con i polinomi locali con la tecnica dell'empirical likelihood. Nel primo step D-ELSIS seleziona le variabili rilevanti, mentre nel secondo identifica le variabili non lineari. Le simulazioni presentate mostrano come il metodo di screening D-ELSIS funzioni in modo soddisfacente.*

Key words: screening selection, high-dimensions, nonparametric regression.

1 Introduction

Statistical analysis with high-dimensional data has the main purpose of identifying a set of relevant variables that contribute to the explanation of a given response variable. Often, however, we are also interested in the type of relationship between the explanatory variables and the response. Suppose that we have a random sample $\{(\mathbf{X}_i, Y_i)\}_{i=1}^n$ from the data model

$$Y_i = m(\mathbf{X}_i) + \varepsilon_i \tag{1}$$

where Y is the response variable, $\mathbf{X}$ is the vector of p candidate variables and ε is the error, with $E(\varepsilon|\mathbf{X}) = 0$. Let X_j denote a generic univariate covariate. Furthermore, $m(\cdot)$ is the unknown regression function. In our method, we do not impose any particular form to the function $m(\cdot)$, so we consider a general class of regression problems, including additive and non-additive models. Regarding the dimensionality p of the variable vector $\mathbf{X}$, this can grow exponentially with the sample size n, and, without loss of generality, we assume that $E(Y) = 0$ implying that $E\{m(\mathbf{X})\} = 0$. Let us denote with

$$M_* = \{1 \leq j \leq p : \text{the } j\text{-th variable in } \mathbf{X} \text{ is relevant for explanation of } Y\}$$

the set of s true relevant covariates in model (1). Moreover, we consider a very sparse model: only a small fraction of the candidate variables contributes to the response ($s \ll p$). Among these s covariates, we assume that l have a linear effect on the response and $s - l$ have a nonlinear effect.

In order to identify the s relevant covariates and the nonlinear ones in M_*, in a high-dimensional nonparametric framework with p very large, we propose a two-step independence model-free feature screening technique that combines two different elements: the local polynomial regression and the empirical likelihood technique. The procedure is called Derivative Empirical Likelihood Independence Screening (D-ELSIS). In the first step, we apply the local polynomial regression to estimate a marginal derivative with respect to the covariate X_j, for $j = 1, \ldots, p$ (so, p derivatives in total). By using the derivatives, we investigate the marginal contribution from each variable in explaining Y to justify whether it is relevant or not. Then, the procedure checks by the empirical likelihood (a nonparametric inference method, see Owen (2001)) if these derivatives are uniformly zero (or not) on the support of each variable. Those variables for which the test is passed are chosen as relevant covariates. In the second step, we choose the top ranked variables from the first step, and we consider, for each of these, the difference between the marginal derivative and its mean. If this difference is uniformly zero on the support, then we conclude that the covariate taken into consideration is linear. In order to test this difference we use, again, the empirical likelihood. Those variables for which the test is passed are chosen as nonlinear covariates. Until now, based on our knowledge, no other screening method uses the local polynomial estimation of the first marginal

derivative with a twofold purpose: screening of relevant variables and selection of nonlinear ones (see Chang et al. (2016), Lian et al. (2014) and the reference therein).

In Section 2 we review the local polynomials for derivative estimation. In Section 3 we introduce the D-ELSIS procedure to carry out screening of relevant variables and we show how to use it for nonlinear screening. A simulation study in Section 4 assesses the performance of the proposed D-ELSIS method.

2 Derivative estimation by local polynomials

Denoting with $f(x)$ the marginal relation between Y and X, where $X = X_1, \ldots, X_n$ is a one-dimensional explanatory variable, its local polynomial estimation is derived by means of a weighted least squares regression fitted at each point of interest, x, using data from its neighbourhood. Suppose that the $(d+1)^{th}$ derivative of $f(x)$ at the point x exists and is continuous. We approximate locally the marginal function $f(x)$ using Taylor's Expansion by a polynomial of order d. Then, we can estimate the expansion terms using weighted least squares by minimizing the following equation:

$$\sum_{i=1}^{n} \left[Y_i - \sum_{v=0}^{d} \beta_v(x)(X_i - x)^v \right]^2 K_h(X_i - x) \tag{2}$$

where h, called the bandwidth, controls the size of the neighbourhood around x, $K_h(\cdot)$ controls the weights and $K_h(x) \equiv K(x/h)/h$ with K a kernel density function. Let $\hat{\beta} = (\hat{\beta}_1, \ldots, \hat{\beta}_d)$ be the solution of (2), then $\hat{f}^{(v)}(x) = v!\hat{\beta}_v$ is an estimator for $f^{(v)}(x)$ with $v = 0, \ldots, d$. In matrix notation, let $\mathbb{X}$ be the design matrix centred at x:

$$\mathbb{X} = \begin{pmatrix} 1 & (X_1 - x) & \ldots & (X_1 - x)^d \\ \vdots & \vdots & & \vdots \\ 1 & (X_n - x) & \ldots & (X_n - x)^d \end{pmatrix}, \tag{3}$$

$\mathbf{Y} = (Y_1, \ldots, Y_n)^T$ and $\mathbf{W}$ a diagonal matrix of weights with diagonal elements $K_h(X_i - x)$, for $i = 1, \ldots, n$. Then, the local estimate of $f^{(v)}(x)$ with a dth degree polynomial is

$$\hat{f}^{(v)}(x; d, h) = v!\mathbf{e}_{v+1}^T (\mathbb{X}^T \mathbf{W} \mathbb{X})^{-1} \mathbb{X}^T \mathbf{W} \mathbf{Y} = v! \sum_{i=1}^{n} W_{i,d,h}(x) Y_i \tag{4}$$

for $v = 0, \ldots, d$, where $W_{i,d,h}(x) = \mathbf{e}_{v+1}^T (\mathbb{X}^T \mathbf{W} \mathbb{X})^{-1} \mathbb{X}^T \mathbf{W} \mathbf{e}_i$. Here $\mathbf{e}_r$ is the $(d+1) \times 1$ vector having 1 in the rth entry and zeros elsewhere. In general, we need a polynomial of order $d = v + 1$ (see Fan and Gijbels (1996)), so we use the local quadratic estimator, *i.e.* $d = 2$, in order to estimate the first derivative ($v = 1$).

3 The proposed procedure

In the first step of the procedure, we estimate the first marginal derivative of our nonparametric model (1) using (4) with $d = 2$. In order to use an univariate local estimator, we consider $f_j(x) = E(Y|X_j = x)$, that is the marginal contribution of X_j locally at x. Although this significantly alters the regression function, it does not entail significant consequences in terms of variable selection, since both the original (non-additive) model and the one we work with (its marginalized additive approximation) depend on the same set of relevant variables.

In order to implement the proposed method for each variable X_j we select n_{X_j} equally spaced points between the first and the third quartile of the support $\mathscr{X}_j$, obtaining the set $C_j = (x_{1j}, \ldots, x_{n_{X_j}j})$. For assessing $f_j'(x) := f^{(1)}(x) = 0$ at given x without distributional assumptions, we construct the following empirical likelihood ratio (*e.l.r.*) statistic, following the same steps of Chang et al. (2016):

$$EL_j(x,0) = \sup_w \left\{ \prod_{i=1}^{n} w_i : w_i \geq 0, \sum_{i=1}^{n} w_i = 1, \sum_{i=1}^{n} w_i W_{i,2,h}(x) Y_i = 0 \right\}. \tag{5}$$

Applying the Lagrange multiplier method, we obtain the logarithm of the *e.l.r.*

$$l_j(x,0) = -2\log\{EL_j(x,0)\} - 2n\log n = 2\sum_{i=1}^{n} \log\{1 + \lambda W_{i,2,h}(x) Y_i\} \tag{6}$$

where λ is the univariate Lagrange multiplier solving $\sum_{i=1}^{n} \frac{W_{i,2,h}(x)Y_i}{1+\lambda W_{i,2,h}(x)Y_i} = 0$.
Since $\sum_{i=1}^{n} W_{i,2,h}(x)Y_i$ converges in probability to the marginal derivative of X_j evaluated at x, a large value of $l_j(x,0)$ is taken as evidence against $f_j'(x) = 0$. Then, $l_j(x,0)$ is a statistic for testing whether or not (4) with $d = 2$ has zero mean locally at x. For assessing $f_j'(x) \equiv 0$ uniformly on $\mathscr{X}_j$, we use

$$l_j(0) = \sup_{x \in \mathscr{X}_j} l_j(x,0) \quad \forall\, j = 1, \ldots, p.$$

We evaluate the statistic l_j using $l_j(0) = \max_{1 \leq i \leq n_{X_j}} l_j(x_{ij}, 0)$. With this expedient, we can use the univariate optimisation to solve (6) by the Lagrange multiplier method. For feature screening purposes, we sort l_j for all $j = 1, \ldots, p$ in decreasing order. In this way, we identify, for a given threshold γ_n, the set of relevant covariates

$$\widehat{M}_{\gamma_n} = \{1 \leq j \leq p : l_j \geq \gamma_n\}.$$

Since γ_n is difficult to estimate, we only consider the top ranked covariates.

In the second step of the procedure, we consider the null hypothesis that the covariate j is linear, which means $f_j'(x) - E(f_j'(\cdot)) = 0$ for each $x \in C_j$. Moreover, let $\widehat{\mu}_j = 1/n_{X_j} \sum_{u=1}^{n_{X_j}} \widehat{f}_j'(\mathrm{x}_{uj})$ be an estimator of the expected value of $f_j'(\cdot)$. Then, we construct the following empirical likelihood statistic for non linear covariates

$$ELN_j(x,0) = \sup_w \left\{ \prod_{i=1}^{n} w_i : w_i \geq 0, \sum_{i=1}^{n} w_i = 1, \sum_{i=1}^{n} w_i [W_{i,2}(x) Y_i - \widehat{\mu}_j] = 0 \right\}, \quad (7)$$

and the respective logarithm of *e.l.r.*

$$ln_j(x,0) = -2\log\{ELN_j(x,0)\} - 2n\log n = 2\sum_{i=1}^{n} \log\left\{1 + \lambda\left[W_{i,2}(x)Y_i - \widehat{\mu}_j\right]\right\} \quad (8)$$

where λ is the univariate Lagrange multiplier solving $\sum_{i=1}^{n} \frac{W_{i,2}(x)Y_i - \widehat{\mu}_j}{1+\lambda\left[W_{i,2}(x)Y_i - \widehat{\mu}_j\right]} = 0$. Since $\sum_{i=1}^{n}\left[W_{i,2}(x)Y_i - \widehat{\mu}_j)\right]$ converges in probability to the difference between the marginal derivative of X_j evaluated at x and its mean, a large value of $ln_j(x,0)$ is taken as evidence that the covariate j is nonlinear, which means $f_j'(x) - E(f_j'(\cdot)) \not\equiv 0$. For assessing $f_j'(x) - E(f_j'(\cdot)) \equiv 0$ uniformly on $\mathscr{X}_j$, we use

$$ln_j(0) = \sup_{x \in \mathscr{X}_j} ln_j(x,0) \quad \forall\ j = 1, \ldots, p.$$

Again, we evaluate the sup by the max of the test-statistic over C_j. For nonlinear feature screening purposes, we sort ln_j for all $j = 1, \ldots, p$ in decreasing order and we take the top ranked covariates as the nonlinear covariates of model (1).

4 Simulations

Several simulation experiments are conducted to investigate the performance of the proposed D-ELSIS method. Concerning the empirical likelihood, we used the R package **emplik**, while for the estimation of the bandwidth we used the R package **NonpModelCheck**. We set $n = (200, 500)$ and $p = (50, n/2, 2n)$. We report three criteria: (i) the median of the Minimum Model Size (MMS), *i.e.* the minimum number of predictors needed to keep all the relevant ones, for 100 repetitions; (ii) the IQR divided by 1.34 (SD), *i.e.* a robust measure of the standard error of MMS; (iii) the True Positive Rate in percentage (TPR) that controls the precision measuring the proportion that all active predictors are selected. To calculate the TPR we consider that the predicted relevant variables are included in the first 20, while the nonlinear ones are in the first 10. We consider a model with both linear and non linear covariates. This case is taken from Example 2 of Chang et al. (2016). Data are generated from the model

$$Y = 5X_1 + 3(2X_2 - 1)^2 + 4\frac{\sin(2\pi X_3)}{2 - \sin(2\pi X_3)} + 6\big[0.1\sin(2\pi X_4) +$$
$$0.2\cos(2\pi X_4) + 0.3(\sin(2\pi X_4))^2 + 0.4(\cos(2\pi X_4))^3 + 0.5(\sin(2\pi X_4))^3\big] + \sigma\varepsilon.$$

Here the predictors X_j are *i.i.d* random variables of Uniform distribution $U(0,1)$, and $\varepsilon \sim N(0,1)$ is independent of all X_j. In this case we have 3 relevant nonlinear

Table 1 Simulation results

n	p		relevant variables				linear vs nonlinear			
			$\sigma^2=1$	$\sigma^2=1.74$	$\sigma^2=2$	$\sigma^2=3$	$\sigma^2=1$	$\sigma^2=1.74$	$\sigma^2=2$	$\sigma^2=3$
200	50	MMS(SD)	4(0.00)	4(0.00)	4(0.00)	4(0.00)	3(0.75)	3(0.75)	3(0.75)	3(0.75)

	1000	MMS(SD)	4(0.00)	4(0.00)	4(0.75)	4(0.19)	3(0.00)	3(0.00)	3(0.75)	3(0.00)
		TPR	100.00	100.00	100.00	100.00	100.00	100.00	100.00	100.00

covariates and 1 relevant linear covariate. We consider four different signal to noise ratios by varying σ^2, as in Chang et al. (2016).

From Table 1 we are able to correctly identify the set of the 4 true relevant variables in the first 20 top ranked covariates and the 3 true nonlinear variables in the first 10 position for all signal to noise ratio considered, with a precision at least of 98%. In the first step we have a value 4 for the median of MMS, while in the second step this value is 3. This means that the only linear covariate is identified among the relevant ones in the first step, while in the second step it is positioned in the ranking after the nonlinear ones. The (average) computational times in seconds for one iteration of D-ELSIS procedure, using a Windows 10 PC with Intel Core i7, Dual-Core 2.70 GHz, are reported in the following table:

n	200			500		
p	50	100	400	50	250	1000
	5.85	8.79	40.71	7.24	27.71	120.07

Adjusted scores for inference in negative binomial regression

Funzioni di punteggio aggiustate per l'inferenza nella regressione binomiale negativa

Euloge C. Kenne Pagui, Alessandra Salvan, Nicola Sartori

Abstract Overdispersion is often encountered when fitting a Poisson model. An alternative model to handle the issue can be the negative binomial characterized by the mean with an additional dispersion parameter. With small sample sizes, the maximum likelihood estimator of the dispersion parameter may be subject to a significant bias. This paper studies negative binomial regression using the adjusted scores of Firth (1993) and Kenne Pagui et al. (2017) for mean and median bias reduction, respectively. A simulation study based on an application compares the proposed methods with maximum likelihood.

Abstract La sovradispersione si riscontra spesso quando si adatta un modello di Poisson. Un modello alternativo puo` essere la binomiale negativa carat-terizzata dalla media e con un parametro di dispersione aggiuntivo. Con campioni di piccole dimensioni, lo stimatore di massima verosimiglianza del parametro di dis-persione puo` essere soggetto ad una distorsione significativa. Questo articolo studia l'inferenza nel modello di regressione binomiale negativa usando le funzione di punteggio aggiustate di Firth (1993) e Kenne Pagui et al. (2017) per la riduzione della distorsione in media e in mediana, rispettivamente. Lo studio di simulazione basato su un'applicazione confronta i metodi proposti con quello della massima verosimiglianza.

Key words: Overdispersion, bias reduction, likelihood, count data.

1 Introduction

The negative binomial model (e.g. Fisher, 1941; Engel, 1984; Lawless, 1987; Saha and Paul, 2005) is often used in the analysis of count data when the latter display overdispersion. With moderate sample sizes, the maximum likelihood estimator of the dispersion parameter may be subject to a substantial bias that can influenced the inferential conclusions.

Saha and Paul (2005) proposed a bias corrected maximum likelihood (ML) estimator for the mean and dispersion parameters of the negative binomial. Their paper does consider model with regression structure on the mean.

This paper extends the work of Saha and Paul (2005) by developing mean bias reduction (meanBR) for negative binomial regression following Firth (1993), whose adjusted score does not depends on the ML estimate. The estimator, solution of the bias reducing estimating equation has smaller mean bias with respect to the ML estimator. A second alternative adjusted score is proposed in Kenne Pagui et al. (2017), aiming at median bias reduction (medianBR). The resulting estimator is componentwise third-order median unbiased, and is equivariant under componentwise monotone reparameterization. We analyse the properties of the ML, meanBR and medianBR estimators in a simulation study based on real dataset.

2 Negative binomial regression model

Let y_i, $i = 1,\ldots,n$, be independent realizations of negative binomial random variables with mean $\mu_i = g^{-1}(\eta_i)$ and dispersion parameter κ, where $g^{-1}(\cdot)$ is the inverse of the link function, $\eta_i = x_i\beta$, $\beta = (\beta_1,\cdots,\beta_p)^\top$ and $x_i = (x_{i1},\ldots,x_{ip})$ is a row vector of covariates. The probability mass function of Y_i is

$$f_{Y_i}(y_i;\mu_i,\kappa) = \frac{\Gamma(y_i+\kappa^{-1})}{y_i!\Gamma(\kappa^{-1})}\left(\frac{\kappa\mu_i}{1+\kappa\mu_i}\right)^{y_i}\left(\frac{1}{1+\kappa\mu_i}\right)^{\kappa^{-1}}, \quad y_i = 0,1,\cdots, \qquad (1)$$

with $\kappa > 0$ and $\beta \in \mathbb{R}$. Noting that for any $\kappa > 0$, $\Gamma(y+\kappa^{-1})/\Gamma(\kappa^{-1}) = \kappa(\kappa+1)\cdots(\kappa+y-1)$, the log likelihood is

$$\ell(\beta,\kappa) = \sum_{i=1}^{n}\left\{\sum_{j=0}^{y_i^*}\log(1+\kappa j) + y_i\log\frac{\mu_i}{1+\kappa\mu_i} - \frac{1}{a}\log(1+\kappa\mu_i)\right\},$$

where $y_i^* = y_i - 1$ and $\sum_{j=0}^{y_i^*}$ is zero when $y_i^* < 0$. Let us denote by $\theta = (\beta^\top,\kappa)^\top$ and by $\hat{\theta}$ the maximizer of $\ell(\theta)$.

3 Bias reduction

For a general parametric model with p-dimensional parameter θ and log likelihood $\ell(\theta)$, based on a sample of size n, let $U_r = U_r(\theta) = \partial\ell(\theta)/\partial\theta_r$ be the r-th component of the score function $U(\theta)$, $r = 1,\dots,p$. Let $j(\theta) = -\partial^2\ell(\theta)/\partial\theta\partial\theta^\top$ be the observed information and $i(\theta) = E_\theta\{j(\theta)\}$ the expected information.

Firth (1993) proposes a suitable adjusted score for meanBR, of the form

$$\tilde{U}(\theta) = U(\theta) + A^*(\theta),$$

where the vector $A^*(\theta)$ has components $A^*_r = \frac{1}{2}\mathrm{tr}\{i(\theta)^{-1}[P_r + Q_r]\}$, with $P_r = E_\theta\{U(\theta)U(\theta)^\top U_r\}$ and $Q_r = E_\theta\{-j(\theta)U_r\}$, $r = 1,\dots,p$. The resulting estimator, $\hat{\theta}^*$, has a mean bias of order $O(n^{-2})$, compared with $O(n^{-1})$ of the ML estimator.

The medianBR estimator, $\tilde{\theta}$, is obtained as solution of the estimating equation based on the adjusted score (Kenne Pagui et al., 2019)

$$\tilde{U}(\theta) = U(\theta) + \tilde{A}(\theta),$$

with $\tilde{A}(\theta) = A^*(\theta) - i(\theta)F(\theta)$. The vector $F(\theta)$ has components $F_r = [i(\theta)^{-1}]_r^\top \tilde{F}_r$, where $\tilde{F}_r$ has elements $\tilde{F}_{r,t} = \mathrm{tr}\{h_r[(1/3)P_t + (1/2)Q_t]\}$, $r,t = 1,\dots,p$, with the matrix h_r obtained as $h_r = \{[i(\theta)^{-1}]_r[i(\theta)^{-1}]_r^\top\}/i^{rr}(\theta)$, $r = 1,\dots,p$. Above, we denoted by $[i(\theta)^{-1}]_r$ the r-th column of $i(\theta)^{-1}$ and by $i^{rr}(\theta)$ the (r,r) element of $i(\theta)^{-1}$.

In the continuous case, each component of $\tilde{\theta}$, $\tilde{\theta}_r$, $r = 1,\dots,p$, is median unbiased with error of order $O(n^{-3/2})$, i.e. $\Pr_\theta(\tilde{\theta}_r \le \theta_r) = \frac{1}{2} + O(n^{-3/2})$, compared with $O(n^{-1/2})$ of ML estimator. Moreover, the asymptotic distribution of $\hat{\theta}^*$ and $\tilde{\theta}$ is the same as that of the ML estimator, that is $\hat{\theta} \dot{\sim} \mathcal{N}_p(\theta, i(\theta)^{-1})$.

4 Applications: ants and favourite sandwich

Consider the Ants dataset, obtained through an experiment conducted by students of a degree course in Applied Sciences of an Australian university (Mackisack, 2017). The goal of the experiment is to evaluate the preference of ants of the species Iridomyrmex purpureus, with respect to different types of sandwich. For each of 4 types of bread, Bread (1, rye; 2, wholemeal; 3, multigrain; 4, white), 3 types of filling, Filling (1, Vegemite; 2, peanut butter; 3 ham and pickles), and presence or not butter, Butter (1, present; -1, absent), two sandwich samples have been positioned, at random times near the entrance of an anthill. After 5 minutes, on each a glass was placed and the number of captured ants was counted, Ant_count. The interest is in evaluating how the number of ants depends on the characteristics of the sandwich. In this analyses, we consider only two covariates, Filling and Butter. We assume model (1), with

$$\log \mu_i = \beta_1 + \beta_2 x_{i2} + \beta_3 x_{i3} + \beta_4 x_{i4} + \beta_5 x_{i2} x_{i4} + \beta_6 x_{i3} x_{i4},$$

where x_{i2} is coded 1 if Filling is peanut butter o 0 otherwise, x_{i3} is 1 if Filling is ham and pickles o 0 otherwise while x_{i4} is 1 if Butter is present o 0 otherwise.

The parameter estimates of model (1) and their corresponding standard errors are displayed in Table 1. The regression coefficient estimates are very close for the three methods, ML, meanBR and medianBR. On the other hand there is difference in the dispersion parameter estimate for ML as compared with the meanBR and medianBR.

Table 1 Ants and favourite sandwich. Estimates of parameters of (1) using ML, meanBR and medianBR. The quantities in parentheses are the corresponding estimated standard errors.

	ML		meanBR		medianBR	
β_1	3.426	(0.121)	3.434	(0.130)	3.431	(0.131)
β_2	0.097	(0.170)	0.097	(0.183)	0.097	(0.185)
β_3	0.468	(0.166)	0.468	(0.180)	0.468	(0.181)
β_4	0.063	(0.170)	0.063	(0.183)	0.063	(0.185)
β_5	0.248	(0.237)	0.248	(0.256)	0.248	(0.259)
β_6	0.277	(0.233)	0.276	(0.252)	0.277	(0.255)
ϕ	0.084	(0.022)	0.103	(0.026)	0.105	(0.026)

To assess the properties of ML, meanBR and medianBR estimators, we performed a simulation study. We considered 10000 replications with parameter values equal to the ML fit of model (1) displayed in Table 1 and covariates held fixed at the observed values. Estimators performance are evaluated in terms of empirical relative bias (RB%), $100\times$ B/$|\beta|$; empirical relative increase in mean squared error from its absolute minimum due to bias (IBMSE%), $100\times$ B^2/SD^2; empirical percentage of underestimation (PU%) and coverage of nominally 95% Wald-type confidence intervals (WALD%). Here, B denotes the absolute bias estimation and SD, its standard deviation. The quantity PU is calculated as the proportion of times that the estimate is smaller than the corresponding true parameter value. Simulation results are shown in Table 2. Both meanBR and medianBR estimators achieve the desired goals and are preferable to ML estimator, especially in terms of coverage of confidence intervals.

Estimation of the treatment effect variance in a difference-in-differences framework

Stima della varianza dell'effetto del trattamento nel metodo della differenza nelle differenze

Marco Doretti and Giorgio E. Montanari

Abstract We compare two regression-based estimators of treatment/policy effects in a standard difference-in-differences setting without additional covariates. These two estimators, deriving from what we term the *piled* and *unpiled* regression models, produce identical finite-sample estimates, thus sharing the same theoretical variance. However, they are not equivalent with regard to the estimation of such a variance. We show that under the assumed model the piled approach should be preferred since it results in a more efficient variance estimator, thereby returning more reliable standard errors for the treatment effect. We further show that this result holds even when the normality assumption for the regression error terms is violated.

Abstract *Nel metodo della differenza nelle differenze, l'effetto del trattamento può essere stimato secondo due diversi modelli di regressione lineare, detti* impilato *e* non impilato*. I due approcci producono le medesime stime nel campione finito, condividendo di fatto la stessa varianza teorica. Tuttavia, essi non sono equivalenti per quanto concerne la stima di questa varianza. In questo lavoro si mostra come, sotto le assunzioni fatte, l'approccio impilato vada preferito, in quanto caratterizzato da uno stimatore della varianza più efficiente. Questo risultato vale anche in caso di violazione dell'ipotesi di normalità degli errori nella regressione.*

1 Introduction

Difference-in-differences (DiD) is a well-known technique to estimate a treatment/policy effect in the presence of repeatedly measured data [4]. In the most basic setting, an outcome of interest is measured on two groups of units over two temporal occasions, in between of which one group receives the treatment while the other - also called control group - does not. The name of the method stems from the fact that the target effect is identified by subtracting the difference between the post- and pre-treatment outcome expectations in the control group from the same difference in the treated group. In a causal inference perspective, the DiD method identifies an average treatment effect on the treated [1].

Identification of DiD effects relies on the so called *parallel trends* assumption, stating that the expected difference in the outcome between the two time points in the treated group, had its units not received the treatment, would have been equal to that of the control group. In other words, the spontaneous (*i.e.*, not due to the treatment) dynamic governing the temporal evolution of the outcome, possibly driven by unobserved factors, has to be the same for the two groups. When some factors make the spontaneous dynamic differ between the two groups - and data for them are available - a covariate adjustment is in principle possible, though with some provisos concerning endogeneity.

In the basic setting without additional covariates, which is the one considered here, there are many equivalent techniques to estimate the target effect. The most intuitive one is based on a trivial replacement of expectations with sample averages in the DiD identification formula. However, several alternatives including linear regression exist; see for example [2]. All the resulting estimators are known to be algebraically equivalent, yielding exactly the same results in finite samples. As a consequence, they all share the same theoretical variance. However, the way this variance is estimated changes with the undertaken approach. In detail, the considered techniques give rise to two regression-based variance estimators with different performances, thus justifying a choice between them. In this paper, we address this comparison, which - to the best of our knowledge - has not been discussed in the literature yet.

The paper is arranged as follows. In Section 2, we formalize the DiD framework introducing the target effect as well as its equivalent estimators together with their common theoretical variance. The focus on variance estimation is contained in Section 3, where we describe the two competing regression-based variance estimators and state which estimation method should be favoured.

2 Difference-in-differences effect estimators

As typical in a standard DiD framework, we use the index $t = \{0,1\}$ to label the pre- ($t = 0$) and post-treatment ($t = 1$) temporal occasions, while $g = \{0,1\}$ indicates the control ($g = 0$) and treatment ($g = 1$) unit groups. In this setting, y_{gti} denotes

the outcome at time t for the i-th unit of the g-th group, with $i = 1,\ldots,n_0$ for the control group and $i = 1,\ldots,n_1$ for the treatment group. The data generating process is assumed to follow the linear model

$$y_{gti} = \mu + \alpha t + \beta g + \delta gt + e_{gti}, \tag{1}$$

where e_{gti} are independent and identically distributed error terms with $E(e_{gti}) = 0$ and $V(e_{gti}) = \sigma_e^2$, β captures the pre-treatment average difference between the two groups and α represents the trend effect, that is, the aforementioned spontaneous dynamic of the outcome. As a consequence, the interaction parameter

$$\delta = \big\{E(y_{11i}) - E(y_{10i})\big\} - \big\{E(y_{01i}) - E(y_{00i})\big\}$$

isolates the additional effect due to the treatment/policy only, identifying the DiD effect under investigation. Such a parameter can estimated by

$$\hat{\delta} = (\bar{y}_{11} - \bar{y}_{10}) - (\bar{y}_{01} - \bar{y}_{00}),$$

where $\bar{y}_{gt}$ is the sample average of the outcome for units of group g at time t ($g,t = \{0,1\}$). Due to the independence of the error terms, the variance of the $\hat{\delta}$ estimator is given by

$$V(\hat{\delta}) = \sum_{g,t=0}^{1} V\left(\frac{1}{n_g}\sum_{i=1}^{n_g} y_{gti}\right) = 2\sigma_e^2\left(\frac{1}{n_0} + \frac{1}{n_1}\right) = 2\sigma_e^2\frac{n}{n_0 n_1}, \tag{2}$$

where $n = n_0 + n_1$ is the total sample size. Another formulation originates from differentiating Equation (1) with respect to time. Specifically, we have

$$d_{gi} = \alpha + \delta g + u_{gi}, \tag{3}$$

where $d_{gi} = y_{g1i} - y_{g0i}$ and $u_{gi} = e_{g1i} - e_{g0i}$ is a compound error term with $V(u_{gi}) = \sigma_u^2 = 2\sigma_e^2$. The $\hat{\delta}$ estimator can be analogously obtained as $\hat{\delta} = \bar{d}_1 - \bar{d}_0$, with $\bar{d}_g$ representing the sample average of the post- and pre-treatment differences for units in group $g = \{0,1\}$. Clearly, the estimator variance remains as in (2), a fact that can be straightforwardly verified considering that $V(\bar{d}_g) = \sigma_u^2/n_g$.

As mentioned in the Introduction, a regression approach can also be adopted. In detail, two regression models based on Equations (1) and (3) can be fitted to obtain exactly the same effect estimate as above, that is, $\hat{\delta}$. In the first one, the $2n$ observations resulting by piling the pre- and post-treatment outcome values are regressed against an intercept, the two binary indicators of time and group and their interaction. In the second one, the n temporal differences in the outcome d_{gi} are first computed and then regressed against an intercept term and the group indicator only. Henceforth, we will refer to these models as to the *piled* and the *unpiled* model, respectively. In this regression-based perspective, it is easy to analytically show that the variance of the estimated effect $\hat{\delta}$ remains as in (2) in both regression models.

3 Variance estimation

In a classical linear regression framework with homoskedastic, independent and normally distributed error terms, the residual sum of squares divided by the number of residual degrees of freedom of the model is the usual estimator of the error variance. In our simplified context without additional covariates, the regression fitted values reduce to group sample averages. Therefore,

$$S_e^2 = \frac{1}{2n-4} \sum_{g,t=0}^{1} \sum_{i=1}^{n_g} (y_{gti} - \bar{y}_{gt})^2 \tag{4}$$

turns out to be the residual-based estimator of σ_e^2 in the piled regression (1) while

$$S_u^2 = \frac{1}{n-2} \sum_{g=0}^{1} \sum_{i=1}^{n_g} (d_{gi} - \bar{d}_g)^2 \tag{5}$$

is the analogous estimator of $\sigma_u^2 = 2\sigma_e^2$ in the unpiled model (3). It is important to note that the mathematical relationship between the two theoretical variances is not preserved when estimation comes about, meaning that in finite samples we generally have $S_u^2 \neq 2S_e^2$. In other words, the two regression models originate two distinct estimators - namely, S_e^2 and $S_u^2/2$ - of the same variance parameter σ_e^2. As already mentioned, a comparison of these two alternative estimators is therefore sensible. Since both estimators are known to be unbiased, the whole problem reduces to the evaluation of their variances.

In the classical setting outlined above, standard results about the variance of the residual-based estimator of the error variance apply. Indeed, denoting by σ^2 the true error variance and by $\hat{\sigma}^2$ its estimator, it is known that

$$\frac{(N-p)\hat{\sigma}^2}{\sigma^2} \sim \chi^2_{N-p},$$

with $N-p$ being the number of residual degrees of freedom of the model. Consequently, $V(\hat{\sigma}^2) = 2\sigma^4/(N-p)$. An application to our two variance estimators gives

$$V(S_e^2) = \frac{2\sigma_e^4}{2n-4} = \frac{\sigma_e^4}{n-2} \tag{6}$$

and

$$V(S_u^2/2) = \frac{2\sigma_u^4/(n-2)}{4} = \frac{2\sigma_e^4}{n-2}, \tag{7}$$

showing that the ratio $V(S_u^2/2)/V(S_e^2)$ is equal to 2. Therefore, the variance estimator resulting from the piled model is twice as efficient as the unpiled variance estimator, in line with the intuition suggesting to use the former because it is based on a double amount of information. Thus, the piled approach should be preferred

since it provides a less variable estimate of σ_e^2 and, consequently, a more reliable standard error for the DiD effect $\hat{\delta}$.

The standard theory leading to (6) and (7) provides exact results if the error terms e_{gti} follow a normal distribution, which implies also the u_{gi} terms do. Alternatively, a large sample size is required to rely on central-limit-theorem approximations. If the sample size is small and deviations from the normality assumption occur, $V(\hat{\delta})$ is still given by (2) and S_e^2 and $S_u^2/2$ remain unbiased estimators of σ_e^2. Nevertheless, the variance expressions in (6) and (7) are no longer appropriate. Distribution-free formulas for them can still be obtained under the assumption that the error terms e_{gti} are independent and identically distributed.

To derive the requested generalizations of (6) and (7), it is worth to bear in mind two further probability results. The first one states that, given N independent and identically distributed observations $x_1,\ldots,x_N$ from a (not necessarily normal) population with variance σ^2 and kurtosis K (that is, the standardized fourth moment), the variance of the sample variance estimator $s^2 = (N-1)^{-1}\sum_{i=1}^{N}(x_i-\bar{x})^2$, with $\bar{x}$ denoting the sample mean, is

$$V(s^2) = \frac{\sigma^4}{N}\left(K-1+\frac{2}{N-1}\right); \tag{8}$$

see [3]. The second result states that the kurtosis of the difference of two independent random variables having a common variance and a common kurtosis K is equal to $(K+3)/2$; see Appendix 5 for a proof. On the one hand, (8) is of use since the numerators of both (4) and (5) can be thought of as linear combinations of independent sample variances within the respective unit groups; notice that this is not the case with more complex models involving additional covariates. On the other hand, the second result allows to express the kurtosis of the u_{gi} error terms as a simple function of the kurtosis of the error terms e_{gti}, say K_e.

Building on the two probability results above, some algebraic derivations lead to update the variance formulas (6) and (7) when normality of the errors is not invoked. Specifically, we have

$$V(S_e^2) = \frac{\sigma_e^4}{2(n-2)^2}\left\{(K_e-1)\left(n-4+\frac{n}{n_0n_1}\right)+2\left(2-\frac{n}{n_0n_1}\right)\right\} \tag{9}$$

and

$$V(S_u^2/2) = \frac{\sigma_e^4}{(n-2)^2}\left\{\frac{K_e+1}{2}\left(n-4+\frac{n}{n_0n_1}\right)+2\left(2-\frac{n}{n_0n_1}\right)\right\}. \tag{10}$$

In the normal case, it is immediate to verify that (9) and (10) reduce to (6) and (7) respectively because $K_e = 3$. In general, it is easy to show that the ratio between (10) and (9) is always greater than 1, thereby confirming that the piled regression approach should be preferred also when non-normality in the error terms is spotted. Since such a variance ratio is essentially driven by $(K_e+1)/(K_e-1)$, the efficiency gain is higher for smaller values of K_e, and tends to vanish as K_e grows.

4 Conclusions

This paper suggests the use of the piled rather than the unpiled approach for the estimation of treatment/policy effects in a standard DiD framework, even when normality of the regression errors is questionable. However, all the derivations rely on the assumptions of the basic DiD setting, including the absence of additional covariates as well as of a temporal correlation between the error terms e_{g0i} and e_{g1i}. Removing these assumptions might lead to novel variance estimators or, more importantly, to alternative effect estimators with different variances. These topics are worth investigating in future lines of work.

5 Appendix

Let X and Y be two independent random variables with a common variance σ^2 and a common kurtosis K. For simplicity we assume $E(X) = 0 = E(Y)$ so that $K = E(X^4)/\sigma^4 = E(Y^4)/\sigma^4$, though generality is by no means lost. The kurtosis of the difference random variable $Z = X - Y$ is

$$K(Z) = E\left\{\left(\frac{X-Y}{\sqrt{2}\sigma}\right)^4\right\} = E\left(\frac{X^4 - 4X^3Y + 6X^2Y^2 - 4XY^3 + Y^4}{4\sigma^4}\right)$$
$$= \frac{1}{4}\left\{\frac{E(X^4)}{\sigma^4} + 6\frac{E(X^2)E(Y^2)}{\sigma^4} + \frac{E(Y^4)}{\sigma^4}\right\} = \frac{2K+6}{4} = \frac{K+3}{2},$$

which hols true since all the odd-power terms in the right-hand side of the second equality have a null expectation because of the independence assumption.

Exploring multicollinearity in quantile regression

Analisi della multicollinearità nella regressione quantile

Cristina Davino, Tormod Naes, Rosaria Romano and Domenico Vistocco

Abstract The aim of the paper is to propose a simulation study to explore the multicollinearity problem in quantile regression, as compared to the classical linear regression. The simulation exploits the concept of a relevant subspace and relevant predictors, considering different degrees of collinearity among the involved predictors. The approach is based on principal components and consists in evaluating the degree of dependence between the predictors on the basis of the eigenvalue structure of their covariance matrix. It is well known that in case of highly intercorrelated predictors the least squares coefficients, although determinate, posses large standard errors, causing precision problems for their estimation. For this reason, results of the simulation study focus on standard errors estimated according to different collinearity levels. A possible solution based on regression on principal components is briefly presented.

Abstract *L'articolo presenta uno studio di simulazione che mira ad esplorare il problema della multicollinearità nella regressione quantile, offrendo al contempo un parallelo con la regressione lineare classica. Lo studio sfrutta il concetto di sottospazio rilevante e predittori rilevanti, prendendo in considerazione diversi gradi di collinearità tra i predittori. L'approccio, basato sulle componenti principali, consiste nel valutare il grado di dipendenza tra i predittori rispetto alla struttura degli autovalori della loro matrice di covarianza. In caso di predittori altamente intercorrelati, è infatti noto che i coefficienti dei minimi quadrati, sebbene determinati, presentano errori standard elevati, causando problemi di precisione delle stime. risultati presentati si concentrano pertanto sugli errori standard dei coefficienti, stimati in base a diversi livelli di collinearità. Una possibile soluzione al problema è mostrata sfruttando la regressione sulle componenti principali, in luogo dei regressori originari, al fine di eliminare il problema di collinearità.

Key words: multicollinearity, least squares regression, quantile regression, principal component regression

1 Introduction

Regression is widely used in the analysis of socio-economic phenomena to study the dependence of a response variable on a set of predictors. One typical problem in such fields concerns the structure of relations among the predictors, engendering the well-known problem of collinearity [**?**]. Multicollinearity has been extensively explored for least square regression (LS). This is not the case for quantile regression (QR), a well established statistical method aimed to explore the whole conditional distribution of a response variable without posing any parametric assumption for the error (and hence response) distribution ([**?**]; [**?**]). QR estimates separate models for different quantiles $\tau \in [0,1]$, namely QR provides a regression model for each conditional quantile of interest [**?**]. Even if an infinite number of conditional quantiles can be estimated (the quantile process [**?**]), in practice the researcher defines few quantiles of interest, in most cases, the three quartiles, $\tau = [0.25, 0.50, 0.75]$, along with two extreme quantiles, typically $\tau = [0.10, 0.90]$. For each considered quantile, a regression model is estimated, providing a set of coefficients and a fitted response vector. This paper presents a simulation study to explore the collinearity in quantile regression, as compared to the classical linear regression model. Results of a possible solution based on principal component regression are presented. The simulation scheme considers classical normal i.i.d. errors. Further developments will include normal heteroscedastic errors, costant skewness in the response (error) and increasing skewness in the response (error).

2 Simulation study

2.1 Experimental design

The concept of a relevant subspace has been exploited to simulate different degrees of correlation among predictors. It essentially consists of the subspace of the predictor space that is relevant for the variation in the response variable. Principal components analysis allows to take into account of different degrees of correlation. We carried out the analysis using the software R [**?**] and the *simrel* package [**?**]

for linear model data simulations. In particular we set the following values for the simulations:

- number of observations: 100
- number of predictors: 3
- number of relevant principal components: 1
- theoretical R^2 for generating data: 0.7
- coefficient controlling the degree of collinearity: γ
- number of iterations: 1000

According to the concept of relevant subspace, and given the small number of selected predictors, we assume that only one component is relevant for prediction. With respect to the γ coefficient, it regulates the speed of decline in eigenvalues (variances) of the principal components. In particular, the eigenvalues are assumed to decline according to an exponential model and the first eigenvalue is set equal to 1. We considered a grid of values for γ ranging from 0 to 5, using an increment of 0.5. In case of low values of γ we expect no or very low collinearity among predictors, while high collinearity should be present by incrementing γ. As an example, Table **??** reports the percentage of cumulated explained variance for the three components ($Comp_1$, $Comp_2$ and $Comp_3$ on the columns) using one random sample for each level of γ (rows).

Table 1 Percentage of cumulated explained variance on the three principal components (columns) for the considered scenarios (different values of γ on the rows)).

	$Comp_1$	$Comp_2$	$Comp_3$
$\gamma = 0.0$	36.33	70.20	100.00
$\gamma = 0.5$	45.44	79.60	100.00
$\gamma = 1.0$	55.19	91.56	100.00
$\gamma = 1.5$	65.17	95.88	100.00
$\gamma = 2.0$	66.17	98.10	100.00
$\gamma = 2.5$	72.16	99.19	100.00
$\gamma = 3.0$	85.03	99.77	100.00
$\gamma = 3.5$	91.79	99.91	100.00
$\gamma = 4.0$	95.43	99.97	100.00
$\gamma = 4.5$	97.47	99.99	100.00
$\gamma = 5.0$	97.87	100.00	100.00

For each value of the γ grid, the standard errors of the classical linear regression and QR models were computed. We decided to compute LS standard errors using the bootstrap procedure in order to have a fair comparison with QR, where bootstrap is typically used to this end.

2.2 Main results

Simulation results for LS and the three quartiles of QR are shown in Figure **??**. In particular, the different models (LS bootstrap, QR bootstrap for $\tau \in (0.25, 0.5, 0.75)$, where τ denotes the conditional quantile) are depicted on the columns, while rows refer to the regression coefficient ($X1$, $X2$, $X3$). The different boxplot in each panel represent the distribution of the standard error (vertical axis) for the different values of the γ coefficient (horizontal axis). includes several panels. Each panel corresponds to one of the estimated parameters by row ($X1$, $X2$, $X3$).

Results highlight how increasing the degree of collinearity, the distribution of the standard errors increases both in size and variability for each predictor. This trend can be found both in the LS and in the QR. In case of QR the inaccuracy of the estimates is even larger and no particular pattern stands out with respect to the considered quantile. This effect is higher for extreme quantiles (results not shown).

Principal component regression (PC–R) exploits principal component analysis to overcome multicollinearity [**?**]. It exploits the principal components of regressors as explanatory variables. Typically, only a subset of the principal components is used, and in particular the ones with higher variances. Therefore PC–R is considered also a shrinkage method [**?**]. Since in this first simulation study only three regressors have been considered, we present PC–R results on all the three principal components. Figure **??** presents the same structure of the previous Figure **??**, the two columns representing results for the two extreme conditional quantiles ($\tau = 0.1$ and $\tau = 0.9$) being the only exception. It is safe to say that rows in Figure **??** refers to the principal components (and not to the origiginal regressors). It is evident how PC–R represents a possible solution also for QR in case of multicollinearity: the first two regression coefficients become really stable, the only variability remains on the third coefficients.

2.3 Concluding remarks

The simple simulation study shows that QR coefficients suffer the same problem of LS coefficients in case of strong collinearity among regressors. In fact, they become unstable, and this in particular for quantiles far from the median. PC–R is a possible solution to deal with such problem, providing more stable solutions.

This early study will be expanded considering different error (response) distribution, that is normal heteroscedastic response, constant skewness in the response and increasing skewness in the response. Moreover, the influence of prediction performances will be studied in the various scenarios, both for prediction inside the sample, i.e. inside the typical range of the regressor(s), and for prediction outside the sample. We expect that prediction performances will not be necessarily influenced from collinearity when the input is inside the range of the data used for model fitting. As soon as one moves outside, collinearity can have a huge effect on the performance. The small eigenvalue directions are the most susceptible to this because

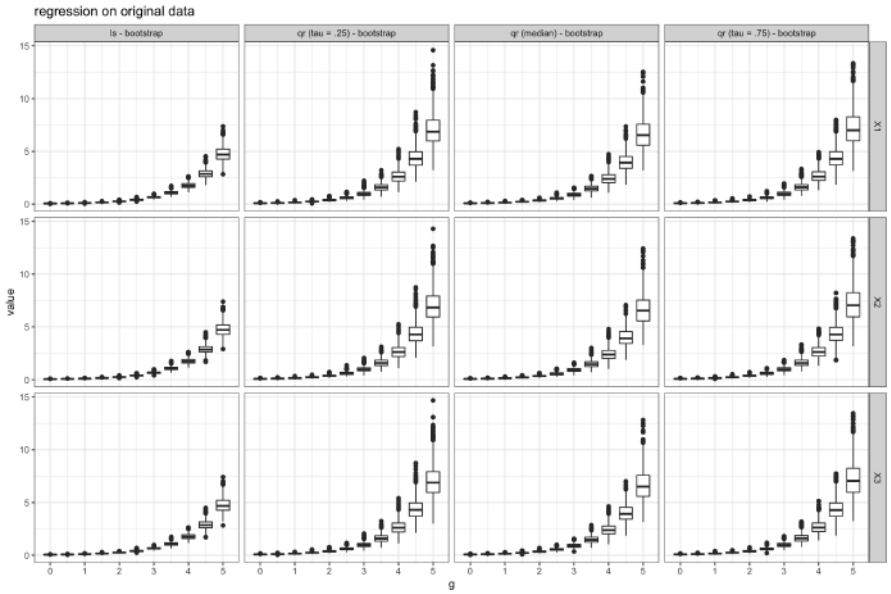

Fig. 1 Results from the simulation study: standard errors of the involved coefficients (different boxplots) for LS and QR models (columns) for three selected values of the γ coefficient (rows), regulating the degree of collinearity.

they are more unstable. Also in this case, we expect that PC–R may help to overcome the problem.

Generalized M-quantile random effects model

Modello di regressione M-quantile generalizzato ad effetti misti

Francesco Schirripa Spagnolo and Vincenzo Mauro

Abstract In this paper we extend the linear M-quantile random intercept model (MQRE) to discrete data and use the proposed model to evaluate the effect of selected covariates on two count responses: the number of generic medical examinations and the number of specialized examinations for Health Districts in three regions of central Italy. The proposed approach represents an outlier-robust alternative to the Poisson generalized linear mixed model with Gaussian random effects and allows estimating the effect of the covariates at various quantiles of the conditional distribution of the target variable.

Abstract *L'obiettivo del lavoro è quello di estendere il modello di regressione M-quantile ad effetti misti al fine di modellare dati discreti. Il modello proposto è stato applicato per studiare l'effetto di alcune covariate sul numero di visite generiche e sul numero di visite specialistiche nei distretti sanitari di tre regioni del Centro Italia. Tale metodo rappresenta un'alternativa robusta ai modelli lineari generalizzati ad effetti misti e permette di stimare l'effetto delle covariate a diversi quantili della distrubuzione condizionata della variabile risposta.*

1 Introduction

Generalized linear mixed models (GLMM) represent the most common method to analyse discrete, binary, or count outcomes in presence of clustered data including random effects to account for between-group variations. Standard GLMM approaches have two main drawbacks. Firstly, the estimation of the parameters is implemented by means of parametric assumptions like the normal distribution of random effects. Secondly, they target the expected value of the conditional distribution of the outcome given a set of covariates. However, when the entire conditional distribution is concerned, it is not recommended to analyse only the central tendency (i.e. the conditional mean) and it is better to use regression models that allow to summarise the behaviour at different percentage points (quantiles) of the target variable. Moreover, when the distribution of the outcome is asymmetric and data contain outliers, the assumptions of the standard GLMM approaches do not hold and classical estimators present very poor performance, producing misleading results. In this work we propose an extension of the linear M-quantile random intercept model (MQRE) to discrete data. Compared to quantile regression, M-quantile (MQ) approach represents a more flexible alternative in modelling different parts of the conditional distribution of the outcome variable.

2 Model

M-quantile regression is usually defined as a 'quantile-like' generalization of regression based on influence functions (M-regression) able to estimate the differential effect of a set of covariates $\mathbf{X}$ at different levels of the conditional distribution of the response variable. The M-quantile of order q, $q \in (0,1)$, for the conditional distribution of y given the set of covariates $\mathbf{X}$, $f(y|\mathbf{X})$, is defined as the solution $MQ_y(q|\mathbf{X},\psi)$ of the estimating equation $\int \psi_q[y - MQ_y(q|\mathbf{X};\psi)]f(y|\mathbf{X})dy = 0$, where $\psi_q(u) = 2\psi(u)\{qI(u>0) + (1-q)I(u\leq 0)\}$ and ψ is a influence function.

Given $\mathbf{X}$, the linear M-quantile regression model for the qth conditional M-quantile of y is defined by

$$MQ_y(q|\mathbf{X};\psi) = \mathbf{X}\beta_{\psi q}, \tag{1}$$

where $\beta_{\psi q}$ represents the vector of the regression parameters.

To model clustered data, [7] extend M-quantile regression in order to include random effects to take into account a two-level hierarchical structure of the data. The M-quantile random intercept model (MQRE) is defined as follows:

$$MQ_y(q|\mathbf{X},\mathbf{u}_q;\psi) = \mathbf{X}\beta_{\psi q} + \mathbf{Z}\mathbf{u}_q, \tag{2}$$

where $\mathbf{u}_q$ is a vector of group random effects at the qth M-quantile and $\mathbf{Z}$ represents and incidence matrix to identify the groups.

In order to model discrete outcomes an MQ regression for discrete data has been proposed in [2, 6]:

$$MQ_y(q|\mathbf{X};\psi) = \eta_{1q} = \mathbf{X}\beta_{\psi q}. \tag{3}$$

Following the idea of [7] we can include a group-specific random intercept in the Eq. (3) in order to define a Generalized MQRE (G-MQRE) suitable to model a discrete outcome in the presence of clustered data:

$$MQ_y(q|\mathbf{X};\mathbf{u}_q;\psi) = \eta_q + \mathbf{e}_q = \mathbf{X}\beta_{\psi q} + \mathbf{Z}\mathbf{u}_q + \mathbf{e}_q, \tag{4}$$

where $\mathbf{u}_q$ is a vector of group random effects at the qth M-quantile (as in Eq. (2)) and $\mathbf{e}_q$ is a vector of level 1 (unit) residuals at the qth M-quantile with no distributional assumption imposed.

Using the same idea of [4], we define a new variable $\mathbf{y}_q^\star = \mathbf{X}\beta_{\psi q} + \mathbf{Z}\mathbf{u}_q + \mathbf{e}_q^\star$ and then it is possible to obtain the estimating equation of the model in Eq. (4) where $\mathbf{e}_q^\star = \mathbf{e}_q\left(\partial\eta_q/\partial\mu_q\right)$ is an adjusted error term.

In particular, following [7] and [5] it is possible to define the following modified estimating equations for estimating the regression coefficients and the variance parameters in the G-MQRE:

$$\mathbf{X}^T\mathbf{V}_q^{\star-1}\mathbf{U}_q^{\star 1/2}\psi_q\left\{\mathbf{U}_q^{\star-1/2}(\mathbf{r}_q^\star)\right\} = \mathbf{0}, \tag{5}$$

$$\psi_q\left\{\mathbf{U}_q^{\star-1/2}(\mathbf{r}_q^\star)\right\}\mathbf{U}_q^{\star 1/2}\mathbf{V}_q^{\star-1}(\partial_{\theta_k}\mathbf{V}_q^\star)\mathbf{V}_q^{\star-1}\mathbf{U}_q^{\star 1/2}\psi_q\left\{\mathbf{U}_q^{\star-1/2}(\mathbf{r}_q^\star)\right\}^T - \mathrm{tr}(K_{2q}(\partial_{\theta_k}\mathbf{V}^\star)\mathbf{V}_q^{\star-1}) = 0, \tag{6}$$

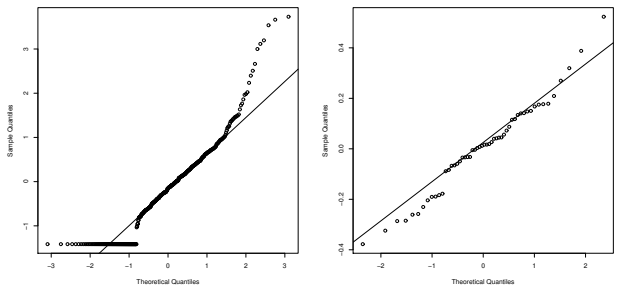
where $\mathbf{V}_q^\star = \delta\Sigma_{e_q}^\star + \mathbf{Z}\Sigma_{u_q}^\star\mathbf{Z}^T$; $\mathbf{r}_q^\star = \mathbf{y}^\star - \mathbf{X}\beta_{\psi q}$; $\mathbf{U}_q^\star$ is a diagonal matrix with diagonal elements equal to the diagonal elements of the variance-covariance matrix $\mathbf{V}_q^\star$.

3 Modelling the number of visits to physicians for Health Districts in Liguria, Toscana and Umbria (Italy).

The proposed methodology is applied to model the number of generic medical examinations and the number of specialized examinations for Health Districts (HD) in three administrative regions of Italy, namely Liguria, Toscana, and Umbria. Data are obtained using the 1999/2000 wave of Health Conditions and Appeal to Medicare Survey (HCAMS), a national, multistage sample survey periodically conducted by the National Institute of Statistics in Italy. The two target variables are the generic and specialised visits that took place in the last four weeks for the elderly (aged 65 and above) in the 60 HDs of Toscana, Liguria and Umbria. The total sample size for the three regions is $n = 4021$.

3.1 Preliminary analysis

We here fit a Poisson GLMM and present some diagnostics in order to motivate the use of the alternative approach proposed in this paper. The covariates included in the model are: five-year age groups (65-69, baseline; 70-74; 75-79; 80-84; 85 and above), gender (baseline: female) and region (baseline: Liguria). Figures 1 and 2 present normal probability plots of level 1 and level 2 Pearson residuals derived by fitting GLMM on Generic visits and GLMM on Specialized visits, respectively. These plots suggest severe departures from the Gaussian assumptions of the level 1 residuals for GLMM for both outcomes. Conversely, the distribution of the random effects can be considered approximately normal as confirmed by the Shapiro-Wilk test ($W = 0.978$ with $p - value = 0.430$ for random effects obtain fitted a GLMM on generic visits and $W = 0.968$ with $p - value = 0.161$ for GLMM on specialized visits). The skewed distribution of level 1 residuals and the presence of large values is confirmed by the plots in Figure 3, plotting the distribution of level 1 residuals by health districts. For both outcomes, some health districts contain some positive outliers, i.e. residuals exceeding 2.



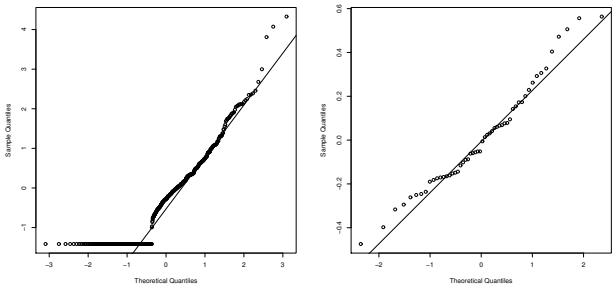
(a) (b)

Fig. 1 Normal probability plots of level 1 (a) and level 2 (b) Pearson residuals derived by fitting the Poisson GLMM on Generic visits

As the diagnostics reported in this subsection provide some evidence towards the adoption of an approach alternative to the standard Poisson GLMM, we decided to fit a G-MQRE model, whose results are presented in the next section.

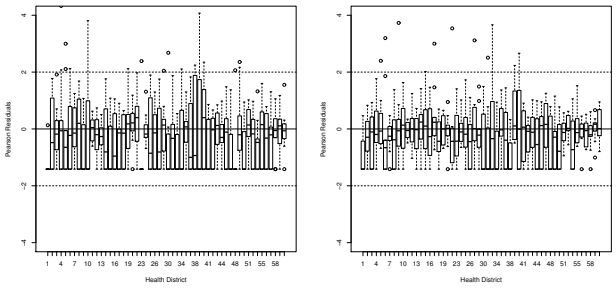
3.2 G-MQRE on HCAMS data

The influence function ψ in the G-MQRE is set to be the Huber Proposal 2 [3]. Given the presence of level 1 outliers, we set the tuning constant on fixed effects $c = 1.6$ [1]. On the other hand, given the approximately normal distribution of the



(a) (b)

Fig. 2 Normal probability plots of level 1 (a) and level 2 (b) Pearson residuals derived by fitting the Poisson GLMM on Specialized visits



(a) (b)

Fig. 3 Box-plots of level 1 Pearson residuals by health districts for the Poisson GLMM on Generic visits (a) and on Specialized visits (b)

level 2 residuals obtained after fitting GLMMs, we set a large c for the estimation of random effects.

For both outcomes, the effects measured by the regression coefficients tend to be different at different quantiles. The number of generic visits increases as people grow older, even if at a slower pace as the quantiles increase. After controlling for the effects of variables "age" and "region", women seems to report more generic visits than men, but also for this variable the effect seems to be less sharp at higher quantiles. People tend to visit generic physicians more often in Tuscany and Umbria than in Liguria, but as quantiles increase, the effect is stable for Tuscany while it decreases for Umbria. The model for specialized visits reports slightly different results. The number of specialized visits seems to be lower for elder people, as shown by the negative coefficient for people over 85 for all the quantiles analysed. The hypothesis of an overall decreasing trend in the number of specialised visits as people get older is consistent with an observed decrease of the number of visits for the 80-84 range (it must be noted that the lack of significance of the latter effect

is only due to the choice of the baseline, so that the difference between the 80-84 age class and the previous class is highly significant). As observed in the model for generic visits, women seem to schedule more specialized than men, but the effect tends to be sharper at $q = 0.90$. The differences for the variable "Region" does not appear significant.

Goodness-of-fit assessment in linear quantile regression

Bontà di adattamento delle regressioni quantili lineari

Ilaria Lucrezia Amerise and Agostino Tarsitano

Abstract In this paper we examine three summary statistics used to evaluate the reduction in variation due to fitting a quantile regression to data. The goal is to identify characteristics and behaviors that enable a coefficient of determination to validly assess the agreement between observed and estimated responses.
Abstract *Obiettivo del presente lavoro è di esaminare caratteristiche e comportamenti di tre statistiche utilizzabili per misurare la bontà di adattamento nella regressione quantile.*

Key words: Goodness-of-fit, Coefficient of determination, Model validation.

1 Goodness-of-fit for quantile regression

Let y be the response variable of interest and $\mathbf{x}=(x_1,x_2,\cdots,x_m)$ be a m-dimensional vector of regressors. Suppose we observe a random sample $(y_i,\mathbf{x}_i), i=1,2,\cdots,n$. Let $Q_{y|\mathbf{x}_i}$ denote the τ-th conditional quantile of y given $\mathbf{x}(\tau)$. In recent years, there has been a growing interest in quantile regression, meaning that rather than focus on $E(y|\mathbf{x}_i)$, the goal is to model $Q_{y|\mathbf{x}_i}(\tau)$, that is,

$$y_i=\mathbf{x}_i\beta_\tau+e_i, \qquad Q_{y|x_i}(\tau)=\mathbf{x}_i\beta_\tau, \quad i=1,2,\cdots,n\,, \tag{1}$$

where β is a $(m\times 1)$ vector of unknown parameters specific of the τ-th quantile regression (QR). The $\mathbf{x}_i$ are rows of a $n\times m$ design matrix $\mathbf{X}$ with full rank m and

Ilaria Lucrezia Amerise
Universitá della Calabria – Dipartimento di Economia, Statistica e Finanza, Via Pietro Bucci, Cubo 1c, 87036 Rende (CS) - Italy e-mail: ilaria.amerise@unical.it

Agostino Tarsitano
Universitá della Calabria – Dipartimento di Economia, Statistica e Finanza, Via Pietro Bucci, Cubo 1c, 87036 Rende (CS) - Italy e-mail: agostino.tarsitano@unical.it

$m<n$. We assume that $x_{i,1}=1\ \forall\ i$ so that the design matrix $\mathbf{X}$ contains a column of ones. We further assume that the e_i are unobservable independent (not necessarily identically distributed) random variables, each with $Q_\tau=0$.

QR is considered a methodological improvement with respect to multiple linear regression (MLR) because it can depict a more detailed picture of the relationship between response and regressors by estimating multiple slopes along the entire response distribution. However, MLR can rely on the variance decomposition formula that subdivides the total variance of into two components: the variance explained by the model and the one associated with the experimental error. The idea is condensed in the classical ratio between explained and total variance, R^2, which is in common use. Unfortunately, the variance decomposition formula does not generally hold for a metric different from the Euclidean metric. Therefore, one must look to other measures for goodness-of-fit based on the absolute deviations of the observed responses from their median or other quantiles.

To judge the relative effectiveness of model (1), it is natural to resort to the coefficient of determination, which is well-known in the field of linear mean regression. Some proposals in this direction are reported in the following sections.

1.1 Koenker-Machado criterion

[3] generalizes the proposal of [4] for median regression to an arbitrary quantile,

$$\begin{aligned} V_\tau &= 1-\frac{\tau\sum_{y_i\geq\hat{y}_{i,\tau}}|y_i-\hat{y}_{i,\tau}|+(1-\tau)\sum_{y_i<\hat{y}_{i,\tau}}|y_i-\hat{y}_{i,\tau}|}{\tau\sum_{y_i\geq\widehat{q}_\tau}|y_i-\widehat{q}_\tau|+(1-\tau)\sum_{y_i<\widehat{q}_\tau}|y_i-\widehat{q}_\tau|}, \\ &= 1-\frac{C(y_i-\hat{y}_{i,\tau})}{C(y_i-\widehat{q}_\tau)} \end{aligned} \tag{2}$$

where $C(n_i)=\sum_{i=1}^{n} n_i[\tau-I(n_i<0)]$, $I()$ is the indicator function that takes 1 if the argument is true and 0 otherwise, $\widehat{q}_\tau$ is the estimated intercept in an intercept-only model and $\hat{y}_{i,\tau}$ is the i-th estimated response at the τ-th quantile. Notice that $\widehat{q}_\tau$ coincides with the τ-th unconditional quantile of the response. The difference $y_i-\hat{y}_{i,\tau}$ are regression residuals while $y_i-\widehat{q}_\tau$ are residuals from a model which only contains a constant term.

[4] lists some desirable properties for a coefficient of determination and V_τ satisfies many but not all of the properties. For example, it is dimensionless, ranges between zero ($\widehat{y}_{i,\tau}=\widehat{q}_\tau,\ \forall\ i$) and one ($\widehat{y}_{i,\tau}=y_i,\ \forall\ i$), with a larger value indicating better model fit. However, the quality of the fit does not change in the expected direction if a regressor is added to or deleted from the model. [3] claim that V_τ constitutes a local measure of goodness of fit for a particular quantile rather than a global measure of goodness of fit over the entire conditional distribution. Therefore, it should not be surprising that a regressor might exert a significant effect on one tail of the conditional distribution of the response but might have no effect or even an opposite effect in the other tail, with the final balance uncertain. However, coef-

ficient (2) maintains a strong analogy with the R^2 in least squares regression, which we consider not appropriate in the setting of QR.

1.2 Amerise criterion

To develop an index alternative to (2), [1] considered the triangle inequality

$$\tau \sum_{y_i \geq \widehat{y}_{i,\tau}} |y_i - \widehat{y}_{i,\tau}| + (1-\tau) \sum_{y_i < \widehat{y}_{i,\tau}} |y_i - \widehat{y}_{i,\tau}| \leq \tau \sum_{y_i \geq \widehat{y}_{i,\tau}} |y_i - \widetilde{q}_\tau| + (1-\tau) \sum_{y_i < \widehat{y}_{i,\tau}} |y_i - \widetilde{q}_\tau| + \tau \sum_{y_i \geq \widehat{y}_{i,\tau}} |\widehat{y}_{i,\tau} - \widetilde{q}_\tau| + (1-\tau) \sum_{y_i < \widehat{y}_{i,\tau}} |\widehat{y}_{i,\tau} - \widetilde{q}_\tau|. \quad (3)$$

The coefficient of determination proposed is:

$$R_\tau \quad = 1 - \frac{C_\tau (y_i - \widehat{y}_{i,\tau})}{C_\tau (y_i - \widetilde{q}_\tau) + C_\tau (\widehat{y}_{i,\tau} - \widetilde{q}_\tau)}. \quad (4)$$

The numerator is a weighted sum of absolute deviations between observed y_i and estimated $\widehat{y}_{i,\tau}$ responses. The denominator provides a standardization factor so that the coefficient varies in a limited range. More specifically, the first and second addends, respectively, are proportional to the weighted sum of absolute deviations of the $y_{i,\tau}$ and $\widehat{y}_{i,\tau}$ from $\widetilde{q}_\tau$ with no contribution from regressors. In terms of the classical variance decomposition, the denominator quantifies the total variability in the response (as expressed by the weighted sum of absolute deviations) and $C_\tau (y_i - \widehat{y}_{i,\tau})$ represents the variability of residuals. Therefore, the ratio R_τ is a measure of what percentage of the total variability in the response is explained by the regressors at the given quantile.

Coefficient (4) is, by construction, invariant to units of measurement, takes values in the $[0,1]$ interval and becomes larger as the fit tends to be perfect. It turns out that $R_\tau = 1$ if $y_i = \hat{y}_{i,\tau}, i = 1,2,\ldots,n$, that is, when the observed responses coincide with the τ-th conditional quantile regression. $R_\tau = 0$ if $\widehat{y}_{i,\tau} = \widetilde{q}_\tau \ \forall i$ implying that a model with only a constant as a regressor provides an explanation for the responses. Of course, $R_\tau > V_\tau$ simply because $\widehat{q}_\tau$ minimizes the asymmetrical liner loss function so that $C_\tau (y_i - \widehat{q}_\tau) < C_\tau (y_i - \widetilde{q}_\tau)$ for each τ.

The choice of $\widetilde{q}_\tau$ in (3) over $\widehat{q}_\tau$ can be illustrated as follows. Suppose that the variations of the estimated values were entirely due to random errors, that is, $\widehat{y}_{i,\tau} = \theta + e_i$. In this case, $\widehat{y}_{i,\tau} = \widetilde{q}_\tau$ with $R_\tau = 0$. If deviations were computed from $\widehat{q}_\tau$, then $C_\tau (\widehat{y}_{i,\tau} - \widehat{q}_\tau) > 0$ and, consequently, $R_\tau > 0$, suggesting that random regressors have some predictive power, which is the wrong conclusion. On the other hand, if $y_i = \theta + e_i$ then $R_\tau = 0$ if and only if $\widehat{q}_\tau = \widetilde{q}_\tau$. Obviously, R_τ and V_τ constitute local measures of fit because they are specific to the τ-th quantile and have little, if any, meaning for the other.

1.3 A new criterion

Let $\widetilde{q}_\tau$ be the τ-th quantile of the estimated responses $\widehat{y}_\tau$, which, in general, is different from the corresponding quantile $\widehat{q}_\tau$ of the observed response y. To judge the overall goodness of fit of a QR we can generalize the proposal of ([2], p. 223) for median regression and adapt it to an arbitrary quantile. The suggested statistic is

$$B_\tau = \frac{C_\tau(\widehat{y}_{i,\tau} - \widetilde{q}_\tau)}{C_\tau(\widehat{y}_{i,\tau} - \widetilde{q}_\tau) + C_\tau(\widehat{y}_{i,\tau} - y_i)}. \tag{5}$$

The index B_τ is a true proportion of two quantities of which the numerator is part of the denominator. Thus, the criterion is dimensionless and varies between 0 and 1. In particular, $B_\tau = 0$ denotes a non-informative model $\widehat{y}_i = \widetilde{q}_\tau \ \forall\, i$. The value of B_τ increases as $\widehat{y}_{i,\tau} \to y_i \ \forall\, i$. Finally, $B_\tau = 1$ if $y_i = \widehat{y}_i, \ \forall\, i$, that is, the model perfectly fits the observed data. The B_τ criterion can be interpreted as the relative reduction (but not necessarily monotonically) in the sum of weighted absolute deviations due to fitting the complete model with respect to fitting an intercept-only model.

2 Applications

We offer two examples; the first illustrates how the coefficients of determination are sensitive to the presence of outliers and heterosckedasticity in the data set. The second example demonstrates the usefulness of various criteria in interpreting regression fits when the number of regressors varies. Both examples are based on well-known data sets freely available on [6].

2.1 Skeena River Sockeye salmon data

Spawning stock and resulting recruitment of sockeye salmon were recorded over the years 1940–1967 in Skeena River in British Columbia (see [7]). The data set consists of $n = 28$ yearly values. The most prominent aspect of the data is their heterosckedasticity. The year 1951 (Observation 12) is an outlier resulting from a rock slide that interfered with spawning. The year 1955 (Observation 16) has a low value of S since the spawning population that year came from 1951.

Table 1 reports the coefficient of determination of ordinary least squares together with those computed for linear quantile regression at $0.25, 0.50, 0.75$. The first row concerns the original data set. Successive rows show analogous computations after excluding the design points indicated in the first column of the row.
Observation 12 is highly influential and, in fact, its exclusion alters the fit of the quantile hyperplanes considerably. Additional deletion of data point 16 has a negative impact on the agreement between observed and estimated responses because,

in these case, V_τ, B_τ and R_τ decrease. In general, the values of the QR goodness-of-fit indices look similar in all the model fits, but only apparently. On a closer examination, it is pretty evident that the QR criteria are more stable than R^2, thus demonstrating their robustness. From Table 1, it emerges also that R_τ not only is the index least affected by deletion of observations but also ranges in a wider interval.

It is important to consider the magnitude of the differences between the criteria across the quantiles. This result is in line with what is expected on the basis of the local character of the criteria, which can be satisfactory in the upper tail of the response, but gradually attenuated to the point that it appears negligible below the median. This is the case for B_τ and R_τ. Index V_τ is low around the median, but it is more acceptable at the first and third quartiles. Such a behavior may be explained by noting that V_τ includes the term $C(y_i - \widehat{q}_\tau)$, which deviates widely in presence of outliers and heterosckedasticity.

2.2 Hald cement data

The data set has been widely used in the statistics literature to illustrate collinearity and variable selection methods. The data resulted from a five-component mixture experiment that was concerned with the effect of the composition of cement on heat evolved during hardening. See [5], for more details. The data frame includes $n = 13$ observations and $m = 4$ regressors. The response variable y is the heat evolved in a cement mix. The four explanatory variables are ingredients of the mix, x_1 (tricalcium aluminate), x_2 (tricalcium silicate), x_3 (tetracalcium alumino ferrite), x_4 (dicalcium silicate). An important feature of these data is that the variables x_1 and x_3 are highly correlated, as well as the variables x_2 and x_4. Thus we should expect any subset of (x_1, x_2, x_3, x_4) that includes one variable from highly correlated pair to do as any subset that also includes the other member.

Table 2 displays the results of the quantile regression analysis for the best fit of each order for three different quantiles: $0.25, 0.50, 0.75$.
Since the data are well behaved in this example, it is not surprising that the four coefficients are in close agreement and, furthermore, conclusions concerning this data set based on them cannot be too dissimilar from those based on least squares. It is worth noting that the quantile criteria V_τ, B_τ and R_τ do not always increase when a regressor is added to the model. This happens, for example, for B_τ when $\tau = 0.75$ and x_3 joins the other three regressors.

Table 2 Goodness-of-fit statistics for various models

		$\tau = 0.25$			$\tau = 0.50$			$\tau = 0.75$		
m	R^2	V_τ	B_τ	R_τ	V_τ	B_τ	R_τ	V_τ	B_τ	R_τ
2	0.666	0.721	0.759	0.755	0.496	0.628	0.728	0.642	0.642	0.654

3 Concluding remarks

As a premise we note that the debate on how important goodness of fit is as a tool in quantile regression analysis is not well developed in the literature. To our knowledge only [3] has dealt with this issue. Our goal in this paper is to compare their index with other two indices originally proposed to measure the closeness between observed ad the estimated response in the case of the median regression. The comparison is carried out by means of two well-known data sets, namely, Brownlee's stack loss plant data and Hald cement data. Our findings reveal that QR criteria are sufficiently robust to suspect outliers and hence especially useful in situation of long tailed residuals. A critical characteristic of all the three indices is that they are quantile-specific and can vary significantly depending on the tail of the conditional distribution where regressors exert their effects. This prevents using them as measures for assessing how well the dependent variable can be predicted from knowledge of the independent variables.

The conclusions can be expressed by a simple recommendation: rather than searching for an optimal local measure of goodness of fit, it is more useful to combine the individual goodness-of-fit indices to form a global synthetic index of goodness-of-fit concerning all the conditional distributions of interest.

Joint Redundancy Analysis by a multivariate linear predictor

Analisi di ridondanza condivisa sulla base di un predittore lineare multivariato

Laura Marcis, Renato Salvatore

Abstract A common multi-group Redundancy Analysis is introduced, when the reduced space is given by a singular value decomposition of a multivariate best linear predictor. The algorithm finds a nearby *OLS* fixed-effects estimates by a least squares closed-form solution, provided by the standardized predictor. The empirical predictor is given by an extension of the distribution-free variance least squares method to an iterative multivariate response algorithm.

Abstract *Il lavoro introduce una Analisi di Ridondanza sulla base di gruppi indipendenti, utilizzando la decomposizione ai valori singolari di un predittore lineare multivariato. L'algoritmo fornisce stime di effetti fissi vicini alle stime OLS, attraverso una soluzione esatta sulla base del predittore standardizzato. La stima del predittore empirico è basata sull'estensione del metodo ai minimi quadrati della varianza del modello al caso multivariato, seguendo un approccio iterativo.*

1 Introduction

Redundancy Analysis (*RDA*) was originally introduced [7] in order to capture the effects on a reduced space of the linear dependence by a set of criterion variables $\mathbf{Y}$ from a set of predictors $\mathbf{X}$. Partial *RDA*, constrained *RDA* and ridge-type regularized *RDA* were also introduced, where the goal is substantially of two types: firstly, to highlight the effects of a subset of some conditioning predictors [2], to remove, and, secondly, to assess a ridge estimator to reduce the mean squared error of the multivariate regression by some nearby collinear predictors [6]. Even though the *RDA* provides a constrained analysis of the whole linear relations between the two sets of variables, and an unconstrained analysis given by the set of multivariate regression residuals, it is straightforward to relate *RDA* with principal component analysis (*PCA*), see for example [4]. One of research issues in the field of the *PCA* is the simultaneous *PC*-reduction of a set of independent groups of observations, collected by a multivariate random vector $\mathbf{Y}$ ([5],[1]). A general linear mixed model [3] is usually employed to represent the relationship between the sets of criterion and predictor variables, when the goal is to predict a specific group (subject) contribution to the linear dependence. For this reason, a *RDA* of the predicted criterion variables by the best linear unbiased predictor at group level may be quite representative into this contribution. Further, it is also useful to perform *RDA* of the modeled predicted data to investigate the "common" groups redundancy on the criterion variables, and on the multivariate mixed model conditioned residuals. This paper introduces a joint *RDA* by a least-squares solution for an optimal fixed-effects estimate from the data collected by the linear mixed model predictors of the dependent variables. The singular value decomposition of the resulting linear regression model estimates gives the best projection in the common reduced subspace of the best unbiased predictor by the whole set of random effects. The application uses an extension to the multivariate case of the variance least squares algorithm to estimate a variance components MANOVA model for data repeated over time.

2 Joint Redundancy Analysis. Estimation of model parameters

Given a q-variate random vector $\mathbf{Y}$, consider the case when $\mathbf{Y}$ is partitioned in n subjects (groups), each of them with n_i individuals. We assume that the population model for the n subjects is $\mathbf{y}_{i|q\times 1} = \mathbf{B}'_{q\times p}\mathbf{x}_{i|p\times 1} + \mathbf{a}_{i|q\times 1}$, where $\mathbf{B}$ is the

matrix of fixed regression coefficients, and $\mathbf{a}_i \sim N(0,\Sigma_a)$ is a q-variate random effect. Given a sample of N units (repeated measurements), then the multivariate random effects model assumes the general structure $\mathbf{Y}_{N\times q} = \mathbf{X}^{+}_{N\times p}\mathbf{B}_{p\times q} + \mathbf{Z}^{+}_{N\times n}\mathbf{A}_{n\times q} + \mathbf{E}_{N\times q}$, with $\mathbf{X}^{+}$ the matrix of data covariates, $\mathbf{Z}^{+}$ the design matrix of random effects, and $\mathbf{E}$ the matrix of regression within-subject errors. Further both $\mathbf{Y}$ and $\mathbf{X}^{+}$ are assumed as columnwise centered and standardized. Rewriting the last model in the vector form, with $\mathbf{y}^{*} = vec(\mathbf{Y})$, $\mathbf{X} = (\mathbf{I}\otimes\mathbf{X}^{+})$, $\beta = vec(\mathbf{B})$, $\mathbf{Za} = vec(\mathbf{ZA}) = (\mathbf{I}\otimes\mathbf{Z})vec(\mathbf{A})$, and given for the sake of simplicity a balanced design ($n_i = k$), the multivariate linear best predictor is given by $\widetilde{\mathbf{y}}^{*} = vec(\widetilde{\mathbf{Y}}) = \mathbf{X}\widehat{\beta} + \mathbf{Z}\widetilde{\mathbf{a}} = \left\{\mathbf{I} - (\Sigma_a\otimes\mathbf{ZZ}')cov(\mathbf{y}^{*})^{-1}\right\}\mathbf{X}\widehat{\beta} + (\Sigma_a\otimes\mathbf{ZZ}')cov(\mathbf{y}^{*})^{-1}\mathbf{y}^{*} = \Gamma\mathbf{y}^{*} + (\mathbf{I}-\Gamma)\mathbf{X}\widehat{\beta}$.

Here $\widehat{\beta} = \widehat{\beta}_{gls}$, $\mathbf{Z}\widetilde{\mathbf{a}} = (\Sigma_a\otimes\mathbf{ZZ}')cov(\mathbf{y}^{*})^{-1}(\mathbf{y}^{*} - \mathbf{X}\widehat{\beta})$, $cov(\mathbf{y}^{*}) = (\mathbf{I}\otimes\mathbf{Z})\ (\Sigma_a\otimes\mathbf{I}_k)(\mathbf{I}\otimes\mathbf{Z}') + cov(vec(\mathbf{E})) = (\Sigma_a\otimes\mathbf{ZZ}') + (\Sigma_e\otimes\mathbf{I}_n)\otimes\mathbf{I}_k$, $\Gamma = (\Sigma_a\otimes\mathbf{ZZ}')cov(\mathbf{y}^{*})^{-1}$.

By standard *Redundancy Analysis* (*RDA*), a reduced-rank subspace is given by a *singular value decomposition* (*SVD*) of the multivariate regression predicted values $\widehat{\mathbf{Y}} = \mathbf{X}\widehat{\mathbf{B}}_{ols}$. To get a reduced subspace by the multivariate linear best predictor $\widetilde{\mathbf{Y}}$, thus we set $\widetilde{\mathbf{Y}} = \mathbf{X}^{+}\widehat{\mathbf{B}} + \mathbf{Z}\widetilde{\mathbf{A}} = \mathbf{U}_{\widetilde{Y}}\Lambda_{\widetilde{Y}}\mathbf{V}'_{\widetilde{Y}}$ as a possible *SVD* representation of the redundant information in the criterion variables, captured by the dispersion matrix $\Sigma_{\mathbf{y}^{*}|\mathbf{X}} = var(\mathbf{y}^{*}) - cov(\mathbf{y}^{*},\mathbf{X})var(\mathbf{X})^{-1}cov(\mathbf{X},\mathbf{y}^{*})$. Even though a joint-subject reduction subspace is given by the fixed-effects model estimates $\widehat{\mathbf{Y}} = \mathbf{X}\widehat{\mathbf{B}}_{gls}$, we are interested in the simultaneous representation of all the predicted $\widetilde{\mathbf{a}}_i$'s, given by a common projection subspace. To do this, we find the matrix of fixed effects $\mathbf{B}$ closest to the fixed $\widehat{\mathbf{B}}_{ols}$, by setting the minimum Froebenius norm by the multivariate predictor $\widetilde{\mathbf{Y}}$, of the difference $F = \widetilde{\mathbf{Y}}^{**}var(\widetilde{\mathbf{y}})^{-\frac{1}{2}} - \mathbf{X}^{+}(\mathbf{B}), \widetilde{\mathbf{Y}}^{**} = \widetilde{\mathbf{Y}} - E(\widetilde{\mathbf{Y}}) = \widetilde{\mathbf{Y}} - \mathbf{1}_N E[(\widetilde{\mathbf{y}}_{|q\times 1})']: \|F\|^2 = tr(\mathbf{f}'\mathbf{f}) = \left\|\widetilde{\mathbf{Y}}^{**}\Sigma^{-\frac{1}{2}} - \mathbf{X}^{+}(\mathbf{B})\right\|^2 = \min$.

Note that $var(\widetilde{\mathbf{y}}) = \Sigma = E\left\{(\widetilde{\mathbf{Y}}-\mathbf{Y})'(\widetilde{\mathbf{Y}}-\mathbf{Y})\right\}$, with $(\widetilde{\mathbf{Y}}-\mathbf{Y})'(\widetilde{\mathbf{Y}}-\mathbf{Y})$ the random matrix of $q\times q$ cross products $\widetilde{\mathbf{Y}}'\widetilde{\mathbf{Y}}$ given on the basis of the subjects covariances $cov(\widetilde{\mathbf{y}}^{*}_i - \mathbf{y}^{*}_i) = \mathbf{X}_i(cov\widehat{\beta}_{gls})\mathbf{X}'_i + \mathbf{Z}_i cov(\widetilde{\mathbf{a}}_i - \mathbf{a}_i)\mathbf{Z}'_i + cov(vec(\mathbf{E}))$.

Now, setting $\mathbf{f} = vec(F) = (\Sigma^{-\frac{1}{2}}\otimes\mathbf{I}_N)\widetilde{\mathbf{y}}^{**} - (\mathbf{I}_q\otimes\mathbf{X}^{+})\overline{\beta} = \overline{\Sigma}^{-\frac{1}{2}}\widetilde{\mathbf{y}}^{**} - \mathbf{X}\overline{\beta}$, $\overline{\beta} = vec(\mathbf{B})$, $\overline{\Sigma}^{-\frac{1}{2}} = (\Sigma^{-\frac{1}{2}}\otimes\mathbf{I}_N)$, we come the following properties of $\overline{\beta}$: $tr(\mathbf{f}'\mathbf{f}) = tr\left\{(\overline{\Sigma}^{-\frac{1}{2}}\widetilde{\mathbf{y}}^{**} - \mathbf{X}\overline{\beta})'(\overline{\Sigma}^{-\frac{1}{2}}\widetilde{\mathbf{y}}^{**} - \mathbf{X}\overline{\beta})\right\} = (\widetilde{\mathbf{y}}^{**} - \overline{\mathbf{X}}\overline{\beta})'\overline{\Sigma}^{-1}(\widetilde{\mathbf{y}}^{**} - \overline{\mathbf{X}}\overline{\beta})$, where $\overline{\mathbf{X}} = \overline{\Sigma}^{\frac{1}{2}}\mathbf{X}$. Thus, $\widehat{\overline{\beta}} = (\overline{\mathbf{X}}'\overline{\Sigma}^{-1}\overline{\mathbf{X}})^{-1}\overline{\mathbf{X}}'\overline{\Sigma}^{-1}\widetilde{\mathbf{y}}^{**}$ is the q-variate vector in the subspace spanned by the columns of the matrix $\overline{\mathbf{X}}$, with $\widetilde{\mathbf{y}}^{**}$ orthogonal to the columns of $\overline{\mathbf{X}}$ in the metric of $\overline{\Sigma}^{-1}$, $\widetilde{\mathbf{y}}^{**\prime}\overline{\Sigma}^{-1}\overline{\mathbf{x}} = 0$. Then, $P_{\overline{X}} = \overline{\mathbf{X}}(\overline{\mathbf{X}}'\overline{\mathbf{X}})^{-1}\overline{\mathbf{X}}'$ is the projection matrix of the predictor $\widetilde{\mathbf{y}}^{**}$ onto the joint subspace by $\overline{\mathbf{X}}$. The *SVD* of $\widehat{\overline{\mathbf{Y}}}^{**} = \mathbf{X}^{+}\widehat{\overline{\beta}}$

gives the common rescaled predictor's coordinates, $\mathbf{U}_{\widetilde{Y}}\Lambda_{\widetilde{Y}}\mathbf{V}'_{\widetilde{Y}}$, further noticing that $\mathbf{U}^*_{\widetilde{Y}} = \widetilde{\mathbf{Y}}\mathbf{V}^{-1}\Lambda_{\widetilde{Y}}$ contains the row joint reduced coordinates in the space of $\widetilde{\mathbf{Y}}$.

In order to avoid distributional assumptions for the multivariate data vector $\mathbf{Y}$, we introduce an Iterative multivariate Variance Least Squares (*IVLS*) estimation. The objective function to minimize is $VLS = trace(\Xi - \mathbf{U} - \mathbf{D})^2$, with $\Xi_{|N\times N}$ the empirical model covariance matrix. The algorithm is based on alternating least squares in a two-step iterative optimization process. At every iteration IVLS first fixes $\mathbf{U}$ and solves for $\mathbf{D}$, and following that it fixes $\mathbf{D}$ and solves for $\mathbf{U}$. Since *LS* solution is unique, in each step the *VLS* function can either decrease or stay unchanged, but never increase. Alternating between the two steps iteratively guarantees convergence only to a local minima, because it ultimately depends on the initial values for $\mathbf{U}$. The iterations are related to the following steps: a) from the group covariance matrices $\mathbf{U}$, first minimize VLS to obtain the estimates of $\mathbf{D}$, where Ξ is given by the multivariate *OLS* cross-products of residuals; b) after the estimation of the matrix $\widehat{\mathbf{B}}_{GLS}$, minimize VLS, setting the same error covariance matrix among groups, and c), Iterate a) and b), until convergence to the minimum. The number of iterations may vary by the choice of the specific model random effects and error covariance matrices. Applications of the *Joint RDA* may be related to different types of available data, and then accommodate a variety of patterned covariance matrices. Further, groups can be dependent or independent, even in space, time, and space-time correlated data. The *IVLS* estimator at each step is unbiased, by the following Lemma.

Lemma *(Unbiasedness of the IVLS estimator)*. Under the balanced p -variate variance components model $\mathbf{Y} = \mathbf{XB} + \mathbf{ZA} + \mathbf{E}$, with covariance matrix $\mathbf{D} + \mathbf{U}$, $\mathbf{D} = (\mathbf{I} \otimes \mathbf{Z})cov(vec(\mathbf{A}))(\mathbf{I} \otimes \mathbf{Z}')$, $\mathbf{U} = cov(vec(\mathbf{E}))$, and known matrix $\mathbf{U}$, for the *IVLS* estimator of the parameters θ in $\mathbf{D}$ we have $E\left\{\mathbf{D} = D(\widehat{\theta}_{IVLS})\right\} = D(\theta)$.

3 Application and concluding remarks

Recent national laws reformed the Italian Budget law, provided that the "Benessere Equo e Sostenibile (BES) - Fair and Sustainable Well-being (FSW)" [8] indicators should contribute to define those economic policies which largely affect some fundamental dimensions for the quality of life. The Italian Statistical Institute provide these indicators annually. The Ministry of Finance and Economics most recent publication is the Budget Law 2019 where it is possible to find the trend and programmatic forecasts relating to the 12 FSW indicators and the anal-

ysis of most recent trends, at the levels NUTS2 and NUTS3. We analyze 5 of the 12 FSW indicators available in the years 2013-2016 (4 time istants), at the level of NUTS2. The random multivariate vector is partitioned in repeated observations of the same administrative Region of Italy in the 4 time instants. We take in consideration a balanced multivariate Mixed *MANOVA* Model (*MMM*), with an *AR(1)* error stucture: $\mathbf{Y}_{|mk\times p} = \mathbf{X}_{|mk\times l}\mathbf{B}_{|l\times p} + \mathbf{Z}_{|mk\times pm}\mathbf{A}_{|pm\times p} + \mathbf{E}_{|mk\times p}$, where $p = 5$, $m = 20$, $k = t = 4$, that is a balanced model, with a random intercept and an *AR(1)* error. Then: $vec(\mathbf{Y}) = (\mathbf{I}_p \otimes 1_{mt})vec(\mathbf{B}) + (\mathbf{I}_p \otimes Z)vec(\mathbf{A}) + vec(\mathbf{E})$; $\mathbf{y}^* = vec(\mathbf{Y}), \mathbf{X}^* = (\mathbf{I}_p \otimes \mathbf{X}) = (\mathbf{I}_p \otimes \mathbf{1}_{mt})$, $\beta^* = vec(\mathbf{B})$, $\mathbf{Z}^*\mathbf{a}^* = (\mathbf{I}_p \otimes \mathbf{Z})vec(\mathbf{A})$.

Further we have $cov(\mathbf{y}^*) = (\mathbf{I}_p \otimes \mathbf{I}_m \otimes \mathbf{1}_k)(\Sigma_a \otimes \mathbf{I}_m)(\mathbf{I}_p \otimes \mathbf{I}_m \otimes \mathbf{1}_k') + cov(vec(\mathbf{E})) = \Sigma_a \otimes (\mathbf{I}_m \otimes \mathbf{1}_k\mathbf{1}_k') + (\Sigma_e \otimes \mathbf{I}_n) \otimes \Omega$. Finally, after the iterative *VLS* estimation, the predictor is given by $\widetilde{\mathbf{y}}^* = \mathbf{X}^*\widehat{\beta}^*_{GLS} + \mathbf{Z}^*\widetilde{\mathbf{a}}^* = \Gamma\mathbf{y}^* + (\mathbf{I} - \Gamma)\mathbf{X}^*\widehat{\beta}^*_{GLS}$, $\Gamma = (\Sigma_a \otimes \mathbf{Z}\mathbf{Z}')cov(\mathbf{y}^*)^{-1}$. Note that the matrix Γ specifies both the contribution of the regression model and the observed data to the prediction.

We assume equicorrelation both of the multivariate random effects and the residual covariance, together with the *AR(1)* structure of the error:

$$\Sigma_a = \sigma_a^2 \times \begin{bmatrix} 1 & \rho_a & \cdots & \rho_a \\ \rho_a & 1 & \cdots & \rho_a \\ \vdots & \cdots & \ddots & \vdots \\ \rho_a & \rho_a & \cdots & 1 \end{bmatrix}_{5\times 5} \Sigma_e = \sigma_e^2 \times \begin{bmatrix} 1 & \rho_e & \cdots & \rho_e \\ \rho_e & 1 & \cdots & \rho_e \\ \vdots & \cdots & \ddots & \vdots \\ \rho_e & \rho_e & \cdots & 1 \end{bmatrix}_{5\times 5} \Omega = \frac{1}{1-\rho_t^2} \begin{pmatrix} 1 & \rho_t & \rho_t^2 & \rho_t^3 \\ \rho_t & 1 & \rho_t & \rho_t^2 \\ \rho_t^2 & \rho_t & 1 & \rho_t \\ \rho_t^3 & \rho_t^2 & \rho_t & 1 \end{pmatrix}_{4\times 4}$$

Figure 1 reports a comparison between observed and predicted data. Bold lines refer to predicted loadings and black dots are the predicted scores. Dashed lines and grey dots come from the standard *PCA*.

In conclusion, the paper introduces *RDA* of a multivariate predictor to perform a common survey of the predicted data, a joint *RDA* analysis. Given a multivariate vector with independent groups, and a random effects population model, the joint *RDA* relies on the assumption that the linear model itself is able to predict accurately specific subjects or group representatives, even in time and spatial dependent data. After using a linear mixed model, the joint *RDA* explores data that originates in part from regressive process and in part from the observed, to understand the contribution to the linear dependence of the observed and of predictions. We suggest the use of this approach when the research issues are related to the use of model covariates and

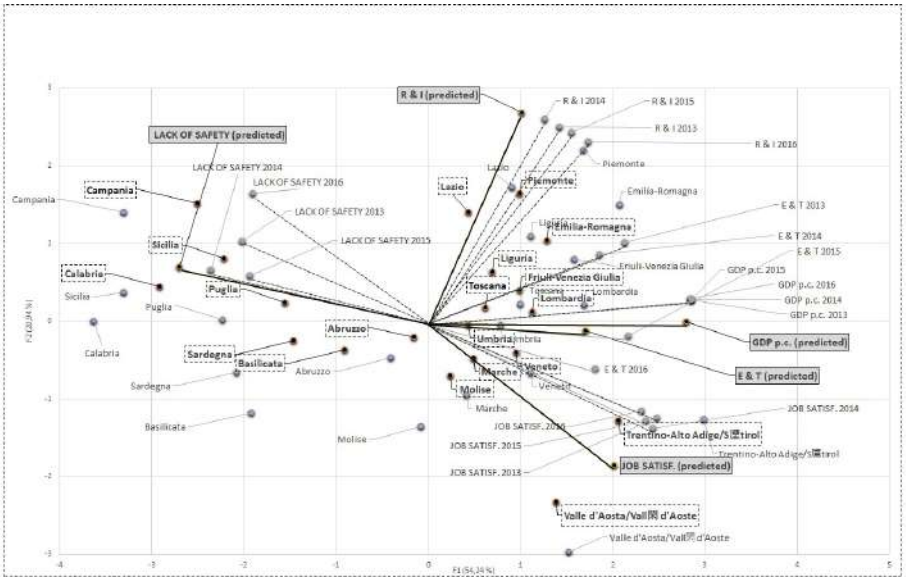

Fig. 1 Multiple Factor Analysis (MFA), observed factor loadings and scores per year (in grey); predicted loadings and scores (in black).

specific patterned covariance matrices. Further, the impact of choosing the model structure is easily recognizable when we investigate changes in the data description by the common factors.

M-quantile regression shrinkage and selection via the lasso

Regressione M-quantilica con regolarizzazione lasso

M. Giovanna Ranalli and Lea Petrella and Francesco Pantalone

Abstract Standard regression analysis investigates the average behavior of a response variable, y, given a vector of predictors, $\mathbf{x}$. However, in some cases, the mean does not give a complete picture of a distribution. Therefore, quantile regression analyzes how the q-th quantile of the conditional distribution of y given $\mathbf{x}$ varies with $\mathbf{x}$, and M-quantile regression generalizes this idea through the use of influence functions. When dealing with a large number of predictors, selection of a subset of them improves the interpretability of the model. Towards this end, in this paper, we introduce M-quantile regression with lasso regularization. This allows us to investigate the extreme behavior of y conditional on $\mathbf{x}$ and to shrink the predictors in order to perform model selection.

Abstract *I classici metodi di regressione studiano il comportamento medio di una risposta, y, dati alcuni predittori,* $\mathbf{x}$*. In alcuni casi, il comportamento medio non fornisce un'informazione adeguata di un fenomeno. Per questo motivo, la regressione quantilica analizza come il q-esimo quantile della distribuzione condizionata di y dato* $\mathbf{x}$ *varia a seconda di* $\mathbf{x}$*, e la regressione M-quantilica la generalizza utilizzando funzioni di influenza. Inoltre, quando il numero di predittori è elevato, selezionarne un sottoinsieme migliora l'interpretibilità del modello. Per questo motivo, in questo lavoro introduciamo la regressione M-quantilica con la regolarizzazione lasso. Questo permette di investigare il comportamento a diversi livelli della distribuzione di y condizionata ad* $\mathbf{x}$ *e di effettuare, allo stesso tempo, la selezione del modello.*

1 Introduction

When investigating the relationship between a response variable y and some predictors $\mathbf{x}$, it may be useful to employ *quantile regression* (Koenker, 1978; Koenker and D' Orey, 1987), that is to analyze how the q-th quantile of the conditional distribution of y given $\mathbf{x}$ varies with $\mathbf{x}$. This is particularly useful when the average behavior of y given $\mathbf{x}$, investigated by means of the classical regression analysis, does not give a complete picture of the distribution. In particular, quantile regression assumes that the q-th quantile of y is a linear function of the predictors, in other words $Q_q(y|\mathbf{x}) = \mathbf{x}^T \mathbf{b}(q)$, and it leads to a family of hyperplanes indexed by the value of the corresponding quantile coefficient $q \in (0,1)$. Given a sample of n observations, the vector $\mathbf{b}(q)$ is estimated by minimizing

$$\sum_{i=1}^{n} |r_i[\mathbf{b}(q)]| \{(1-q) I(r_i[\mathbf{b}(q)] \leq 0) + qI(r_i[\mathbf{b}(q)] > 0)\},$$

with respect to $\mathbf{b}(q)$ through linear programming methods, where $r_i[\mathbf{b}(q)] = y_i - \mathbf{x}_i^T \mathbf{b}(q)$.

M-quantile regression (Breckling and Chambers, 1988) generalizes the quantile regression idea through the use of influence functions. Specifically, the M-quantile regression line of order q is defined as the solution $Q_q(y|\mathbf{x}, \psi_q) = \mathbf{x}^T \mathbf{b}_\psi(q)$ to $\int \psi_q(y - Q_q)\, dF(y|\mathbf{x}) = 0$, where F denotes the distribution of y given $\mathbf{x}$ underlying the data and ψ_q denotes the influence function associated to q-th M-quantile. The general M-estimator of $\mathbf{b}_\psi(q)$ is obtained by solving the set of estimating equations $\sum_{i=1}^{n} \psi_q\left(y_i - \mathbf{x}_i^T \mathbf{b}_\psi(q)\right) \mathbf{x}_i = \mathbf{0}$, with respect to $\mathbf{b}_\psi(q)$. It is assumed that

$$\psi_q\left(r_{iq\psi}\right) = 2\psi\{s^{-1} r_{iq\psi}\}\{(1-q) I\left(r_{iq\psi} \leq 0\right) + qI\left(r_{iq\psi} > 0\right)\},$$

where $r_{iq\psi} = y_i - \mathbf{x}_i^T \mathbf{b}_\psi(q)$ and s is a robust estimate of the scale, such as the MAD estimate for which $s = \text{median}|r_{iq\psi}|/0.6745$. We consider the Huber (Huber, 1981) influence function, given by $\psi(u) = u$, if $-c \leq u \leq c$, and $\psi(u) = c\ \text{sign}(u)$, otherwise, where c is a cutoff constant. In particular, robustness is increased as c decreases, while efficiency is increased as c increases.

Generally, we can improve the interpretability of a model selecting a subset of predictors, and we may improve the efficiency shrinking the coefficients towards zero. One useful tool is the lasso (Tibshirani, 1996), which is a penalized least square method that imposes an L_1-penalty on the coefficients, i.e. the sum of the absolute value of the coefficients must be less than a given constant. In this regard, quantile regression with lasso regularization has been introduced by Li and Zhu (2008).

In this work, we propose an M-quantile regression that takes advantage of a lasso regularization, so that we can analyze the behavior of y given $\mathbf{x}$ and do selection and shrinkage at the same time. The paper is organized as follows. In Section 2, we introduce the proposed method while, in Section 3, we illustrate the method through the use of a classical data set and provide some conclusions and future research.

2 M-quantile regression and the lasso

Suppose we have a regression data set $(\mathbf{X},\mathbf{y})$ with $\mathbf{X}\in\mathbb{R}^{n\times p}$ and $\mathbf{y}\in\mathbb{R}^n$. The lasso-estimator for M-quantile regression coefficients can be defined as

$$\hat{\mathbf{b}}=\left(\hat{b}_0,\hat{\mathbf{b}}_1^T\right)^T=\text{argmin}\{L(\mathbf{X},\mathbf{y},\mathbf{b}):b_0\in\mathbb{R},\mathbf{b}_1\in\mathbb{R}^p\}\text{ subject to }\sum_{j=1}^{p}|b_j|\leq t,$$

where the loss function L is given by

$$L(\mathbf{X},\mathbf{y},\mathbf{b})=\sum_{i=1}^{n}\psi_q\left(r_i(\mathbf{b})/\sigma_q\right), \tag{1}$$

with $r_i(\mathbf{b})=y_i-b_0-\mathbf{x}_i^T\mathbf{b}_1$, and σ_q is the scale of the residuals and it can be estimated by MAD. Here $t\geq 0$ is the tuning parameter and it controls the amount of shrinkage that is applied to the estimates. Setting the derivatives of (1) with respect to $\mathbf{b}$ to zero yields the following system of equations,

$$\mathbf{W}\left(\mathbf{y}-\hat{b}_0\mathbb{1}_n-\mathbf{X}\hat{\mathbf{b}}_1\right)=\mathbf{0}, \tag{2}$$

$$\left(\mathbf{X}^T\mathbf{W}\mathbf{X}\right)\hat{\mathbf{b}}_1=\mathbf{X}^T\mathbf{W}\left(\mathbf{y}-\hat{b}_0\mathbb{1}_n\right), \tag{3}$$

where $\mathbf{W}=\text{diag}\,(w_i)$ and $w_i(t_i)=\psi_q(t_i/2t_i)$. This is a weighted version of normal equations for the classical lasso estimator for the regression coefficients. As usual in M-quantile regression, these weighted normal equations require an iterative procedure. We describe a stable algorithm to solve this system of equations.

Let $\delta_i, i=1,2,\ldots,2^p$ be the p-tuples of the form $(\pm1,\pm1,\ldots,\pm1)$. The condition $\sum_{j=1}^{p}|b_j|\leq t$ is equivalent to $\delta_i^T\mathbf{b}_1\leq t$, $\forall i$. For a given $\mathbf{b}_1$, let $E=\{i:\delta_i^T\mathbf{b}_1=t\}$ and $S=\{i:\delta_i^T\mathbf{b}_1<t\}$. Denote by $\mathbf{G}_E$ the matrix whose rows are δ_i for $i\in E$. The algorithm starts with $E=\{i_0\}$ where $\delta_{i_0}=sign\left(\hat{\mathbf{b}}_1\right)$, $\hat{\mathbf{b}}_1$ being the overall M-quantile estimate where $\hat{b}_0$ and $\hat{\mathbf{b}}_1$ are computed iteratively solving (2) and (3). Then, find $\hat{\mathbf{b}}_1$ to minimize $L(\mathbf{X},\mathbf{y},\mathbf{b})$ subject to $\mathbf{G}_E\hat{\mathbf{b}}_1\leq t\mathbb{1}_p$ by using a constrained M-quantile procedure. Given $\hat{\mathbf{b}}_1$, we can estimate b_0 by using (2). While $\{\sum_{j=1}^{p}|b_{1j}|>t\}$, we add i to the set E where $\delta_i=sign\left(\hat{\mathbf{b}}_1\right)$. Find $\hat{\mathbf{b}}_1$ to minimize $L(\mathbf{X},\mathbf{y},\mathbf{b})$ subject to $\mathbf{G}_E\hat{\mathbf{b}}_1\leq t\mathbb{1}_p$. Given $\hat{\mathbf{b}}_1$, we can estimate b_0 by using (2). The procedure must always converge in a finite number of steps since one element is added to the set E at each step, and there is a total of 2^p elements.

The lasso parameter t can be estimated by cross-validation or generalized cross-validation.

3 Illustration and final remarks

Data used for this illustration come from a study of prostate cancer (Stamey et al., 1989) and are used in Tibshirani (1996) to illustrate the standard lasso. The response variable is the logarithm of prostate-specific antigen (lpsa), while the predictors are given by eight clinical measures: the logarithm of cancer volume (lcavol), the logarithm of prostate weight (lweight), age, the logarithm of the amount of benign prostatic hyperplasia (lbph), the seminal vesicle invasion (svi), the logarithm of the capsular penetration (lcp), the Gleason score (gleason), and the percentage of the Gleason score 4 or 5 (pgg45).

We perform the M-quantile regression with lasso selection at different values of q and compare the results with standard lasso regression and M-quantile regression. The predictors have been standardized. In the case of standard lasso regression and M-quantile regression with lasso the optimal t is computed by means of five-fold cross-validation. The tuning constant c used in the M-quantile regression and M-quantile regression with lasso is kept fixed at 1.345. This value provides fairly high efficiency in the normal case and still offers protection against outliers (Huber, 1981).

In Table 1 we report the estimated coefficients and corresponding standard errors. The latter, in the case of M-quantile regression and M-quantile regression with lasso, are obtained by $M = 1000$ bootstrap replicates, in which the optimal t is computed at each replicate. We can see that OLS and M-quantile provide similar results, and that Lasso and M-quantile lasso provide similar results. This can be explained by the fact that the response variable is on the log-scale and that there are not influential observations. When comparing M-quantile regression with M-quantile lasso, we can see that the shrinkage effectively performs model selection. If we fit OLS, M-quantile regression and M-quantile with lasso for the response variable on the original scale, differences among the methods are more pronounced as the response variable has a distinctive skew distribution (see the second half of Table 1). In fact, OLS and M-quantile provide quite different estimates, by this providing evidence of the need for robustness. In addition, M-quantile lasso provides model selection and standard errors that are generally lower than M-quantile, further improving on efficiency in this case.

In Table 2 we compare the M-quantile and the M-quantile lasso at $q = \{0.25, 0.50, 0.75\}$ for the log-scale response. In Figure 1 we show the value of the estimates for M-quantile lasso as a function of t, and in Figure 2 we show the value of the estimates as a function of q. Again, model selection is performed at different levels of the conditional distribution of the response given the predictors. In addition, we can notice that for most of the predictors, the effect is the same for different values of q, while for others it increases with q (svi).

We plan to make this approach more flexible by extending it to Elastic Net and to allow for non-linear relationships using penalized spline regression.

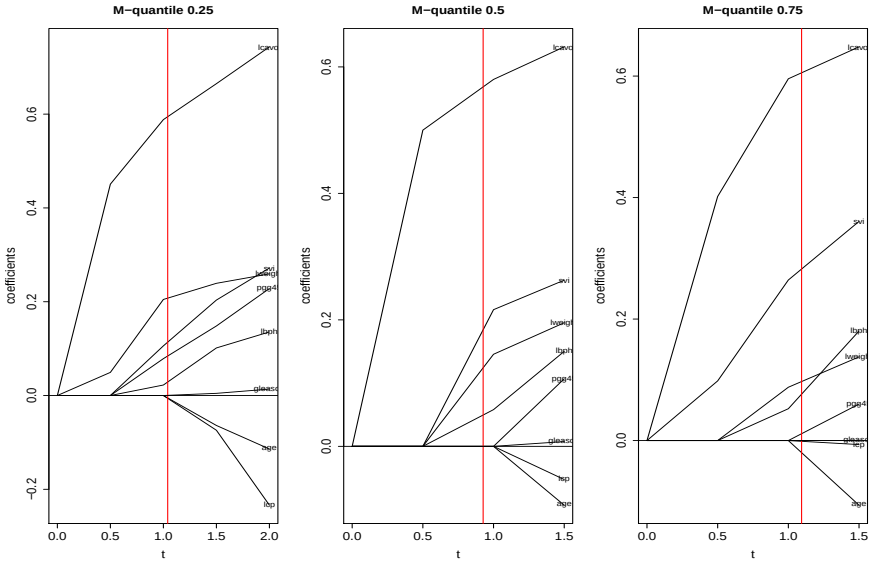

Fig. 1 Solution path for M-quantile regression with lasso at $q = \{0.25, 0.50, 0.75\}$. Each curve represents the value of the estimated coefficient at the corresponding value of t. The red line is at the value of t selected by fivefold cross-validation.

New insights into the Conditioning and Gain Score approaches in multilevel analysis

Alcune riflessioni su approccio condizionato e approccio alle differenze nell'analisi multilivello .

Bruno Arpino, Silvia Bacci, Leonardo Grilli, Raffaele Guetto and Carla Rampichini

Abstract We consider the issue of estimating the effect of a treatment variable on student achievement when a pre-test is available, taking into account the hierarchical structure of the data, with students nested into schools. The treatment variable can be either at student level or at school level. This effect can be estimated alternatively by adjusting for the pre-test score, i.e. conditioning, or by using the difference between post-test and pre-test scores, namely the gain score. The performance of the two approaches depends on pre-test reliability and validity of the common trend assumption. We derive approximated analytical results and we compare the two approaches via a simulation study.

Abstract *Questo lavoro affronta il problema della stima dell'effetto di uno specifico intervento (trattamento) sull'apprendimento degli studenti, nel caso in cui si disponga di una misura dell'abilità sia prima che dopo il trattamento, tenendo in considerazione la natura gerarchica dei dati, con gli studenti raggruppati in scuole. Il trattamento può essere sia a livello di singolo studente che a livello di scuola. Considerando il caso in cui l'assegnazione al trattamento non è casuale, esistono due approcci alternativi per la stima dell'effetto di interesse. Un primo approccio si basa sul condizionamento rispetto al test di abilità effettuato prima del trattamento, mentre il secondo approccio considera il guadagno, cioè la differenza tra i punteggi al test prima e dopo il trattamento. La validità dei due approcci dipende dalla affidabilità del test prima del trattamento come misura dell'abilità dello studente e dall'ipotesi di effetto comune dell'abilità nel determinare il punteggio ai due test. In questo lavoro, mostriamo alcuni risultati teorici e i risultati di uno studio di simulazione per il confronto tra questi due approcci.*

1 Introduction

In the education literature, student achievement is typically measured using multilevel models [1], with students nested into schools. In this contribution we aim to assess the effect of a specific treatment at student level (e.g. an individual support program) or at the school level (e.g. a given school policy). We consider a setting where student achievement is measured by means of a standardized test in two occasions, one before the treatment (pre-test), and the other one after the treatment (post-test). Two main methodological approaches have been proposed to estimate the treatment effect in this setting. The first approach consists in estimating the effect of the treatment on the post-test score, conditionally on the pre-test score (*conditioning* approach). The second approach considers the difference between the post-test score and the pre-test score as response variable, the so called *gain score* approach.

These two approaches give unbiased estimates under different assumptions, which are difficult to evaluate in observational studies. The debate on which of the two methods has to be preferred is still ongoing. Recently, Kim and Steiner [2] reconsidered the choice between the two approaches using graphs to illustrate the conditions under which a method has to be preferred. Despite the important contribution of this and several other studies that we review next, this literature has overlooked the fact that often test scores are collected in data sets with a multilevel structure, like in the educational setting.

We extend the results of Kim and Steiner [2] in two directions. First, we consider the most frequent case of a binary treatment variable rather than a continuous one. Second, we carry out the comparison between the two approaches when data have a multilevel structure, like in education setting, relying on a two level linear model. The multilevel setting has additional characteristics, playing a role in the comparison of the two approaches. In particular, the treatment can be either at student level or at school level. Moreover, the model includes random effects and it may also include cluster means.

2 Conditioning and gain score approaches

We consider individuals ($i = 1,\dots,n_j$) nested into clusters ($j = 1,\dots,J$), for example students nested into schools. Let Y_{1ij} and Y_{2ij} be continuous variables describing the observable scores on the pre-test and the post-test. These scores are error prone measures of a latent ability A_{ij}. The difference $G_{ij} = Y_{2ij} - Y_{1ij}$ is the gain score.

We are interested in assessing the effect of a treatment Z_{ij} on the post-test score Y_{2ij}, taking into account that the unobservable ability A_{ij} acts as a confounder affecting both Z_{ij} and Y_{2ij}. We assume that the two scores are generated by the following random intercept models:

$$Y_{1ij} = \mu_1 + \beta_1 A_{ij} + \psi_1 \bar{A}_j + u_{1j} + \lambda_1 e_{ij} \tag{1}$$

$$Y_{2ij} = \mu_2 + \beta_2 A_{ij} + \psi_2 \bar{A}_j + \tau Z_{ij} + u_{2j} + \lambda_2 e_{ij} + v_{ij}, \tag{2}$$

where $\bar{A}_j$ is the cluster-mean ability, μ_1 and μ_2 are intercepts, β_1 and β_2 are the within effects of the ability on the pre- and post-test scores, respectively, whereas ψ_1 and ψ_2 are the corresponding contextual effects. The treatment effect of interest is τ. The random variables u_{1j} and u_{2j} are the level 2 errors, while e_{ij} is a common level 1 error, and v_{ij} is a level 1 error specific to the post-test. All errors are assumed to be normally distributed with 0 mean and constant variances. Without loss of generality, we assume that both the individual ability and the error terms are normally distributed with mean 0 and unit variance, that is, $E(A_{ij}) = E(e_{ij}) = E(u_j) = 0$, and $Var(A_{ij}) = Var(e_{ij}) = 1$. Then, $Var(Y_{1ij}) = \beta_1^2 + \sigma_u^2 + \lambda_1^2$. When $\lambda_1 = 0$ the ability A_{ij} is measured without error by the pre-test Y_{1ij}. The gain score is defined as $G_{ij} = Y_{2ij} - Y_{1ij}$. The data generating path defined by equations (1) and (2) is represented in Figure 1. In order to estimate the treatment effect τ it is necessary to rely on some assumptions on the unobserved confounding due to the ability A_{ij}.

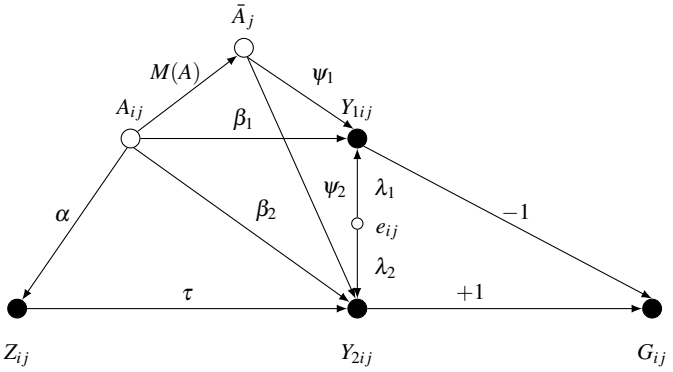

Fig. 1 *Path diagram for conditioning and gain score approaches; different effect of ability at within- and between-levels.*

In particular, according to the conditioning approach, we use the pre-test score Y_{1ij} as a proxy of the latent ability A_{ij}. Thus the conditioning model is specified as follows:

$$Y_{2ij} = \mu_2 + \beta_2 Y_{1ij} + \psi_2 \bar{Y}_{1j} + \tau Z_{ij} + u_{2j} + \varepsilon_{ij}. \tag{3}$$

The treatment effect τ is correctly estimated from model (3) if A_{1ij} is measured without error by Y_{1ij}, i.e. when λ_1 in equation (2) is equal to zero.

On the other hand, considering equations (1) and (2), we obtain $E(G_{ij}) = Y_{2ij} - Y_{1ij} = (\mu_2 - \mu_1) + (\beta_2 - \beta_1)A_{ij} + (\psi_2 - \psi_1)\bar{A}_j + \tau Z_{ij}$. Thus, under the common trend assumption, i.e. $\beta_2 = \beta_1$ and $\psi_2 = \psi_1$, the gain score is unaffected by the ability and the treatment effect τ can be estimated without bias from the following model:

$$G_{ij} = \tilde{\mu} + \tau Z_{ij} + \tilde{u}_j + \tilde{\varepsilon}_{ij}. \tag{4}$$

3 Main results

Considering a binary treatment, we derived the bias formula for the conditioning approach using model (3) without random effects, e.g. for the OLS estimator of τ, thus extending the results of Kim and Steiner [2]. We checked by a simulation experiment that this formula is a good approximation of the bias for the GLS estimator of τ in the random effects model (3).

The simulation study is based on 1000 data sets, each of them being composed of $10,000$ individuals uniformly distributed in 100 groups. Values of parameters used to generate data mimic the structure of Invalsi data [3]. In particular, the true value of τ (treatment effect) is equal to 2.

Table 1 displays the main results of the simulation study. Nine different configurations are taken into account, which distinguish for: (i) absence ($\lambda_1 = \lambda_2 = 0$) or presence of the measurement error, only on the pre-test ($\lambda_1 \neq 0$) and also on the post-test ($\lambda_2 \neq 0$), and (ii) validity of the common trend assumption, at level 1 ($\beta_2 = \beta_1$), at level 2 ($\psi_1 = \psi_2$), or at both levels. For each configuration, we show the mean of the estimated treatment effects and the corresponding relative error.

Table 1 Simulation study: Means of estimated treatment effect ($\hat{\tau}$) and corresponding relative error ($\%err$), individual-level treatment: conditioning and gain score approaches.

Conf.	Measurement error	Common trend level 1	Common trend level 2	Conditional $\hat{\tau}$	Conditional %err	Gain $\hat{\tau}$	Gain %err
1	no ($\lambda_1 = \lambda_2 = 0$)	yes	yes	2.0	0.0	2.0	0.0
2	no ($\lambda_1 = \lambda_2 = 0$)	no	yes	2.0	0.0	9.0	348.1
3	no ($\lambda_1 = \lambda_2 = 0$)	no	no	2.0	0.0	9.0	348.5
4	yes ($\lambda_1 = 6$; $\lambda_2 = 0$)	yes	yes	3.9	95.5	2.0	0.0
5	yes ($\lambda_1 = 6$; $\lambda_2 = 0$)	yes	no	3.9	95.5	2.0	0.0
6	yes ($\lambda_1 \neq \lambda_2$)	yes	yes	3.0	47.5	2.0	0.0
7	yes ($\lambda_1 = \lambda_2 = 6$)	yes	yes	2.0	0.0	2.0	0.0

Our simulations show that the results of Kim and Steiner generalize to a multilevel setting with some adjustments and further assumptions. Indeed, the treatment effect is correctly estimated using the conditioning approach when the pre-test is measured without error (configurations 1, 2, 3), whereas the gain score approach gives unbiased estimates when the common trend assumption is satisfied (configurations 4, 6, 7). Thus, under the common trend assumption, the gain score approach has to be preferred to the conditioning one in presence of measurement error on the pre-test, even if the reliability is quite high (say around 0.85).

As a further peculiarity, the conditioning approach provides satisfactorily results when the measurement error acts both on the pre-test and the post-test, but at the same extent (configuration 7). In addition, when the treatment is at level 1 (i.e., the target of the treatment are the single students), as in the simulation study here presented, its effect is correctly estimated using the gain score approach if the common trend assumption holds at level 1, even if it is violated at level 2 (configuration 5).

For the future development of this work, we intend to extend the simulation study to consider when the treatment acts at level 2 (i.e., the target of the treatment are the schools). We expect that in such a situation the common trend assumption at level 2 is crucial.

Simultaneous confidence regions and curvature measures in nonlinear models

Regioni di confidenza simultanee e misure di curvatura nei modelli nonlineari

Claudia Furlan and Cinzia Mortarino

Abstract Accuracy measures for parameter estimates require specific procedures for nonlinear models. For low parameter dimensions, routines for evaluating *approximate* simultaneous confidence regions (sCRs) are available in the most common software programs; however, the degree of accuracy may be very low. In this paper, we investigate on the relationship between coverage probability and degree of nonlinearity for approximate and bootstrap sCRs, using simulation results. Given our results, we provide a rule based on the value of the maximum parameter effects curvature to decide whether relying on the approximate sCR or on the bootstrap sCR, even if the latter usually gives coverage probability slightly lower than the nominal level.

Abstract *L'analisi dei modelli nonlineari prevede procedure specifiche per determinare l'accuratezza delle stime dei parametri. Per i casi in cui la numerosità parametrica è limitata, sono disponibili nei più comuni software routine di calcolo della regione di confidenza simultanea approssimata. Tuttavia la sua accuratezza può essere molto bassa. In questo lavoro, sulla base di simulazioni, esaminiamo la relazione fra la probabilità di copertura e il grado di nonlinearità per la regione approssimata e per la regione bootstrap. Anche se quest'ultima ha probabilità di copertura leggermente inferiori al livello nominale, a partire dai risultati ottenuti, proponiamo una regola per decidere quale delle due regioni utilizzare sulla base della curvatura dovuta alla parametrizzazione.*

1 Introduction

Nonlinear models are an essential tool to describe many real-world phenomena. Unlike linear models, accuracy measures for parameter estimates, such as confidence intervals or confidence regions, may represent a difficult task due to nonlinearity. The issue of constructing a simultaneous confidence region (sCR) was mostly developed in the 1960s-1980s, but this research was limited by the computational difficulties of that time, especially for exact regions, [7]. A few approximations have been derived [8], given the complexity of obtaining an exact sCR. For instance, the so-called *approximate* sCR, $\mathfrak{I}(\Theta)$, is derived by approximating the nonlinear model via a linear Taylor expansion of the first order, taking advantage of the asymptotic normal distribution of the estimator. Thus, the approximate sCR's confidence levels are valid asymptotically. The approximate sCR is computationally attractive, since it corresponds to hyperellipsoids, and its use is facilitated by default routines available in the most common software programs, such as R or Mathematica, at least for low parameter dimensions.

Recently, Furlan and Mortarino [6] compared two exact sCRs and the approximate sCR with a parametric and a non parametric bootstrap sCR, for the specific class of nonlinear diffusion models, via simulation studies and real data. The authors focused on two of the most widespread S-shaped diffusion models for the lifecycle of products: the Bass model (BM) and the Generalized Bass model (GBM), with three and six parameters, respectively [1, 2], fitted to cumulative data. The GBM is defined by:

$$y(t) = m\frac{1-e^{-(p+q)\int_0^t w(\tau)d\tau}}{1+\frac{q}{p}e^{-(p+q)\int_0^t w(\tau)d\tau}} + \varepsilon(t), \tag{1}$$

where $y(t)$ are the cumulative sales of a product at time t, m is the market potential, p is the innovation coefficient, q is the imitation coefficient, and $w(t)$ can be any integrable function (in [6], $w(t)$ is a function of 3 parameters). The BM corresponds to Eq. (1) with $w(t) = 1$.

Since new observations at the end of the finite lifecycle do not provide useful information, some parameters of the BM cannot be estimated consistently and asymptotic normality does not apply [5]. However, estimation variance decreases with increasing lifecycle stage, that is, when observations cover a longer portion of the finite lifecycle. Furlan and Mortarino [6], then, examined situations observed at different lifecycle stages and, for the approximate sCR, found that the coverage probability is seriously affected by the parameter dimension, the lifecycle stage and the error variability. The parametric bootstrap sCR, $\mathfrak{B}_p(\Theta)$, proposed in [6], conversely reaches coverage probability values less affected by lifecycle stage, parameter dimension, and error variability. The coverage level of $\mathfrak{B}_p(\Theta)$, however, is systematically lower than the nominal level.

In assessing the appropriateness of the linear approximation, what is important is the overall degree of nonlinearity, irrespective of the causes contributing to it (i.e., parameter dimension, error variability, and lifecycle stage for nonlinear diffusion models). In this work, we make a further step in the assessment of the applicability

of the approximate sCR, by measuring the overall degree of nonlinearity of situations studied in [6]. Moreover, we explore the relationship between coverage probability and the degree of nonlinearity. At the same time, we explore the reliability of $\mathfrak{B}_p(\Theta)$, especially for situations when $\mathfrak{I}(\Theta)$ cannot be trusted.

2 Intrinsic and parameter-effects curvature

Nonlinearity is based on the notion of curvature and is of two different types: the intrinsic nonlinearity, which is due to the bending and twisting of the expectation surface; and the parameter-effects nonlinearity, which is due to the parametrization [4, 8]. Bates and Watts [3] proposed some measures of nonlinearity based on the notion of curvature, which indicate the adequacy of the linear approximation, and are independent of scale changes in both the data and the parameters.

To use the approximate sCR, it is necessary that both planar and uniform coordinate assumptions are satisfied, that is if "expectation surface is sufficiently flat to be replaced by the tangent plane" and if "straight, parallel equispaced lines in the parameter space map into nearly straight, parallel equispaced lines on the expectation surface", respectively [4]. It means that both the intrinsic and the parameter-effects nonlinearity need to be small.

In this work we use, as measures of nonlinearity, the two indicators γ^N_{max} and γ^T_{max} proposed by Bates and Watts [3], which are the maximum intrinsic and parameter-effects curvature, respectively, over the direction h in the parameter set (see Seber and Wild [8] for details). To determine the impact of nonlinearity upon a sCR, the two maximum curvature measures γ^N_{max} and γ^T_{max} must be compared to $1/\sqrt{F(k,n-k;1-\alpha)}$, which can be seen as the radius of the curvature of the 100(1-α)% confidence region. In the rest of the paper, we will omit the degrees of freedom and confidence level, denoting this threshold simply as $1/\sqrt{F}$. If the ratio $\gamma^T_{max}/\sqrt{F}$ is small compared to 1, than the expectation surface is sufficiently flat over the confidence region, and if the ratio $\gamma^N_{max}/\sqrt{F}$ is small compared to 1, the uniform coordinate assumption is good. If both assumptions are satisfied, then the approximate sCR can be substantially trusted.

Bates and Watts [3] found that the parameter-effects curvature is much higher than the intrinsic curvature. In their study, the author found that in 13 out of 16 examples, the maximum of the intrinsic curvature is fine and the ratio $\gamma^N_{max}/\sqrt{F}$ is even smaller than 0.5, while in 13 examples the maximum of the parameter-effects curvature, γ^T_{max}, is unacceptable.

3 Simulation results

In [6], three real cases were considered, different in terms of both the lifecycle stage and pattern, with a moderate sample size. The real cases were represented by the annual sales (in millions of units) of music cassettes in the United States from 1973 to 2005, the Austrian thermal solar capacity, in MW_{th}, with annual data from 1982 to

Table 1 Simulation settings: name of the setting, model used, parameter dimension (k), simulation length (n), lifecycle stage (%) (see [6], for further details).

Setting	Model	k	n	lifecycle stage (%)
Gas.2	restricted BM	2	46	61
Sol.2	restricted BM	2	27	54
Tgas.2	restricted BM	2	35	52
Cass.3	BM	3	33	100
Gas.3	BM	3	46	61
Sol.3	BM	3	27	54

Sol.6	GBM	6	27	68
Gas.6	GBM	6	46	58
Tgas.6	GBM	6	35	44

2008, and the Algerian natural gas production, in billion cubic metres (BCM), with annual data from 1970 to 2015. The latter series was also analyzed with truncated data until 2004. Furlan and Mortarino [6] investigated the coverage probability of the sCRs, with $1-\alpha = 0.95$ in 10 settings, by simulating from the restricted BM[1], BM, and GBM, and using the estimates found in the real cases as true values for the parameters (see Table 1, for the list of the settings analyzed). Using the three nested models allows to explore different parameter sizes, besides different sample sizes and different lifecycle lenghts. For each setting, $N = 1,000$ time series have been generated, and independent errors ε_t, $t = 1,2,\ldots,n$, have been sampled from a normal distribution with a zero mean and variance σ^2. $B = 1,000$ replications are used for the parametric bootstrap. For analyzing the effect of the variability of the data around the mean trajectory, different values of the error variance σ^2 were used. Since the market potential is different across the settings, $(\sigma/m)^2 \times 10^6$ represents a comparable measure of variability: it ranges from 0.1 to 150, allowing the processes to vary from essentially the trajectory of the model, to an extremely distressed pattern[2].

The results in [6] show that $\mathfrak{I}(\Theta)$, although it is the most used sCR, is often unreliable, but the degree of inaccuracy cannot be directly linked to a specific parameter size or lifecycle stage. In other words, it is difficult to suggest a strategy to decide whether $\mathfrak{I}(\Theta)$ can be trusted. For this reason, in this paper we try to examine the relationship between accuracy (measured by coverage probability) and maximum curvature measures.

With regard to the maximum parameter-effects curvature, Figure 1 shows the box-plots of the ratios $\gamma^T_{max}/\sqrt{F}$ for the simulated datasets[3] of the four settings with $k = 3$, for the different values of $(\sigma/m)^2 \times 10^6$. Values above 1 (red line) represent situations for which the parameter-effects curvature value advises against using

[1] The restricted BM corresponds to the BM with m fixed (parameter dimension: $k = 2$).

[2] The 11 values used for $(\sigma/m)^2 \times 10^6$ were: $0.1, 0.5, 1, 5, 7.5, 10, 12.5, 15, 20, 100, 150$.

[3] For space reasons, we cannot present here the results for $k = 2$ and $k = 6$.

$\mathfrak{I}(\Theta)$. We notice that curvature is related to lifecycle stage: the four settings are ordered according to this quantity, with decreasing levels of lifecycle stage. We also underline, that, given lifecycle stage, increasing variance corresponds to increasing curvature, but the variance level at which curvature exceeds 1 changes for different settings. Notice that we do not discuss here results for γ^N_{max}, because the intrinsic curvature came out to be very small in our simulations (the largest value for $\gamma^N_{max}/\sqrt{F}$ was equal to 0.131), confirming the outcomes obtained in [3] with real cases.

Let us examine, now, the relationship between coverage probability for $\mathfrak{I}(\Theta)$ (as assessed by simulations in [6]) and maximum parameter-effects curvature, by using, for each setting, the median of the N ratios $\gamma^T_{max}/\sqrt{F}$ (Fig. 2). In the plot, the two vertical lines correspond to thresholds 0.5 and 1. We observe that the coverage probability is essentially set on the nominal level when the ratio $\gamma^T_{max}/\sqrt{F}$ is smaller than 0.5, irrespectively for lifecycle stage or variance level. Conversely, curvature ratios between 0.5 and 1 lead to coverage probabilities always below the nominal level, but to a different extent according to different settings. For values above 1, we observe that the decrease of coverage probability is almost linear with the maximum parameter-effects curvature for all the settings. This turns out to produce a simple rule to predict coverage probability of $\mathfrak{I}(\Theta)$, given evaluated $\gamma^T_{max}/\sqrt{F}$.

Fig. 3 shows the same kind of plot for $\mathfrak{B}_p(\Theta)$ coverage probability. The relationship between coverage probability and the maximum parameter-effects curvature is here much less definite than we observed for $\mathfrak{I}(\Theta)$. Coverage probabilities are almost always below the nominal level, but we do not observe large discrepancies that, conversely, affected $\mathfrak{I}(\Theta)$. Moreover, Fig. 3 suggests that a poor performance for $\mathfrak{B}_p(\Theta)$ does not correspond to higher nonlinearity measures, making bootstrap a good alternative to $\mathfrak{I}(\Theta)$ whenever the maximum parameter-effects curvature exceeds $1/\sqrt{F}$.

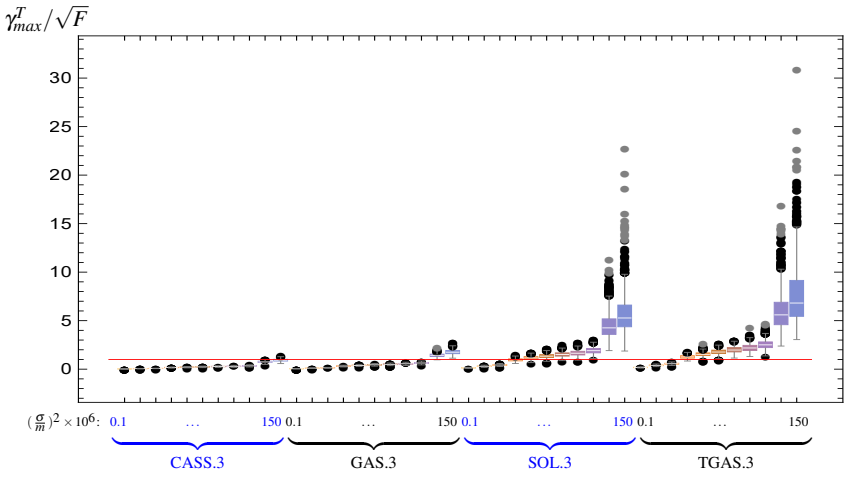

Fig. 1 Box-plots of the ratios $\gamma^T_{max}/\sqrt{F}$ for the 1000 simulated datasets of the four settings with $k = 3$, for the 11 different values of $(\sigma/m)^2 \times 10^6$. The red line corresponds to 1.

Design-based consistency of the Horvitz-Thompson estimator for spatial populations

Consistenza da disegno dello stimatore di Horvitz-Thompson per popolazioni spaziali

L. Fattorini, M. Marcheselli, C. Pisani and L.Pratelli

Abstract Spatial populations are usually located on a continuous support and can be distinguished into surfaces giving the value of the survey variable at any point of the support, finite collections of units, scattered onto the support, with attached values of the survey variables, or finite collections of areal units partitioning the support where the survey variable is the total amount of an attribute within each areal unit. Fattorini et al. (2020) prove design-consistency of the Horvitz-Thompson estimator of totals by focusing on the properties of the sampling design sequences under the minimal requirement that the survey variable is bounded.

Abstract *Le popolazioni spaziali sono di solito situate su un supporto continuo e si possono distinguere in popolazioni continue, identificabili con una superficie che rappresenta in ogni punto il valore della variabile di interesse, insiemi finiti di unità dislocate sul supporto, a ciascuna delle quali è associato un valore della variabile, o insiemi finiti di unità areali che costituiscono una partizione del supporto, in cui la variabile di interesse è il totale di un attributo all'interno di ciascuna unità areale. Fattorini et al. (2020) dimostrano la consistenza basata sul disegno dello stimatore di Horvitz-Thompson del totale sulla base delle caratteristiche della successione di disegni di campionamento sotto l'ipotesi minimale che la variabile di interesse sia limitata.*

Key words: continuous populations, finite populations, Horvitz-Thompson estimation

1 Introduction

In the framework of design-based inference, spatial populations are constituted by fixed sets of locations on a continuous support with fixed values of the survey variable attached to each location. In particular, spatial populations can be distinguished into continuous populations, finite populations of units and finite populations of areal units. Continuous populations arise when a spatial phenomenon on a continuous support is conceptualized as a population constituted by a continuous set of locations with a surface giving the value of the survey variable at each location. Finite populations of units are constituted by a finite set of regularly or irregularly units scattered over the support with the value of the survey variable attached to each unit, usually referred to as the mark of the unit. Finally, partitioning the support into spatial subsets gives rise to a finite population of areal units and the survey variable turns out to be the total amount of an attribute of interest within each areal unit, where the total can refer either to a continuous or a finite population of units scattered over the support.
Design-based inference has been widely adopted for estimating spatial populations totals (e.g. Thompson, 2002). When a finite population of units or areal units is considered, unbiased estimation is performed by using the Horvitz-Thompson (HT) estimator (e.g. Särndal et al., 1992) and when continuous populations are of interest it is usually performed extending the HT criterion (e.g. Cordy, 1993).
In this paper we present and discuss the results by Fattorini et al. (2020), which, in the spirit of Isaki and Fuller (1982), give conditions for the design-based consistency of the HT estimators which involve the characteristics of the design sequence and hold under minimal and realistic assumptions regarding populations.

2 Consistency results

2.1 Consistency for continuous populations

Let y be a Borelian and bounded function on the compact support $\mathscr{A}$ with values on $[0,L]$, where $y(p)$ is the value of the survey variable Y at the location $p \in \mathscr{A}$. The population total is $T = \int_{\mathscr{A}} y(p)\lambda(dp)$, where λ is the Lebesgue measure on $\mathbf{R}^2$.

Following Cordy (1993), suppose a sequence of designs $\{d_k\}$, each of them selecting an increasing number n_k of points onto $\mathscr{A}$, say $P_{k,1},...,P_{k,n_k}$ in such a way that the n_k-tuple $(P_{k,1},\ldots,P_{k,n_k})$ is a random vector. Let $g_i^{(k)}$ be a version of the marginal probability density of $P_{k,i}$ with respect to λ and $g_{ih}^{(k)}$ be a ver-

sion of the marginal probability density of $(P_{k,i}, P_{k,h})$ with respect to $\lambda \otimes \lambda$, with $i \neq h = 1, ..., n_k$.

Denoting by $\pi_k(p) = \sum_{i=1}^{n_k} g_i^{(k)}(p)$ the inclusion function and by $\pi_k(p,q) = \sum_{i \neq h=1}^{n_k} g_{ih}^{(k)}(p,q)$ the pairwise inclusion function, if $\pi_k(p) > 0$ for each $p \in \mathscr{A}$, then the extension of the HT estimator

$$\widehat{T}_k = \sum_{i=1}^{n_k} \frac{y(P_{k,i})}{\pi_k(P_{k,i})}$$

is an unbiased estimator of T.

Fattorini et al. (2020) prove that if the design sequence is such that

$$\lim_{k \to \infty} \sup_p \frac{1}{\pi_k(p)} = 0$$

$$\lim_{k \to \infty} \sup_{p \neq q} \left\{ \frac{\pi_k(p,q)}{\pi_k(p)\pi_k(q)} - 1 \right\}^+ = 0$$

then $\lim_{k \to \infty} \operatorname{var}(\widehat{T}_k) = 0$ and $\widehat{T}_k$ converges in probability to T.

2.2 Consistency for finite populations of units

Following the approach by Isaki and Fuller (1992), let $\{U_k\}$ be a nested sequence of populations of units of increasing size N_k scattered throughout the compact support $\mathscr{A}$ and Y be a survey variable with values on $[0, L]$, in such a way that y_j is the mark of unit $j \in U_k$. It is at once apparent that the population sequence determines a corresponding sequence of totals $\{T_k\}$.

Supposing a sequence of designs $\{d_k\}$, each of them selecting a sample S_k from U_k of increasing size n_k, the HT estimator is given by

$$\widehat{T}_k = \sum_{j \in S_k} \frac{y_j}{\pi_j^{(k)}}$$

where $\pi_j^{(k)}$ denotes the first-order inclusion probability of the j-th unit.

Denoting by $\pi_{jh}^{(k)}$ the second-order inclusion probability of units j and h ($h > j \in U_k$), if the design sequence ensures

$$\lim_{k \to \infty} \max_{h > j} \left\{ \frac{\pi_{jh}^{(k)}}{\pi_j^{(k)} \pi_h^{(k)}} - 1 \right\}^+ = 0$$

and there exists $\pi_0 > 0$ such that $\min_j \pi_j^{(k)} \geq \pi_0$, then $\lim_{k \to \infty} \operatorname{var}(\widehat{T}_k / T_k) = 0$ and $\widehat{T}_k / T_k$ converges in probability to 1.

2.3 Consistency for finite populations of areal units

Consider a sequence of partitions $\{\mathscr{P}_k\}$ of the compact support $\mathscr{A}$ constituted by an increasing number M_k of areal units $\mathscr{A}_1^{(k)},\ldots,\mathscr{A}_{M_k}^{(k)}$ of decreasing size, so that $\lim_{k\to\infty} \max_l \lambda(\mathscr{A}_l^{(k)}) = 0$. Suppose a sequence of designs $\{d_k\}$, each of them selecting a sample Q_k of increasing size m_k from $\mathscr{P}_k$ and let $\pi_l^{(k)}$ and $\pi_{lh}^{(k)}$ for $h > l \in \mathscr{P}_k$ be the first- and second-order inclusion probabilities, respectively.

If a continuous population is considered and y is a Borelian function on $\mathscr{A}$, with values on $[0,L]$, let $T = \int_{\mathscr{A}} y(p)\lambda(dp)$ be the population total and let $T_l^{(k)} = \int_{\mathscr{A}_l^{(k)}} y(p)\lambda(dp)$ be the total amount of the survey variable within $\mathscr{A}_l^{(k)}$. Since $T = \sum_{l=1}^{M_k} T_l^{(k)}$ for each k, estimating the total of a continuous population can be approached as the total estimation in a finite population of units, whose list is always available. In this setting, the HT estimator is given by

$$\widehat{T}_k = \sum_{l\in Q_k} \frac{T_l^{(k)}}{\pi_l^{(k)}}. \tag{1}$$

and if the design sequence is such that

$$\lim_{k\to\infty} \max_l \frac{\lambda(\mathscr{A}_l^{(k)})}{\pi_l^{(k)}} = 0 \tag{2}$$

and

$$\lim_{k\to\infty} \max_{h>l} \Big(\frac{\pi_{lh}^{(k)}}{\pi_l^{(k)}\pi_h^{(k)}} - 1\Big)^+ = 0 \tag{3}$$

then $\lim_{k\to\infty} \mathrm{var}(\widehat{T}_k) = 0$ and $\widehat{T}_k$ converges in probability to T. Note that a sufficient condition for (2) to hold is $\min_l \pi_l^{(k)} \geq \pi_0 > 0$ for any k.

On the other hand, if a finite population of units is scattered throughout $\mathscr{A}$, consistency cannot be proven taking the population fixed, but it is mandatory to consider a sequence of nested populations U_k of increasing size N_k. Let y_j be the value of the survey variable on unit $j \in U_k$, so that the total for k-th population is $T_k = \sum_{j\in U_k} y_j$.

Similarly to the continuous case, estimation of the total of finite populations of units can be switched into estimation in finite populations of areal units, whose lists are always available.

Let $T_l^{(k)} = \sum_{j\in U_l^{(k)}} y_j$ be the total amount of the survey variable within the areal unit $\mathscr{A}_l^{(k)}$, where $U_l^{(k)}$ denotes the sub-population of the $N_l^{(k)}$ units located within $\mathscr{A}_l^{(k)}$. As $T_k = \sum_{l\in\mathscr{P}_k} T_l^{(k)}$, the HT estimator $\widehat{T}_k$ is given by (1) .

For finite populations of units, if (3) holds and

$$\lim_{k\to\infty} \max_{l} \frac{T_l^{(k)}}{\pi_l^{(k)} T_k} = 0$$

then $\lim_k \mathrm{var}(\widehat{T}_k/T_k) = 0$ and $\widehat{T}_k/T_k$ converges in probability to 1.

There is a perfect analogy with the continuous case. In the case of finite populations of units, it suffices to replace $\lambda(\mathscr{A}_l^{(k)})$ with $T_l^{(k)}/T_k$. However, while in the continuous case only partitions are involved, in the discrete case it is necessary to presume a sort of eveness in the enlargements of the nested populations, in such a way that population units do not aggregate into some areal units.

3 Discussion

Consistency is obtained, under minimal assumptions regarding populations, by considering the design sequences, whose characteristics are related to the sampling scheme actually adopted to select the sample. Indeed, for continuous populations, it suffices to hold the support and the surface as fixed and simply considering a design sequence selecting an increasing number of sample points in the support.

For with-list finite populations of units scattered onto a support, the asymptotic framework by Isaki and Fuller (1982) is exploited taking the support fixed and considering a sequence of nested populations increasing within and a sequence of designs selecting sample of increasing size. On the other hand, when the list of the population units is not available, as frequently happens in environmental surveys, and hence it is necessary to sample them by points, eventually identifying plots or transects, the total estimator can be rephrased as a Monte Carlo estimator. In this case, the population can be held fixed and consistency can be achieved from the scheme adopted to locate an increasing number of points on the support.

Finally, when populations of areal units are considered, consistency is obtained both if a continuous population and a finite population of units are located on the support. In the first case, the support and the surface are held fixed and consistency is achieved from the scheme adopted to select areal units from a sequence of partitions constituted by an increasing number of areas of decreasing extents. In the second case, in addition, consistency requires the introduction of a sequence of nested populations and conditions on their enlargement.

Consistency can be easily proven for the simplest sampling schemes and for some widely applied schemes ensuring spatial balance, which is usually pursued in spatial surveys in order to obtain sample locations evenly spread over the support. As a matter of fact, for continuous populations consistency holds under uniform random sampling and tessellation stratified sampling, for with-list populations of units under simple random sampling without replacement and stratified sampling with proportional allocation and for population of areal units under simple random sampling without-replacement and one-per-stratum stratified sampling.

Finally, it is worth noting that spatial balance can be achieved by means of more complex schemes (see e.g. Grafström et al., 2012, Grafström and Tillé, 2013). Unfortunately, owing to their complexity, we cannot prove consistency for these schemes. However, owing to their effectiveness in providing spatial balance and their empirical performance (Fattorini et al., 2015), consistency presumably holds also for these schemes.

Empirical likelihood in the statistical matching for informative samples

Verosimiglianza empirica nel matching statistico per campioni informativi

Daniela Marella and Danny Pfeffermann

Abstract Statistical matching aims at combining information available in distinct sample surveys referred to the same target population, but composed of nonoverlapping sets of units. The aim of the present paper is to analyze the statistical matching problem under informative sampling designs, when applying the empirical likelihood approach.

Abstract *Lo scopo del presente lavoro è analizzare il problema del matching statistico in caso di campioni informativi utilizzando l'approccio basato sulla verosimiglianza empirica*.

Key words: empirical likelihood, informative sampling.

1 Introduction

The statistical matching problem is becoming nowdays popular. In practice, information usually comes from different micro databases, each of them contains some of the variables of interest. The main target of statistical matching consists in the estimation of the joint distribution of variables separately observed in independent samples. Formally, the problem can be described as follows. Let A and B be two independent samples of sizes n_A and n_B respectively, selected from a

[1]Daniela Marella, Dipartimento di Scienze della Formazione, Università Roma Tre; email: daniela.marella@uniroma3.it.

Danny Pfeffermann, Central Bureau of Statistics and Hebrew University of Jerusalem, University of Southampton ; email: D.Pfeffermann@soton.ac.uk.

population of N identically distributed (*i.i.d.*) records, generated from some joint probability distribution function (*pdf*, for short). We assume that the population is large such that the samples A and B have no units in common. The statistical matching problem is that (X,Y,Z) are not completely observed in the two samples: only (X,Y) are observed for the units in sample A and only (X,Z) are observed for the units in sample B, see D'Orazio *et al.* (2006). Due to the lack of joint information on Z and Y given X, the joint distribution of (X,Y,Z) is not identifiable since the available sample information is not able to discriminate among a set of plausible models for (X,Y,Z) leading to uncertainty about the data generating model. See Conti *et al.* (2016) and reference therein for a discussion of the statistical matching uncertainty. Alternative techniques have been proposed in literature to overcome the identification problem: (i) techniques based on the conditional independence assumption between Y and Z given X (CIA); (ii) techniques using external auxiliary information regarding the statistical relationship between Y and Z.

The aim of the present paper is to analyze the statistical matching problem for the case where the sampling processes used to select the samples A and B are informative. The sample selection in survey sampling involves complex sampling designs based on different levels of clustering and differential inclusion probabilities. When the inclusion probabilities are related to the value of the target outcome variable even after conditioning on the model covariates, the observed outcomes are no longer representative of the population outcomes and the model holding for the sample data is then different from the model holding in the population. This, quite common phenomenon is known as *informative sampling*, see Pfeffermann and Sverchkov (2009). Returning to statistical matching, knowledge of the sampling designs underlying the selection of the samples A and B and accounting for them is crucial for successful matching. The case of informative sampling designs in the statistical matching problem in a parametric setting is analysed in Marella and Pfeffermann (2019).

The paper is organized as follows. In Section 2 the empirical likelihood (EL) approach under informative sampling designs is discussed. Finally, in Section 3 a simulation study has been performed.

2 Statistical framework under informative sampling designs

In this section an empirical likelihood method based on the sample likelihood as proposed in Pfeffermann (2011) is developed to deal with the statistical matching problem. The empirical likelihood (Owen (1988)) is essentially the likelihood of the multinomial distribution used in Hartley and Rao (1968), where the parameters are the point masses assigned to the distinct sample values. The main advantages of empirical likelihood approach are: (i) it is much more flexible and easy to implement

since it does not require to specify the population model; (ii) it facilities the use of calibration constraints.

Associated with the *i*th population unit are values of (X,Y,Z), where X is a categorical variable taking K values with probability $P(X=k)=p_k^X$ (for $k=1,...,K$) while (Y,Z) are continuous random variables. We assume that the finite population values are generated from a multinomial distribution with parameter $p_i^{XYZ}=P(x_i,y_i,z_i)$. Under the CIA, p_i^{XYZ} can be factorized as follows

$$p_i^{XYZ}=P(x_i=k,y_i,z_i)=P(x_i=k)P(y_i\mid x_i)P(z_i\mid x_i)=p_k^X\,p_i^{Y|X}\,p_i^{Z|X} \qquad (1)$$

for $k=1,...,K$. It is assumed that X has its support both in sample A and in sample B, $p_i^{Y|X}$ has its support in sample A and $p_i^{Z|X}$ has its support in sample B. Suppose that the value k arises $n_{k,A}^X$ ($n_{k,B}^X$) in sample A (B), for $k=1,...,K$. If Z was observed in A, then following Pfeffermann (1998), the marginal *pdf* of (x_i,y_i,z_i) for $i\in A$ is defined as

$$p_{i,A}^{XYZ}=P(x_i=k,y_i,z_i\mid I_i^A=1)=p_{k,A}^X p_{i,A}^{Y|X}\,p_{i,A}^{Z|XY} \qquad (2)$$

where I_i^A is the sampling indicator taking the value 1 if the ith population unit is drawn to the sample A and 0 otherwise. Then, the sample distribution in A is also multinomial, with cell probabilities given by (2), where

$$p_{k,A}^X=\frac{\tau_{k,A}^X p_k^X}{\sum_{j=1}^K \tau_{j,A}^X p_j^X}\ ,\ p_{i,A}^{Y|X}=\frac{\tau_{i,A}^{XY} p_i^{Y|X}}{\sum_{i\in A_k}\tau_{i,A}^{XY} p_i^{Y|X}}\ ,\ p_{i,A}^{Z|XY}=\frac{\tau_{i,A}^{XYZ} p_i^{Z|X}}{\sum_{i\in A_k}\tau_{i,A}^{XYZ} p_i^{Z|X}} \qquad (3)$$

with $A_k=\{i\in A: x_i=k\}$ and $\tau_{i,A}^{XYZ}=E_p(I_i^A=1\mid x_i=k,y_i,z_i)$,

$\tau_{i,A}^{XY}=\sum_{i\in A_k}\tau_{i,A}^{XYZ}\,p_i^{Z|X}$, $\tau_{k,A}^X=\sum_{i\in A_k}\tau_{i,A}^{XY}\,p_i^{Y|X}$.

An expression analogous to (2) and (3) can be obtained for sample B. Under independence between observations corresponding to different sampling units (Pfeffermann (1998)), the *observed sample empirical likelihood* of the sample $A\cup B$ is given by

$$EL_{Obs}^{A\cup B}\propto\prod_{k=1}^K (p_{k,A}^X)^{n_{k,A}^X}\prod_{i\in A_k} p_{i,A}^{Y|X}\prod_{k=1}^K (p_{k,B}^X)^{n_{k,B}^X}\prod_{i\in B_k} p_{i,B}^{Z|X} \qquad (4)$$

and the EL estimators of the probabilities p_k^X, $p_i^{Y|X}$, $p_i^{Z|X}$ are obtained maximizing the likelihood (4) under the constraints

$$p_k^X \geq 0, p_i^{Y|X} \geq 0, p_i^{Z|X} \geq 0, \sum_{k=1}^{K} p_k^X = 1, \sum_{i \in A_k} p_i^{Y|X} = 1, \sum_{i \in B_k} p_i^{Z|X} = 1 \quad (5)$$

for $k = 1,...,K$. The solution is

$$\hat{p}_k^{X(A)} = [n_{k,A}^X (\tau_{k,A}^X)^{-1}] / \sum_{j=1}^{K} [n_{j,A}^X (\tau_{j,A}^X)^{-1}], \quad \hat{p}_k^{X(B)} = [n_{k,B}^X (\tau_{k,B}^X)^{-1}] / \sum_{j=1}^{K} [n_{j,B}^X (\tau_{j,B}^X)^{-1}],$$

$$\hat{p}_i^{Y|X} = (\tau_{i,A}^{XY})^{-1} / \sum_{j \in A_k} (\tau_{j,A}^{XY})^{-1}, \quad (6)$$

$$\hat{p}_i^{Z|X} = (\tau_{i,B}^{XZ})^{-1} / \sum_{j \in B_k}^{n_B} (\tau_{j,B}^{XZ})^{-1}$$

where $\hat{p}_k^{X(A)}$ and $\hat{p}_k^{X(B)}$ are the estimates of p_k^X obtained from sample A and B, respectively. Such estimates can be harmonized as $\hat{p}_k^X = \lambda \hat{p}_k^{X(A)} + (1-\lambda) \hat{p}_k^{X(B)}$ with $\lambda = n_A / (n_A + n_B)$. Sample estimates of the expectations $\tau_{i,A}^{XY}$, $\tau_{i,B}^{XZ}$ appearing in (6) are needed. The probabilities $\tau_{i,A}^{XY} = 1 / E_A(w_{i,A} \mid x_i, y_i)$ ($\tau_{i,B}^{XZ} = 1 / E_B(w_{i,B} \mid x_i, z_i)$) can be estimated by regressing the sample weights $w_{i,A}$ ($w_{i,B}$) on (x_i, y_i) ((x_i, z_i)) using the observed data in A (B). See Pfeffermann and Sverchkov (2009) for different approaches of modeling and estimating such expectations.

Once the parameters governing the multinomial population model have been estimated, a fused dataset can be constructed where each record includes measurements of (X, Y, Z), which users may treat as a "completely" observed dataset, with a similar distribution to the population distribution.

Finally, when population means of variables measured in the sample A and/or in sample B are known, constraints can be added to the maximization problem of sample empirical likelihood.

3 Simulation

In order to illustrate the effects of ignoring the sampling process in statistical matching and to assess the performance of the sample empirical likelihood approach, a simulation study has been performed according to the following steps:

Step 1. Generate a population of $N = 2000$ measurements (x_i, y_i, z_i) as follows: (i) X is a categorical variable taking the value $k = 10,11,12,13$ with probabilities $(p_1^X, p_2^X, p_3^X, p_4^X) = (0.2,0.3,0.4,0.1)$; (ii) $y_i \mid x_i$ is normal with parameters

$\theta_{Y|X} = (\beta_0 + \beta_1 x_i, \sigma^2_{Y|X})$; $\beta_0 = 2$, $\beta_1 = 1$, $\sigma^2_{Y|X} = 2$; (iii) $z_i \mid x_i$ is normal with parameters $\theta_{Z|X} = (\alpha_0 + \alpha_1 x_i, \sigma^2_{Z|X})$; $\alpha_0 = 1$, $\alpha_1 = 0.5$, $\sigma^2_{Z|X} = 1$.

Step 2. Draw samples A and B of size $n_A = n_B = 400$ from the population by Poisson sampling, with selection probabilities

$$\pi_{i,S} = n_S \frac{\exp(\gamma_X^S x_i + \gamma_Y^S y_i + \gamma_Z^S z_i)}{\sum_{j=1}^{N} \exp(\gamma_X^S x_j + \gamma_Y^S y_j + \gamma_Z^S z_j)}$$

where $\gamma^S = (\gamma_X^S, \gamma_Y^S, \gamma_Z^S)$ (for $S = A, B$) represent the sampling parameters.

Step 3. The population parameters p_k^X, $p_i^{Y|X}$, $p_i^{Z|X}$ are estimated: (i) by ignoring the sample selection effects; (ii) by maximizing the sample empirical likelihood (4). The expectations $E_A[w_{i,A} \mid x_i, y_i; \gamma^A]$ ($E_B[w_{i,B} \mid x_i, z_i; \gamma^B]$) are estimated by an exponential regression model of $w_{i,A}$ ($w_{i,B}$) against (x_i, y_i) ((x_i, z_i)).

Step 4. Repeat Step 2-3 500 times for different sampling parameters γ^S.

Figure 1 shows the population *pdf of* $Y \mid X = 10$ and the kernel density estimate of the sample *pdf* when ignoring the selection effects, for $\gamma^A = (0.5, 0.5, 0)$. As clearly seen, the sample *pdf* is very different from the population *pdf* due to the use of informative sampling .

In order to study the effect of ignoring informative sampling mechanisms we proceed comparing the estimates of the population parameters p_k^X, $p_i^{Y|X}$, $p_i^{Z|X}$. The results are shown in Table 1 where the mean of Kolmogorov distance (Kd) over the 500 samples between the X true population *pdf* and the X estimated *pdf*s corresponding to point (i) and (ii) in Step 3 is evaluated. Such distances are denoted by $Kd^{X,I}, Kd^X$, respectively. For $\gamma^A = \gamma^B = (0,0,0)$, Kd^X coincides with $Kd^{X,I}$ since the sampling processes acting in the two samples are not informative. For the remaining values of γ^A, γ^B $Kd^{X,I}$ is always larger than Kd^X. Then, ignoring the sample selection process affects negatively the quality of the estimates of p_k^X.

Analogous results have been obtained for $Y \mid X$ and $Z \mid X$ *pdf*s. Furthermore, if constraints are introduced in the EL maximization a reduction of Kolmogorov distances is obtained. For instance, for $\gamma^A = (0.5, 0.5, 0), \gamma^B = (0.5, 0, 0.5)$ if constraints regarding the knowledge of the population mean of X are introduced, that is

$$\sum_{i \in A} p_i^X x_i = \mu_X = \sum_{i \in B} p_i^X x_i$$

we obtain that $Kd^{X,I} = 0.12$ and $Kd^{X} = 0.02$.

Figure 1: Population *pdf* and Kernel density estimate of the sample *pdf* of $Y \mid X = 10$.

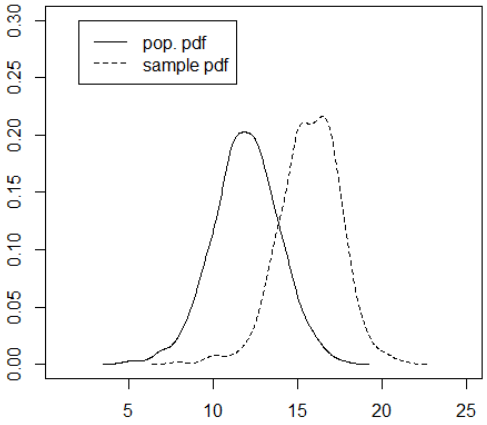

Table 1: *Kolmogorov distances* Kd^{X}, $Kd^{X,I}$ as γ^{A}, γ^{B} vary.

γ^{A}	γ^{B}	Kd^{X}	$Kd^{X,I}$
(0,0,0)	(0,0,0)	0.03	0.03
(0.5,0,0)	(0.5,0,0)	0.04	0.20
(0.5,0.5,0)	(0.5,0,0.5)	0.08	0.29
(0.5,0.5,0.5)	(0.5,0.5,0.5)	0.15	0.34

Evaluating a Hybrid One-Staged Snowball Sampling through Bootstrap Method on a Simulated Population

Campionamento a valanga ibrido ad uno stadio: una valutazione con metodo bootstrap su una popolazione simulata

Venera Tomaselli[1], Giulio Giacomo Cantone[2]

Abstract: Snowball sampling is a design where a number of individuals is surveyed in a population and then is requested to share the survey tool among their 'social links'. The aim is to recruit other people into the sample. One-stage recruitment means that individuals who are recruited by people already participant are not requested to recruit any others. Although surveys adopting snowball are financially less expensive than alternatives, the reliability of asymptotical estimates through this method is often questioned. A hybrid snowball sampling is designed such that a quota is randomly sampled, and another through snowball. Through a simulation of a demographic setup we found that bootstrap statistics of a one-staged hybrid design asymptotically show no significant difference to random design. This does not extend into situations where the random quota is smaller. We conclude that more complex setups will be needed before to generalise these results.

Abstract: *Il campionamento a valanga è un disegno campionario dove un sondaggio è sottoposto ad certo numero di individui, ed è poi chiesto a questi di condividere il sondaggio tra i loro 'legami sociali' al fine di reclutarne altri nel campione. Il reclutamento ad un livello prevede che chi è reclutato da chi è già partecipante non ne recluti altri. Sebbene i sondaggi a valanga siano meno costosi delle alternative, l'affidabilità delle stime di questo metodo è spesso posta in dubbio. Un campionamento a valanga ibrido è un disegno campionario dove una frazione del campione è estratta a sorte ed un'altra reclutata a valanga. Per mezzo di una simulazione di un setup demografico abbiamo trovato che le statistiche bootstrap di un disegno ibrido ad uno stadio non mostrano differenze significative rispetto all'alternativa casuale. Ciò non si estende ad una situazione con una minor frazione di individui estratti a caso. Riteniamo che setup più complessi siano necessari prima di generalizzare questi risultati.*

Key words: hybrid one-staged snowball sampling, bootstrapping, simulated population.

1 Introduction to snowball sampling

The terminology 'snowball sampling' denotes the methodology of social research where "a small [random] sample of persons [is interviewed], asking who their best friends are, interviewing these friends, then asking them their friends, interviewing these, and so on" (Coleman, 1958, 29). Leo Goodman (1961), who was a colleague of Coleman at University of Chicago, adopted "snowball sampling" to refer to a

[2] Giulio Giacomo Cantone, Department of Physics and Astronomy, University of Catania IT, e-mail: prgcan@gmail.com.

mathematical model to "make statistical inferences about various aspects of the relationships present in the population" by "data obtained using an s stage k name snowball sampling procedure" (*idem*, 148).

The aim of Goodman was to formalize conditions such to assume asymptotically unbiased estimates from Coleman's procedure. Goodman's model assumes that *k*, the amount of interviewed people per *s* stages of the chain, is a constant. "Stage 0" or $s = 0$ is the initial sample of *k* cases in the population and is random, instead. Snijders (1992) offered a different formal model with no fixed *k*. Both authors conclude that while a snowball procedure is not a fully randomized method, if 'homophily' among participants is sufficiently low, the sample may be assumed to be representative of a population.

Homophily is a terminology introduced since the '50 in sociological works and later formalized by network scientists as a parametrization of the correlation between the value of the variable in a node and the amount of its edges (Newman, 2010). Nevertheless, the interpretation of homophily is often ambiguous. Crawford, Aronow, Zeng et al. (2017) claim that homophily is often confused with "preferential recruitment" which is when the probability to be drawn in the sample from stage 1 cannot be assumed uniformly distributed.

When Goodman (2011) returned on the topic of snowball sampling, he highlighted an issue: while the model he developed assumed a random primary sample ('stage 0'), many studies performed after lacked this assumption[3]. However, Craig, Hays, Pickard et al. (2013) found that on 7 surveyed panel vendors, 6 had a mean of 20% of their proposed participants involved in at least one other of the 6. This leads to intuitively think that samples can support a certain 'quota' of biased cases within, without a great loss of precision in estimates within a multivariate design.

The research of Etter and Perneger (2000) is very noteworthy in this sense. Authors surveyed a random sample of 1000 residents in Geneva aged 18-70 (primary participants) in 1997. They asked every contacted subject, even those not willing to participate, to mail the questionnaire to all the smoker and ex-smoker residents in Geneva they knew (secondary participants). At the end of the data gathering process, 3,300 residents were mailed with the questionnaire and 1,167 individuals (35%) returned the questionnaire filled. Of these, 578 were primary participants and 566 were secondary participants. According to authors the mean age difference between the samples was only of 1.7 years (*p*-value=0.003). The only other significant difference was in sex ratio (7% difference, *p*-value=0.009) while behavioural traits were reported to be not significantly different in the two groups. As unintended consequence, the authors obtained two samples very similar in size within the one-staged snowball. We call this sampling design 'hybrid one-staged snowball sampling'.

In a study comparing a random statistical approach to a snowball-based approach to estimate morbidity and mortality of the rare disease visceral Leishmaniosis in two districts of the state of Bihar, India in 2011, Siddiqui, Rabidas, Sinha et al. (2016) concluded that snowball approach was found not sensitive enough to be adopted to estimate morbidity of the rare disease. At the same time, authors noticed that comparing costs, snowball approach required 1/6 of man-days and half the financial costs of the random alternative. Since full snowball design could not be suited for many applications, we want to evaluate if adoption of hybrid sampling can overcome losses of accuracy while reducing costs of research.

2 Simulation of a hybrid sampling

Testing procedures on empirical data in population studies raises the following issues:

- usually empirical research is designed for finding information over a phenomenon, not to provide data for evaluative research about methods
- we lack 'true values' on parameters of variables. We can test the hypothesis if two samples are drawn from the same population within confidence level (CL) but this says nothing about which design is better performing on estimation.

We propose instead a combination of two computational methods:

[3] According to the author, this was a result of historical label of 'snowball' mostly for the Coleman's procedure of data collection. Hence, the technique (also referred as 'chain-referral sampling') was associated to qualitative studies on 'rare population' or on 'hidden-populations' (Atkinson and Flint, 2001). Erikson (1979) and Snijders (1992) expressed concern about the actual possibility to randomly sample the stage 0 for hidden populations.

- a simulation model to procedurally generate a virtual dataset of population data from known parameters. Simulated populations can be modeled to fit pre-existing data with a small error (Alfons, Kraft, Templ et al., 2011; Burgard, Kolb, Murkle et al., 2017) or according with a theoretical model i.e. to construct hypotheses
- computational *bootstrap* sampling, falling under the more generic terminology of Monte Carlo methodologies (Gil, Montenegro, González-Rodríguez et al., 2006; Gobet, 2016).

We want to test performance of a sampling design against a standard. Hence, the simulated population does not need to fit empirical data. Still, this virtual population needs to be generated according to non-unrealistic assumptions over expected general outcomes. In particular, assumptions will take form of structural equations made through random variables. Technical sophistications in assumptions of the model may be added once the validity of the simplest models is established.

Bootstrap means that the model is then run many times, and each time estimates are recorded. Hypotheses are tested on the statistics (e.g. the so-called bootstrap-mean) of the distribution of values of the recorded estimates.

The general issues we found for the proposed simulation are two:

Issue 1: How can we simulate non-unrealistic variables in a virtual population?

In order to reflect the complexity of population studies without losing simplicity of linear structural equations, N simulated individual in the population (or 'agent' of the model) will be designed such to show few random variables:

- age: X_0; Gompertz and Weibull are established density functions to model age (Ricklefs and Scheuerlein, 2002). As the Weibull's function has only two parameters, *scale* (λ) and *slope* (k), we adopt it because it is a simpler assumption for our purposes[4].We propose:

$$X_0 \sim Weibull\left(\lambda_{X_0} = 50, k_{X_0} = 3\right). \quad [1]$$

  For ethical issues, data on minors are usually not collected; therefore, any agent with $X_0 < 18$ (~ 4,56% of N) will be removed from the virtual population.
- sex: X_1; a dummy variable with a probability equal to 0.5 per side:

$$p(X_1 = 1) = 0.5 \quad [2]$$

- behaviour: X_2; the research on behavioural metrics is a vast field with many insightful contributions on proper tools to measure behaviour's presence and extension (Kline, 2015). But we aim at keeping unambiguity and simplicity in assumptions before prompting actual 'field knowledge' into it. Therefore, we will just notice the presence/absence of the behaviour into a dummy variable with a probability density. For the proposal of the simulation, we arbitrarily set again 0.5 per side:

$$p(X_2 = 1) = 0.5 \quad [3]$$

- chronic condition: *Y*; the outcome of a structural equation where X_0 of the agent is the baseline, X_1 and X_2 are endogenous factors, β are weights, and ε is a continuous random error variable which sums all exogenous factors of *Y*:

$$Y = \begin{cases} 0, X_0 + \beta_1 X_1 + \beta_2 X_2 + \varepsilon < t_\zeta \\ 1, X_0 + \beta_1 X_1 + \beta_2 X_2 + \varepsilon > t_\zeta \end{cases} \quad [4]$$

t is an integer threshold value such that the probability of *Y*=0 in the whole population asymptotically tends to ζ. To intuitively understand the equation: if we keep out the agents when $X_0 < 18$, set β to be equals to 0 and ε is symmetrical with an expected value equal to 0, then, for ζ =0.5, the value 45 approximates $t_{\zeta=0.5}$. In simple terms, 45 will be the median age of the simulated population, given these parameters.

We can use this information to model our assumptions on β. If we assume:

- normal distribution of ε with μ=0
- age, sex, and behaviour having all equal impact on chronic condition
- $\beta_1 = \beta_2 = 90$

then $t_{\zeta=0.5} = 135$[5].

The threshold *t* can be set equal to 0 by the property of linear transformation of normal distributions (Bryc, 1995). Once $-(t_\zeta)$ is added to μ_ε, we notice that the lower the μ_ε, the higher the ζ. Therefore, we

[4] The Gompertz's assumptions about the parameters may be more suited for fitting synthetic data, instead.

[5] $\boldsymbol{E}(x_0) + \boldsymbol{E}(\beta_1 x_1) + \boldsymbol{E}(\beta_1 x_2) = t_{\zeta=0.5}$.

computationally find a setup pair of values for μ_ε and σ_ε such that the expected value of ζ is approximates a desired value. We want a model where the chronic condition afflicts 1 agent every 20 in the population: for a population of 100,000 agents, decreased to ~ 95445 agents after removal of agents aged < 18, under $\zeta \sim 0.95$, we expect ~ 4775 agents afflicted by the chronic condition. In the next setup, the E(Y) = 0.0505

$$Y = \begin{cases} 0, X_0 + 45(X_1) + 90(X_2) + \varepsilon < 0 \\ 1, X_0 + 45(X_1) + 90(X_2) + \varepsilon > 0 \end{cases} \quad [5]$$

$$\varepsilon \sim Gaussian(\mu_\varepsilon = -295, \sigma_\varepsilon = 90)$$

σ_ε was arbitrarily set such that $\sigma \sim 6(\sigma_{X_0})$.

Issue 2: How can we simulate recruitment in the hybrid sampling?

There are two different processes to simulate a network among individuals of our population. The first is to actually employ a software that connects all the members of the virtual population in a network. The 'primary' sample is randomly drawn, then agents in the primary sample recruits 1 stage of secondary participants among their links. Through this method, both homophily clusters and preferential recruitment are simulated. Unfortunately, this method is unpractical for a high-sized N of population as it requires intense computational resources.

Another approach to simulate hybrid sampling is less computationally intensive:

1. the primary sample ***I*** is drawn randomly and removed from the ***N*** population. Then two new variables are assigned to any *i* agent that is an element of ***I***[6]:
   - Links:
     $$Z_1 \sim Integer\left(ChiSquared\left(df_{Z_1} = 150.5\right)\right) \quad [6]$$
   - Recruitment:
     $$Z_2 \sim Integer\left(ChiSquared\left(df_{Z_2} = 5.5\right)\right)^{7} \quad [7]$$
2. every *i* agent in the first sample randomly draws z_1 other agents j_i from the ***N*** population; j_i agents are not removed from ***N*** – ***I*** but becomes elements of $\boldsymbol{J}_i$
3. for each *i* with a $z_2 > 0$ and all its j_i, a $d_{(i,j)}$ value is assigned. $d_{(i,j)}$ measures statistical distance between *i* and *j* expressed by the value of a structural equation

$$D_{(i,j)}(X_0, X_2): d_{(i,j)} = \left|x_{0_i} - x_{0_j}\right| + \varepsilon_d \quad [8]$$

$$\varepsilon_d \sim \left|\left(Gaussian(\mu_\varepsilon = 0, \sigma_\varepsilon \sim 0)\right) - \left(Gaussian(\mu_\varepsilon = 0, \sigma_\varepsilon \sim 0)\right)\right| \simeq 0^{8}.$$

For each *i*, z_2 elements of $\boldsymbol{J}_i$ are drawn with a probability equal to:

$$1 - \frac{d_{(i,j)}}{\sum d_{j_i}} \quad [9]$$

which is the function of preferential recruitment. In order to reduce endogenous bias introduced by how the structural equation of distance $D_{(i,j)}$ is modelled we perform a re-sample: a sample equal in size of ***I*** is randomly re-sampled into ***I'*** from the ∪(***J***) union of all the *j* agents drawn from each *i*. The union of ***I*** and ***I'*** is the actual 'hybrid sample'.

In this model only age has an impact on statistical distance. Impact of sex and other traits was already a topic in Coleman (1958), but since $\boldsymbol{E}(X_1)$ and $\boldsymbol{E}(X_2)$ are equal per side, any non-complex interaction among endogenous variables in $D_{(i,j)}$ would result in a more 'randomised' estimates in the final sample.

3 Results and conclusions

The simulation and all the procedures were performed with software *R*[9].

[6] This design reflects "layers of friendships" mentioned in Mac Carron, Kaski, and Dunbar (2016). The parameters are then chosen only as standards for the recruitment process.

[7] *Integer* is a function that subtracts to a value its mantissa. This operation was made to force integer values on the random variables. 0.5 was added to the parameters in order to compensate the loss of the mantissa. A different approach is to model the random variables from Poisson's function, or from an exponential one.

[8] While in this model the distance error ε_d representing exogenous factors of $D_{(i,j)}$ is assumed to be equal to 0 by forcing $\sigma_\varepsilon \sim 0$, we kept it in the equation the normal model that in our opinion best fit a random error in distance for future developments.

[9] Packages: base, survival, dplyr, rlist.

The population of N ~ 95445 was simulated only once. The random sample was drawn with a size equal to 1056 agents, which is the minimum size of representative random sample for confidence interval of 3% and a CL equal to 95%. Hybrid sample was drawn from the same population but with a size of ***I*** equal to 528, so the size of the final sample $\boldsymbol{I} \cup \boldsymbol{I'}$ is again 1056.

Both the design were run and recorded 300 times. We noticed that the average amount of ***J*** ~ 2380. Hence, we decided to perform a second hybrid sampling with ***I*** = 264 and ***I'*** = 792. Statistics are reported in table 1 and table 2.

Table 2. Bootstrap statistics (n=300) of samples in random and hybrid sampling design.

	n	***X₀***		***X₁***		***X₂***		***Y***	
		Mean	***Var***	***Mean***	***Var***	***Mean***	***Var***	***Mean***	***Var***
Random Sampling	300	46.15	0.22	0.49	~0	0.49	~0	0.049	~0
Hybrid Sampling (stage 0 = 528)	300	45.95	0.21	0.5	~0	0.49	~0	0.05	~0
Hybrid Sampling (stage 0 = 264)	300	47.5	0.25	0.5	~0	0.49	~0	0.051	~0

We checked if the difference between the mean of population (46.12) and the bootstrap means of all the variables in the random and hybrid samplings (see Table 2) are significant with *p*-value < 0.05. We found:

- no significant difference in all variables in random design, as expected
- no significant differences in variables of hybrid design (stage 0 = 528)
- significant difference in X_0 and Y in hybrid design (stage 0 = 264).

For this reason, we exclude feasibility of hybrid sampling (stage 0 = 264). On the basis of the results from our experiment, we can assert that exists at least a setup of very simple parameters under which hybrid model can be employed instead of random sampling design.

We think the variances in bootstrap statistics are abysmal because complexity in population data is low and recruitment processes show a low variance (i.e. Chi Square functions are leptokurtic).

4 Future developments

We propose the following topics as future developments of the present study:

1. Complexity in the population's equations: in empirical demographic data, age is not independent from sex. Behaviours are complex: some may be dependent from age and sex while others may not. For future applicative applications, the target behaviour may be modelled as a structural equation. A dummy model may result simplistic, so the output may be rescaled into a multipoint scale, instead. Chronic conditions may be results of non-linear interactions among factors. The final model could be driven from a scientific theory. For internal validity of the model, the relevant parameter is the skewness of the variables in the population: if the variables are not symmetrical, even in a population with zero homophily, where $\boldsymbol{J}_i$ are randomly sampled, and if preferential recruitment is modelled such that agents in the ***I*** subsample 'prefer' to draw other agents that are not statistically distant from them, then we expect an increase in estimates' variance.
2. Complexity in the preferential recruitment: we suppose this point is both the most controversial and the most impactful on biases in asymptotical estimates. We already stated that in order to simulate homophily, we would need to simulate a network. We think a practical compromise could

be to import a network dataset and then test sampling through it, although this incurs in issue mentioned in section 2. We admit we don't know how people recruit other respondents into survey tool, neither we feel like we can generalise too much on this issue. Our general intuitions for future developments are: (i) Z_2 should be platykurtic and with a fat right tail, i.e. an exponential distribution. The fatter the right tail, the more the model is stressed; (ii) the weight in likelihood of recruitment should be positively correlated to a statistical distance.

3. Multi-stage and stage-free models: in order to stress more a reduction in size of 'stage 0' ***I***, more stages of recruitment can be added, so that, i.e. a two-staged hybrid sampling would sample the union of ***I, I', I''***, etc., where the latter stage is recursively not randomly drawn among 'friends' of the precedent stage. If a development of the model simulates a network population with complex variables, a more realistic approach may be free of stages: in other terms, every agent can recruit another, until the union of all sampled agents is equal to target *n*.
4. To evaluate with a regressive model the fitness of bootstrap statistics: in the present study, the validity of the sampling design was tested through significance of difference between bootstrap statistics and population parameters. A different evaluative approach is to estimate fitness of bootstrap statistics in a regressive model for each Y, already known as outcome of structural equation.

How optimal subsampling depends on guessed parameter values

Sulla dipendenza dai valori nominali dei parametri nel campionamento ottimale

Laura Deldossi and Chiara Tommasi

Abstract For huge amounts of data, subsampling is useful to downside the data volume to get an inferential goal. We suggest to select a sample of observations applying the theory of optimal design. Assuming a relationship between a response variable and some covariates, the idea is to draw a sample from a large dataset so that it contains the majority of the information about the unknown model parameters. For nonlinear models this optimal selection method depends on the unknown parameters and proper values should be guessed. We analyze how the optimal sample depends on these nominal values in the logistic regression model.

Abstract *Quando si dispone di una ingente quantità di dati, ridurne la dimensione - estraendone un campione - può essere utile ai fini di una analisi inferenziale. Se si assume esista un modello che spieghi la relazione tra una variabile di risposta e alcune covariate, la selezione del campione può essere eseguita secondo la teoria del disegno ottimo, per ottenere un campione che preservi la maggior parte dell'informazione sui parametri incogniti del modello. Quando il modello è non lineare, il disegno ottimo dipende dai parametri ignoti ed è quindi necessario fissare dei valori nominali per poterlo utilizzare. In questo lavoro, assumendo un modello di regressione logistica, ci proponiamo di studiare quanto il metodo di selezione basato sul disegno ottimo sia condizionato dalla scelta dei valori nominali.*

1 Introduction

Big Dataset are a huge amount of data that are automatically accrued. Since they arise from observational studies, the quality of the Big Data information might not be very good. In addition, in large-sample studies, if the inferential goal is to test the effect of an explanatory variable, then the p-value often leads to the rejection of the null hypothesis. That is, even very small effects can become statistically significant because of the increased power due to the huge amount of data. From here, the idea of selecting a subsample of the Big Dataset to achieve an inferential goal. This topic has been already studied by [5], [3], [8], [9] and [1], among others.

To get a subsample of data, we apply the theory of optimal design instead of considering the most commonly used sampling schemes. Indeed, the connection between the sampling and experimental design had been already explored by [11], [12], [13], [4] and [6], among others.

In [2] we propose an optimal subsample selection strategy – which is called the "Optimal Design Based" (ODB) method - consisting of two steps. First, we identify the "most informative" values of the explanatory variables according to an optimality criterion (these optimal "theoretical" values are not necessarily present in the observed Big Dataset). Then, we select the observations from the full data set that are closer to these "theoretical" optimal values. Hence, this "optimal-sampling" approach enables us to select the most "informative" observations from the Big Dataset.

A selection strategy that is based on D-optimality and linear models is the Information-Based Optimal Subdata Selection (IBOSS) method that was proposed by [8]. The ODB method, unlike IBOSS, can be based on any optimality criterion (herein, we consider the D- and A-criteria) and can be applied also to nonlinear models.

Since in nonlinear models optimal designs depend on the unknown model parameters, herein we study the dependence of our selection procedure on nominal values of the parameters in a logistic regression model.

As a measure of the quality of the optimal sample based on a guessed nominal value, with respect to the ODB sample obtained from the true parameter value, we use the so called design efficiency, which is defined in Section 2.1.

The remainder of this paper is organized as follows. In Section 2 we briefly describe the Optimal Design Based sampling method and the related notation. In Section 3, we develop a simulation study to compare the ODB sample based on a nominal value with the ODB sample based on the true value of the parameter.

2 A sampling rule based on an optimality criterion

We assume that the relationship between the binary response Y and a set of p covariates $x_1, \ldots, x_p$ is a logistic regression model:

$$P(Y_i = 1; \mathbf{x}_i, \theta) = \frac{e^{\mathbf{x}_i^T \theta}}{1 + e^{\mathbf{x}_i^T \theta}}, \quad i = 1, \ldots, N, \tag{1}$$

where $\mathbf{x}_i^T = (x_{i1}, \ldots, x_{ip})$ and $\theta = (\theta_1, \ldots, \theta_p)^T$. We are interested in estimating the parameter vector θ as precisely as possible. It is well known that the asymptotic covariance matrix of the maximum likelihood estimator is the inverse of the Fisher Information matrix

$$I(\theta) = \sum_{i=1}^{N} I(\mathbf{x}_i; \theta), \tag{2}$$

where the typical element

$$[I(\mathbf{x}_i; \theta)]_{r,s} = E_Y \left(-\frac{\partial^2 \log P(Y; \mathbf{x}_i, \theta)}{\partial \theta_r \partial \theta_s} \right).$$

When some values of the covariates are repeated then (2) can be written as

$$I(\theta) = N \sum_{i=1}^{k} I(\mathbf{x}_i; \theta) \omega_i,$$

where $\mathbf{x}_i$ are the distinct values of the covariates and ω_i are their frequencies, $i = 1, \ldots, k$.

$$\xi = \begin{Bmatrix} \mathbf{x}_1 & \cdots & \mathbf{x}_k \\ \omega_1 & \cdots & \omega_k \end{Bmatrix}, \quad 0 \leq \omega_j \leq 1, \ \sum_{j=1}^{k} \omega_j = 1$$

is the so called approximate design and

$$I(\xi; \theta) = \sum_{i=1}^{k} I(\mathbf{x}_i; \theta) \omega_i \propto I(\theta)$$

is the information matrix of the design ξ. The available data are observational, but if it had been possible, the best choice for the values $\mathbf{x}_i$ and ω_i for $i = 1, \ldots, k$ would have been according to an optimality criterion $\Phi[I(\xi; \theta)]$ for precise estimation of θ.

Given a model and a concave optimality criterion, it is always possible to compute an optimum design as

$$\xi_\Phi^*(\theta) = \arg\max_{\xi} \Phi[I(\xi; \theta)] = \begin{Bmatrix} \mathbf{x_1^*} & \cdots & \mathbf{x_j^*} & \cdots & \mathbf{x_k^*} \\ \omega_1^* & \cdots & \omega_j^* & \cdots & \omega_k^* \end{Bmatrix}. \tag{3}$$

A wise "data generator" would have generated $N\omega_j^*$ responses at $\mathbf{x_j^*}$, $j = 1, \ldots, k$ and this would have been the "ideal" combination of covariates values to be applied to obtain a precise parameter estimation.

Given a large dataset, we aim at selecting a sample s of $n < N$ observations emulating the optimal design $\xi_\Phi^*(\theta)$. More specifically, since the Φ-optimum design (3) gives the best combination of covariate values for the precise estimation of θ, we suggest to select the $n\omega_j^*$ observations that are as closest as possible to

$\mathbf{x}_\mathbf{j}^*$ for $j = 1,\ldots,k$. As a measure of closeness, the Euclidean, Mahalanobis or any other distance can be applied. When $n\omega_j^*$ is not an integer number, then a suitable rounding-off rule can be applied (see for instance [7]). This selection method is called optimal design based (ODB) sampling scheme; for more detail see [2]. The ODB sample is denoted by s_θ because it depends on θ through the optimal design $\xi_\Phi^*(\theta)$.

2.1 A- and D-efficiencies

In this paper, we consider the well-known A- and D-optimality criteria defined as $\Phi_A[I(\xi;\theta)] = -\mathrm{Tr}\left[I(\xi;\theta)^{-1}\right]$ and $\Phi_D[I(\xi;\theta)] = |I(\xi;\theta)|^{1/p}$ respectively. The A-optimum design minimizes the total variation of θ as $\xi_A^*(\theta) = \arg\min_\xi \mathrm{Tr}\left[I(\xi;\theta)^{-1}\right] = \arg\max_\xi \Phi_A[I(\xi;\theta)]$. The D-optimum design minimizes the generalized variance of θ as $\xi_D^*(\theta) = \arg\min_\xi |I(\xi;\theta)|^{-1/p} = \arg\max_\xi \Phi_D[I(\xi;\theta)]$.

Let θ_0 denote the true value for the parameter vector θ. The "goodness" of any sample s with respect to the ODB sample s_{θ_0} can be measured through the following ratios

$$0 \le \mathrm{Eff}_A(s;\theta_0) = \frac{\mathrm{Tr}[I(s_{\theta_0};\theta_0)^{-1}]}{\mathrm{Tr}[I(s;\theta_0)^{-1}]} \le 1 \quad \text{and} \quad 0 \le \mathrm{Eff}_D(s;\theta_0) = \frac{|I(s_{\theta_0};\theta_0)|^{-1/p}}{|I(s;\theta_0)|^{-1/p}} \le 1$$

which are called A- and D-efficiencies, respectively.

3 Simulation experiments

This section concerns some results of a simulation study that aims at analyzing how the ODB sampling approach depends on the nominal value of the parameter vector. $N = 100000$ data have been generated from the logistic model (1) with $p = 3$ and $\theta = \theta_0 = (0.5, 0.5, 0.5)^T$. To find the ODB sample s_θ it is necessary to know the parameter value, to be able to compute $\xi_\Phi^*(\theta)$ in (3). In real-life problems, however, we do not know the true value θ_0 and a nominal value θ must be guessed.

To explore how the choice of nominal value influences the ODB selection rule, we considered θ such that $(\theta - \theta_0)$ takes values accordingly to a 3^3 factorial design. In other words, let θ_l be the l-th component of θ, $l = 1,2,3$, we fixed $\theta_l = \theta_{0l} + k$ with $k = -1, 0, 1$. In this way we are able to measure the loss in efficiency of s_θ with respect to s_{θ_0}, for guessed θ-values which differ from θ_0 in all directions.

In Table 1, A- and D-efficiencies of s_θ with respect to s_{θ_0} are given for different values of θ, when the covariates are generated from three independent $U(-1,1)$ random variables. Table 2 reports the same efficiencies when $(X_1, X_2, X_3) \sim N(\mathbf{0}, I_3)$.

Table 1 A- and D-efficiencies of s_θ with respect to s_{θ_0} with $\theta_0 = (0.5, 0.5, 0.5)^T$, when the covariates are generated from three independent $U(-1;1)$.

3.1 Comments

Comparing the results in Tables 1 and 2, we can observe that the loss in efficiency due to a wrong nominal value of the parameter is always less than 0.4.

Furthermore, it seems that the ODB selection rule is less influenced by the choice of the nominal value when the covariates follow a Gaussian distribution.

However, the "true" ODB sample s_{θ_0} is less informative when the covariates are generated by a normal distribution than when they come from a uniform random variable. This becomes clear if we compare the efficiency of s_{θ_0} with respect to the optimal design ξ^*_Φ (which does not depend on the distribution of the covariates). In the uniform case,

$$\frac{\mathrm{Tr}[I(\xi_A^*;\theta_0)^{-1}]}{\mathrm{Tr}[I(s_{\theta_0};\theta_0)^{-1}]} = 0.925 \qquad \frac{|I(\xi_D^*;\theta_0)|^{-1/3}}{|I(s_{\theta_0};\theta_0)|^{-1/3}} = 0.923$$

while in the Gaussian case,

$$\frac{\mathrm{Tr}[I(\xi_A^*;\theta_0)^{-1}]}{\mathrm{Tr}[I(s_{\theta_0};\theta_0)^{-1}]} = 0.308 \qquad \frac{|I(\xi_D^*;\theta_0)|^{-1/3}}{|I(s_{\theta_0};\theta_0)|^{-1/3}} = 0.362.$$

This means that the per-unit information contained in s_{θ_0} is larger when data come from the uniform distribution; see [2] for a detailed motivation.

In conclusion, when data follow a Gaussian distribution the ODB selection method seems not depending strongly on the nominal value of the parameters, even if the ODB sub-samples are less informative than in the uniform case.

Indicators for risk of selection bias in non-probability samples

Indicatori per valutare il rischio di distorsione in presenza di campioni non-probabilistici

Emilia Rocco and Alessandra Petrucci

Abstract In recent years, in surveys, is increased the relevance of the non-probability sampling with which the units included in the sample are determined by an unknown self selection process. The self-selection of the units in the sample raises concerns about the potential for biased estimates of population characteristics and consequently it originates the need of indicators for assessing the degree of bias and for identifying potential adjustment/weigting methods for reducing it. Here, we are motivated by a real problem: the risk of bias in a non-probability web survey on the customers' satisfaction with the services provided by the municipal library system in Florence. We suggest and discuss the combined use of three measures, each one for a specific aspect of the data that impacts on the risk of biased estimates.

Abstract *Negli ultimi anni è aumentta la rilevanza del campionamento non probabilistico come strumento di raccolta dei dati nonostante esso implichi che le unità incluse nel campione siano determinate da un processo di auto-selezione incognito. Tale mancaza di casualità nel processo di selezione delle unità solleva preoccupazione sulla possibilità di ottenere stime distorte dei parametri della popolazione e conseguentemente rende necessario definire degli indicatori per quantificare il rischio di distorsione. In questo contributo, motivati da uno specifico caso reale, un'indagine web sulla soddisfazione degli utenti del sistema bibliotecario municipale di Firenze, suggeriamo l'uso congiunto di tre indicatori, che indagano la plausibilità di tre diverse condizioni necessarie per escludere il rischio di distorsione.*

Key words: auxiliary variables, missing data, relative sample size, representativeness

1 Introduction

In recent years data from non-probability samples are becoming more widely used. Several factors contributed to this propagation: more and more surveys have moved online; large amounts of data are available from self-reported administrative datasets or fast and easily collected via social-media; the cost for probability surveys is steadily raising and far higher than that for non-probability surveys; response rates in probability surveys continue to decline in all modes of adminstration.
Unlike to the probability sampling the chance to be selected is unknown in non probability sampling as well as the random selection is absent. This poses new challenges for inference since renders design-based methods of inference, commonly used in probability surveys, inapplicable and raises concerns about the potential for biased results. The selection bias, that refers to the systematic differences betweens statistical estimate and the population parameter, brings the need of measures /indicators to assess the risk of bias and to identify, if possible, any adjustment method. In order to identify such indicators it is worth to note that the selection bias, depending on the composition of the sample, that can vary greatly from that of the surveyed population, may occur not only when non-probability sampling is adopted but also when a probability sample is initially selected and non-response occurs. For this reason many indicators suggested in literature as indirect measures of non-response bias and many statistical adjustment procedures typically used to adjust for non-response bias can be extended to non-probability samples. However, in doing this, it is necessary to take into account that unlike the non-response set, what is a non probability sample is not univocal defined. Non-probability sampling is a collection of methods very different from each other and with in common only the fact that the participants are chosen or choose themselves so that the chance of being selected is not known. Moreover while non respondents in probability surveys are usually identifiable in the population; this does not happen for some non-probability sampling methodologies. Therefore the possibility to use the indicators of non-response bias existing in literature to assess self-selection bias due to non probability sampling depends on the type of non probability sampling: sometimes some methods may be usable and others no, sometimes their use may require some adjustments/ad hoc adaptations. All existing indicators of the risk of non-response bias, apart from the response rate, are based on the use of auxiliary data. Some in addition to the auxiliary data also involve the survey data (i.e. the data for respondents). In this study we are motivated by a real problem: the risk of bias in a non-probability web survey on the customers' satisfaction with the services provided by the municipal library system in Florence. For this case of study we consider the joint use of two indicators of non response bias, one that involves only auxiliary data and the other that in addition to the auxiliary data also involve the survey data. We discuss how they need to be modified for assessing the risk of bias for this specific non probability sample, how they work in the specific real situation and the opportunity to consider in addition to them a third index. Next section describe preliminaries and the suggested indicators. Section 3 presents the application, discuss the results and concludes with some final remarks.

2 Indicators definition

We assume that for a target population U of N units $(i = 1, ...N)$, $\delta_i \in \{0,1\}$ indicate the selection of unit i in a non probability sample s of size n, y_i is the value of the target variable Y for unit i and the data available for estimation purposes are the values $\{y_i; i \in s\}$ of the survey variable and the values $\{\mathbf{z}_i = (z_{1,i}, ...z_{K,i}); i \in U\}$ of a vector of auxiliary variables that may influence the selection mechanism and/or the survey variable. Moreover we shall suppose that the sample inclusion indicators are independent random variables and that the parameter of interest is the mean of Y.
The first indicator that we consider is the "*R-Indicator*" first suggested by Schouten et al. (2009) and developed in Shlomo et al. (2012). The basic idea of the R-indicator is that a selected subset is representative with respect to the auxiliary variables $\mathbf{z}$ when selection probabilities are constant for $\mathbf{z}$. Relying on this idea, and taking into account that selection probabilities are unknown, but may be estimated as the conditional expectation (under a model) of δ_i given the auxiliary variables, the *R-Indicator* measures the extent to which the estimated selection probabilities $\hat{\rho}(zi)$ vary as follows:

$$\hat{R}_\rho = 1 - 2\sqrt{\frac{1}{N-1}\sum_{i\in U}(\hat{\rho}_i - \hat{\bar{\rho}})^2} = 1 - 2\hat{S}_{\hat{\rho}} \tag{1}$$

where $\hat{\bar{\rho}} = \sum_{i=1}^{N}\hat{\rho}_i/N$. Since it may be shown that $\hat{S}_{\hat{\rho}} \leq \sqrt{\hat{\bar{\rho}}(1-\hat{\bar{\rho}})} \leq 0.5$, then $\hat{R}_\rho$ takes values on the interval $[0,1]$. The response propensities, $\hat{\rho}_i$, are commonly estimated with explicit or implicit models linking the response occurrences to the auxiliary variables, for instance, by using a logistic or a probit regression model.
Assuming that the implicit or explicit model used for estimating the response propensities is "correct", a value of $\hat{R}_\rho$ close to 1 denotes a weak association between the sample selection mechanism and the auxiliary variable. A weak association implies that the risk of selection bias is low whatever is the target statistic as long as it may be assumed that the selection/non-selection process is "Missing at Random" (MAR) given the covariates. Unfortunately, however, a value of $\hat{R}_\rho$ not close to 1 - due to an high association between the selection mechanism and the auxiliary variables - is not able to detect the risk of bias for a survey estimate since it also depends on the relation between the covariates and the target variable. In order to judge the risk of bias for a single parameter, when the estimated value of the R-Indicator is not close to 1, we can compare the respondents' averages of the single variable across the percentiles of the predicted response propensities through the following indicator suggested in Rocco (2019) and called R-Statistic-level-Indicator:

$$\hat{R}_{\bar{y}_{p\rho}} = 1 - \frac{\sum_{h=1}^{H}(\bar{y}_{s_h} - \bar{y}_s)^2 n_{s_h}}{\sum_{i\in r}(y_i - \bar{y}_s)^2} \tag{2}$$

that is obtained through the following steps. First the units in the sample are ordered with respect to the estimated selection probabilities, $\hat{\rho}_i$, $i \in s$. Then the ordered sam-

ple is partitioned into H classes, $s_h\,(h = 1,...H)$, of size n_{s_h} = roughly n_s/H on the basis of $(H-1)$ percentiles of the estimated selection probabilities. Finally, the sample mean of the target variable for each class, $\bar{y}_{s_h} = \sum_{i \in s_h} y_i / n_{s_h}$, and the sample mean for the whole sample, $\bar{y}_s = \sum_{i \in r} y_i / n_s = \sum_{h=1}^{H} \sum_{i \in s_h} y_i / n_s$, are calculated and compared through the above expression of the index.
$\hat{R}_{\bar{y}_{p\rho}}$ takes values on the interval $[0,1]$. Under the assumption that the selection process is MAR, a value of $\hat{R}_{\bar{y}_{p\rho}}$ near to 1 indicates a risk of non-response bias negligible whatever is the value of $\hat{R}_\rho$. Only a low value of $\hat{R}_{\bar{y}_{p\rho}}$ associated with a low value $\hat{R}_\rho$ indicates a high risk of selection bias since this condition happens when the covariates are associated both with the selection indicator δ and with the specific variable of interest y. Therefore, under the MAR assumption for the selection process, the two indicators, $\hat{R}_\rho$ and $\hat{R}_{\bar{y}_{p\rho}}$, used jointly, allow to evaluate the risk of selection bias. However the reliability of this assumption needs to be evaluated. To this end we suggest to use, in addition to $\hat{R}_\rho$ and $\hat{R}_{\bar{y}_{p\rho}}$, a third indicator that measures the goodness of fit of the model used to estimate the response probabilities. A very simple indicator is the proportion of correct predictions of the participation (or non-participation) to the survey and may be calculated through a cross-validation procedure. Obviously this indicator works only when the estimated response propensities vary that is when the covariates are related to the selection indicator δ and consequently $\hat{R}_\rho$ is not close to 1. In this case a value of I_{gf} not close to 1 indicates the presence of a residual component of the selection probabilities not explained by the auxiliary variables. This residual part may or may not depend on the target variable. Therefore, in this case, even if the $\hat{R}_{\bar{y}_{p\rho}}$ is close to 1 it is not possible to exclude the risk of a high bias. On the other hand the risk may be excluded when $\hat{R}_\rho$ is not close to 1 but both I_{gf} and $\hat{R}_{\bar{y}_{p\rho}}$ are close to 1.
In some situations the three indicators are not straight exploitable. In some non probability samples the sample units may be not identifiable in the population, in other words it is not possible to associate to each population unit the selection indicator δ_i. In these cases the three indicators cannot be calculated. A small relative size of the sample is another issue for the use of the $\hat{R}_\rho$. A very small relative size of the sample should produce a sort of smoothing of the estimated selection probabilities and consequently a value of $\hat{R}_\rho$ close to 1 that is not able to assess the representativeness of the sample. Unfortunately these situations must be managed differently in each case. In the next section we discuss this issues and suggest a possible solution for a case study.

3 Application and discussion

The case study is a non-probability web survey that has been carried out (between February 6 and March 4, 2019) by the statistical office of the Florence municipality in order to evaluate the customers' satisfaction with the services provided by the municipal library system. The satisfaction questionnaire was administered via web

to the individuals at least 18 years-old present in one or both the following lists: the subscribers to the newsletter of the Florentine Municipal Libraries and the subscribers to at least one of the Florentine Municipal Libraries. The available e-mail addresses were about 95,000, but at the end only 7,680 completed questionnaires returned. The survey collected information on: the knowledge and use of the services offered by the municipal librarian system; the level of satisfaction with the services actually used; the socio-demographic characteristics of the participants (in particular age, gender, education level and professional condition) and the residence. We are interested in evaluating the representativeness of the survey with respect to population of all the citizens of Florence at least 18 years-old. For this reason we consider only the survey data relative to the Florentine residents. The representativeness of such sample would allow the statistical office of the Florence municipality to use the same set of e-mail addresses for other surveys regarding municipal services. In order to evaluate the usability of the three suggested indicators and their ability to assess the representativeness of the survey data we have considered a pseudo real application. From Census 2011 are available for the population units the same socio-demographic variable collected in the survey. Therefore we have assumed as auxiliary variables gender, age and education level and as response variable the professional condition. We evaluate the risk of selection bias for the following parameters of interest: the proportion of employees, the proportion of housewives and the proportion of retired. The data present both the issues discussed at the end of the previous section: it is not possible to identify the survey participants in the population and the participation fraction is very very small (only 1.5%). The small sample size compared to that of the population, suggests that the characteristics of the population would not change significantly if we replaced it with a fictitious population made up of the union of the population and the sample. This allows us to associate to the units of this new population the indicator variable δ_i which assumes value 1 for the units belonging to the web sample and 0 for the others. Consequently we can estimate the probability of participation in the web survey and the three indicators. However this solution does not solve the second issue. To solve both issues, moving from the well known consideration that a simple random sample reproduce on average the same means and proportions of the population, we suggest the following replicated sampling procedure: m fiction populations are obtained as the union of the web sample and a simple random sample selected from the original population. Then for each of these populations the three indicators $\hat{R}_{\rho}^{(h)}$, $R_{\bar{y}_{p\rho}}^{(h)}$ and $I_{gf}^{(h)}$ $(h = 1, ..., m)$ are calculated. Finally, the indicators $\hat{R}'_{\rho}$, $\hat{R}'_{\bar{y}_{p\rho}}$ and I'_{gf} are obtained as the median of the correspondent distributions over the m replications. The results, shown in Table 1 are obtained considering a size of the simple random samples equal to the number of the web survey participants (that is the participation fraction is chosen equal to 0.5 but different values of the sample fraction from 0.2 to 0.8 have been investigated and produce the same conclusions). Table 1 shows the values of the three indicators and the values of the relative true bias (RB_{True}). The RB_{True} is calculated as the difference between the respondent mean and the true population parameter scaled by the population standard deviation. The low value of $\hat{R}'_{\rho}$ suggests

Table 1 Summaries of results

Parameters	RB_{True}	$\hat{R}'_{\rho}$	I'_{gf}	$R'_{\bar{y}_{pp\rho}}$
Employed proportion	0.279	0.451	0.651	0.838
Household proportion	−0.154	0.451	0.651	0.979
Rertired proportion	−0.144	0.451	0.651	0.818

an important association between the selection process and the auxiliary variables, while the low value of $I^{(h)}_{gf}$ denotes the presence of a residual component of the selection probabilities not explained by the auxiliary variables and since this may or may not depend on the target variable, the values of $\hat{R}'_{\bar{y}_{pp\rho}}$ quite high do not allow to exclude the risk of bias that effectively result from the true values.
It is worth to note that the rather high values of the true relative bias may be also due to the very small relative size of the sample. In fact, as shown in Meng (2018) the exact error of the sample mean $(\bar{y}_{n_s} - \overline{Y}_N)$ is about $\sqrt{N}\rho_{\delta,Y}$ times the standard error of the sample mean under a simple random sample of equal size with $\rho_{\delta,Y}$ denoting the correlation coefficient between the selection indicator δ and the outcome variable Y.
Finally, the results show that, specific indicators need for each type of non-probability sampling methodology and by using them the risk of bias of unweighed mean can be assessed only if the following conditions are satisfied: all the variables correlated with both inclusion in the sample and the outcome of interest are know and measured; there are no kinds of unit with distinct values of the outcome variable that are systematically missing from the sample. When these conditions happen it is also possible to reduce the eventual bias through weighting methods.

On the behaviour of the maximum likelihood estimator for exponential models under a fixed and a two-stage design

Stima di massima verosimiglianza per modelli esponenziali in presenza di un disegno fisso e di un disegno adattivo a due stadi

Caterina May and Chiara Tommasi

Abstract We consider two different design strategies for collecting "optimal" data with the aim of estimating as precisely as possible the vector parameter in a dose-response model. In particular, an exponential model with Gaussian errors is considered, and the maximum likelihood method is applied. Through a simulation study we compare the performance of the the maximum likelihood estimator (MLE) when: a) a locally D-optimum design is used to get a sample of independent observations (fixed procedure); b) a two-stage adaptive experimental procedure is applied to collect data, which are dependent since the second stage D-optimal design is determined by the responses observed at the first stage. In the latter case, the theoretical properties of the MLE are described; differently from the most of the literature, asymptotic theory is applied only in the second stage since the first stage sample size is assumed to be finite.

Abstract *Consideriamo qui due diverse strategie per raccogliere dati "ottimali" allo scopo di stimare con precisione il vettore dei parametri in un modello di risposta alla dose. Consideriamo, in particolare, un modello esponenziale con erori Gaussiani. Mediante uno studio di simulazione confrontiamo l'efficienza dello stimatore di massima verosimiglianza quando: a) si utilizza un disegno localmente D-ottimo ottenendo un campione di osservazioni indipendenti (procedura fissa); b) si utilizza una procedure adattiva a due stadi da cui si ottengono dati che sono dipendenti, dato che il disegno D-ottimo al secondo stadio è determinato dalle risposte osservate al primo stadio. In quest'ultimo caso descriviamo le proprietà teoriche dello stimatore di massima verosimiglianza; al contrario di quanto viene fatto normalmente in letteratura, la teoria asintotica viene qui applicata solo al secondo stadio mentre la dimensione campionaria el primo stadio è considerata fissa.*

1 Introduction

The exponential model is applied in many different contexts (medical, enviromental, pharmaceutical) to interpret dose-response relationships. A three-parameters exponential model can be written as

$$Y = \theta_0 + \theta_1 \exp(x/\theta_2) + \varepsilon, \quad \varepsilon \sim N(0;\sigma^2) \tag{1}$$

where $\theta = (\theta_0, \theta_1, \theta_2)^T$ is a vector of unknown parameters and $\eta(x,\theta) = \theta_0 + \theta_1 \exp(x/\theta_2)$ denotes the response mean at the dose $x \in \mathscr{X} = [a,b]$. The inferential goal is to estimate θ and thus efficient experimental designs are very important. An experimental design ξ can be defined as a finite discrete probability distribution over $\mathscr{X}$; the information matrix of ξ is

$$M(\xi;\theta) = \int_{\mathscr{X}} \nabla\eta(x,\theta)\nabla\eta(x,\theta)^T d\xi(x), \tag{2}$$

where $\nabla\eta(x,\theta)$ denotes the gradient of the mean response $\eta(x,\theta)$ with respect to θ. A D-optimal design $\xi^*(\theta)$ minimizes the generalized asymptotic variance of the maximum likelihood estimator (MLE) of θ, i.e.

$$\xi^*(\theta) = \arg\max_{\xi\in\Xi} |M(\xi;\theta)|, \tag{3}$$

where Ξ is the set of all designs (see [4] and [1]).

Since $\eta(x,\theta)$ is a non-linear model, the D-optimal design (3) depends on the unknown parameter θ. A common approach to tackle this problem is to use a locally optimal design, where θ in (2) is replaced by a guessed value $\tilde{\theta} = (\tilde{\theta}_0, \tilde{\theta}_1, \tilde{\theta}_2)^T$; n independent observations are collected according to this locally D-optimal design $\xi^*(\tilde{\theta})$ and then used to compute the MLE.

Another possibility to obtain the data is to adopt a two-stage procedure. At the first stage a locally D-optimal design $\xi^*(\tilde{\theta})$ is applied to collect n_1 responses (with $n_1 < n$), which are used to estimate the unknown parameter. Let $\hat{\theta}_{n_1}$ be the MLE of θ based on first-stage responses. Then, at the second stage, $n_2 = n - n_1$ additional responses are collected according to another locally D-optimal design, $\xi_2^*(\hat{\theta}_{n_1})$, where $\hat{\theta}_{n_1}$ is used in (2) instead of $\tilde{\theta}$. Finally, the MLE is computed employing the whole sample of $n = n_1 + n_2$ data. Let us note that $\xi_2^*(\hat{\theta}_{n_1})$ is a random probability distribution as it depends on the first-stage observations through $\hat{\theta}_{n_1}$; as a consequence, the second-stage observations are not independent on the first-stage ones. Given $\xi_2^*(\hat{\theta}_{n_1})$, however, the second-stage observations are conditionally independent on the first-stage data, and hence it can be proved that the likelihood function is the same in both the following experimental settings (see Sect. 2.1):

1) n independent observations obtained according to $\xi^*(\tilde{\theta})$ (fixed procedure or one-stage);
2) n_1 independent observations accrued according to $\xi^*(\tilde{\theta})$ and then, given $\hat{\theta}_{n_1}$, other $n_2 = n - n_1$ independent responses coming from $\xi_2^*(\hat{\theta}_{n_1})$ (two-stage procedure).

Let $\hat{\theta}_n^{1S}$ and $\hat{\theta}_n^{2S}$ denote the MLEs when the one-stage and the two-stage procedures, respectively, are adopted to collect the data. In this paper we develop a simulation study to compare the performance of $\hat{\theta}_n^{1S}$ and $\hat{\theta}_n^{2S}$.

2 Theoretical properties of the two-stage design

2.1 Likelihood

The total likelihood is

$$\begin{aligned}\mathscr{L}(\theta;\mathbf{y}_{n_2},\mathbf{x}_{n_2},\mathbf{y}_{n_1},\mathbf{x}_{n_1}) &= \mathscr{L}(\theta;\mathbf{y}_{n_2}|\mathbf{x}_{n_2},\mathbf{y}_{n_1},\mathbf{x}_{n_1})\cdot\mathscr{L}(\mathbf{x}_{n_2}|\mathbf{y}_{n_1},\mathbf{x}_{n_1})\cdot\mathscr{L}(\theta;\mathbf{y}_{n_1}|\mathbf{x}_{n_1})\cdot\mathscr{L}(\mathbf{x}_{n_1}) \\ &= \mathscr{L}(\theta;\mathbf{y}_{n_2}|\mathbf{x}_{n_2})\cdot\mathscr{L}(\mathbf{x}_{n_2}|\mathbf{y}_{n_1},\mathbf{x}_{n_1})\cdot\mathscr{L}(\theta;\mathbf{y}_{n_1}|\mathbf{x}_{n_1})\cdot\mathscr{L}(\mathbf{x}_{n_1}) \\ &\propto \mathscr{L}(\theta;\mathbf{y}_{n_2}|\mathbf{x}_{n_2})\cdot\mathscr{L}(\theta;\mathbf{y}_{n_1}|\mathbf{x}_{n_1}) \qquad (4)\end{aligned}$$

From the (4) we can see that the total likelihood for the dependent data of the two-stage design is the same as the likelihood with independent data of the fixed design.

2.2 Asymptotics

In order to obtain the consistency and the asymptotic distribution of $\hat{\theta}_n^{2S}$, the classical approach in the literature is to assume that both the sample sizes n_1 and n_2 grow to infinity (see [6]).

A different approach is considered in [5], where n_1 is fixed and only n_2 goes to infinity; this assumption is more realistic in many experimental situations and, in addition, fixing n_1 should improve the approximation of the finite distribution with the asymptotic one. Despite the second stage observations depend on the first-stage data through $\hat{\theta}_{n1}$, the MLE $\hat{\theta}_n^{2S}$ maintains good properties, as stated in the following theorems (see [5] for the proofs).

Theorem 1. *As $n_2 \to \infty$, $\hat{\theta}_n^{2S}$ converges in probability to the true value θ of the parameter.*

Theorem 2. *As $n_2 \to \infty$, $\sqrt{n}\left(\hat{\theta}_n^{2S} - \theta\right)$ converges in distribution to*

$$\sigma\, M[\xi_2^*(\hat{\theta}_{n_1}), \theta]^{-1/2}\, \mathbf{Z},$$

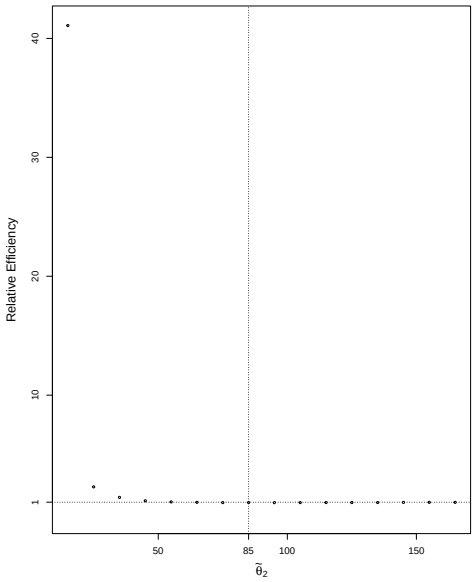

Fig. 1 Relative efficiency $\mathrm{MSE}(\hat{\theta}_n^{1S})/\mathrm{MSE}(\hat{\theta}_n^{2S})$ (on the y-axes) versus different nominal values $\tilde{\theta}_2$ (on the x-axes). The model is exponential with $\theta_0 = -0.08265$, $\theta_1 = 0.08265$, $\theta_2 = 85$ and $\sigma = 0.1$. The vertical line represents the true value of θ_2.

where $\mathbf{Z}$ *is a* 3*-dimensional standard normal random vector independent of the random matrix* $M(\xi_2^*(\hat{\theta}_{n_1}), \theta)$.

Theorem 3. *As* $n_2 \to \infty$*,, the asymptotic variance of* $\sqrt{n}\left(\hat{\theta}_n^{2S} - \theta\right)$ *is*

$$\sigma^2 E\left[\left(\int_{\mathscr{X}} \nabla\eta(x,\theta)\nabla\eta(x,\theta)^{\mathrm{T}}\, d\xi_2^*(\hat{\theta}_{n_1})(x)\right)^{-1}\right] \tag{5}$$

The expression of the asymptotic variance of $\hat{\theta}_n^{2S}$ provided in (5) justifies the use of a D-optimal design to collect the second stage data.

3 Simulations

The goal of the simulation study is to compare the two-stage adaptive procedure with the fixed design in terms of precision of the MLEs, $\hat{\theta}_n^{2S}$ and $\hat{\theta}_n^{1S}$.

The D-optimum design $\xi^*(\theta)$ for the exponential model is provided in [3]. It is a three point design equally supported at the extremes of the experimental domain $\mathscr{X} = [a;b]$ and at

$$x^* = \frac{(b-\theta_2)\exp(b/\theta_2) - (a-\theta_2)\exp(a/\theta_2)}{\exp(b/\theta_2) - \exp(a/\theta_2)}. \tag{6}$$

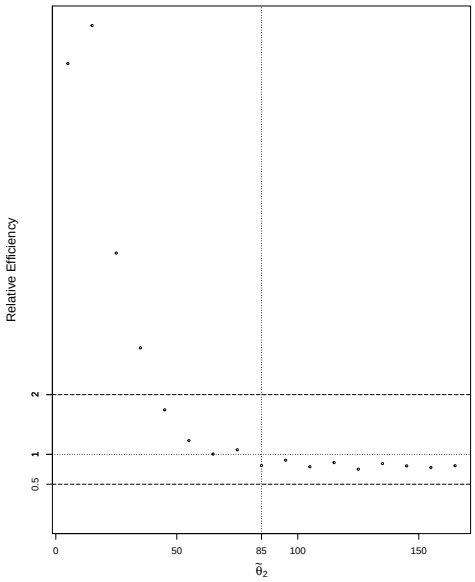

Fig. 2 Relative efficiency $\mathrm{MSE}(\hat{\theta}_n^{1S})/\mathrm{MSE}(\hat{\theta}_n^{2S})$ (on the y-axes) versus different nominal values $\tilde{\theta}_2$ (on the x-axes). The model is exponential with $\theta_0 = -0.08265$, $\theta_1 = 0.08265$, $\theta_2 = 85$ and $\sigma = 0.25$. The vertical line represents the true value of θ_2.

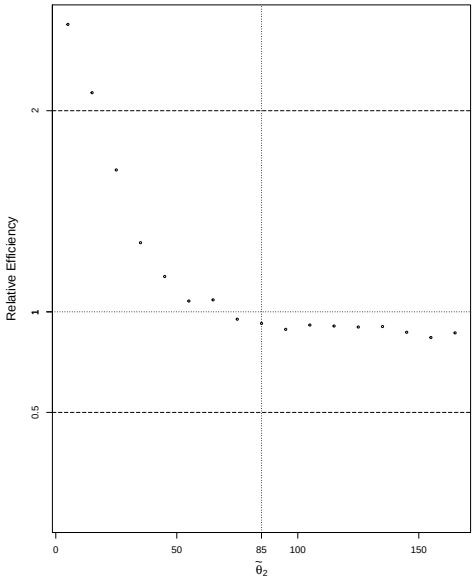

Fig. 3 Relative efficiency $\mathrm{MSE}(\hat{\theta}_n^{1S})/\mathrm{MSE}(\hat{\theta}_n^{2S})$ (on the y-axes) versus different nominal values $\tilde{\theta}_2$ (on the x-axes). The model is exponential with $\theta_0 = -0.08265$, $\theta_1 = 0.08265$, $\theta_2 = 85$ and $\sigma = 0.5$. The vertical line represents the true value of θ_2.

Hence, at each stage, $1/3$ of the observations are taken at a, b and x^*. Note that x^*, and hence $\xi^*(\theta)$, depends only on the non-linear parameter θ_2 of model (1). Herein, we take $a = 0$ and $b = 150$. From model (1) with $\theta_0 = -0.08625$, $\theta_1 = 0.08625$ and $\theta_2 = 85$ and 3 different values for $\sigma = 0.1; 0.25; 0.5$,

1. we generate $n_1 = 30$ independent observations according to $\xi^*(\tilde{\theta}_2)$ to compute the first-stage MLE, $\hat{\theta}_{n_1}$, where $\tilde{\theta}_2 \in (0; 150)$ is a nominal value for θ_2;
2. we generate further $n_2 = 300$ independent observations according to $\xi^*(\hat{\theta}_{n_1})$ to obtain $\hat{\theta}_n^{2S}$;
3. we generate further $n_2 = 300$ independent observations according to $\xi^*(\tilde{\theta}_2)$ to obtain $\hat{\theta}_n^{1S}$.

For each choice of σ and $\tilde{\theta}_2$ we repeat the computation of $\hat{\theta}_n^{1S}$ and $\hat{\theta}_n^{2S}$ 5000 times, to get their Monte Carlo MSEs. Simulations are realized with R package in [2]. Figures 1, 2 and 3 displays the relative efficiency $\mathrm{MSE}(\hat{\theta}_n^{1S})/\mathrm{MSE}(\hat{\theta}_n^{2S})$ for different choices of the nominal value $\tilde{\theta}_2$, and for $\sigma = 0.1; 0.25; 0.5$, respectively.

4 Conclusions

The simulations in Sect.3 show that the two-stage procedure outperforms the one-stage (or fixed) procedure whenever the assumed nominal value $\tilde{\theta}_2$ is much inferior to the true value of θ_2 (in this example $\theta_2 = 85$). For the other values of $\tilde{\theta}_2$, the relative efficiency of the two-stage procedure is around one (never less then 0.5). This behaviour appears to be more pronounced as σ increases. An explanation can be seen in the slope of $x^* = x^*(\theta_2)$ in (6), which is larger for small value of θ_2. Hence, $x^*(\tilde{\theta}_2)$ is far away from the true optimal dose if $\tilde{\theta}_2 < 85$ and replacing $\tilde{\theta}_2$ with the first stage estimate may improve the results.

In conclusion, we suggest to apply the two-stage procedure to collect the data if we do not have enough knowledge about the true value of θ_2, which is often the case in real-life problems.

Pseudo-population based resamplings for two-stage design

Ricampionamento basato su pseudo-popolazioni per il disegno a due stadi

Pier Luigi Conti and Daniela Marella and Vincenzina Vitale

Abstract This communication is devoted to resampling based on pseudo-populations for a class of two-stage sampling design. A resampling scheme is defined, and its main theoretical properties are established.
Abstract *La presente comunicazione è essenzialmente dedicata alla definizione e allo studio di uno schema di ricampionamento per un'ampia classe di disegni campionari a due stadi. In primo luogo alcuni risultati asintotici relativi a disegni ad uno stadio vengono estesi al caso di disegni a due stadi. Viene poi definito uno schema di ricampionamento e ne vengono stabilite le principali proprietà teoriche.*

Key words: two-stage sampling, resampling, empirical process, asymptotics.

1 Introduction

The use of resampling methods in finite populations sampling is widespread, and several approaches have been proposed in the literature; cfr. the survey paper by [1], where different approaches are illustrated, and their properties listed. Among the methodologies proposed, the one based on pseudo-populations plays a particularly relevant role, because of its theoretical properties. In fact, as shown in [2], resampling based on pseudo-populations, under appropriate conditions, possesses

a justification similar to that of the "usual" Efron's bootstrap for *i.i.d.* data: as the sample size increases, the large sample distribution of a sampling statistic tends to the same weak limit as the resampling distribution of the statistic itself.

Results in [2], as well as other asymptotic results for finite populations not involved with resampling (cfr. [3], [4], and, for generalizations, [5]) essentially refer to single-stage sampling designs, and do not cover two-stage type designs.

Generalizations of "direct" resampling schemes to multistage sampling designs are studied in the literature (cfr. [1]), although their theoretical properties are not clear, and a transparent justification is still lacking. In particular, in [6] the pseudo-population procedure is generalized to multi-stage designs.

The goal of the present communication is essentially to define a pseudo-population based resampling scheme for a wide class of two-stage designs, and to provide a justification based on asymptotic arguments similar to [2]. For this reason, asymptotic results in the above mentioned paper will be first extended to two-stage sampling design. This involves the consideration of empirical processes based on two-stage sampling. Then, such results will be applied to show that the limit distribution of a sampling statistic, under fairly general conditions, possesses the same limit distribution as the resampled statistic. As already remarked, this is essentially the justification for Efron's bootstrap provided in [7].

2 Basic assumptions

Let $\mathscr{U}_N$ be a finite population of size N, and suppose it is divided into M clusters (primary units) composed by $N_1, \ldots, N_M$ elementary units, respectively, with $N_1 + \cdots + N_M = N$. The symbol $w_g = N_g/N$ denotes the weight of cluster g $(= 1, \ldots, M)$. Let further Y be the character of interest, and denote by $Y_{g,i}$ the value of Y for unit i of cluster g $(i = 1, \ldots, N_g;\ g = 1, \ldots, M)$.

For the sake of simplicity, clusters are assumed to be "random", *i.e.* there exist M bivariate random variables (r.v.s) (X_g, C_g), $g = 1, \ldots, M$, with

$$w_g = \frac{C_g}{\sum_{h=1}^{M} C_h} = \frac{C_g}{M\overline{C}_M}$$

where $\overline{C}_M = \sum_{h=1}^{M} C_h/M$, and $N_g = [Nw_g]$.

First of all, at a cluster level, the bivariate r.v.s (X_g, C_g) are assumed to be independent and identically distributed (*i.i.d*), with $\mu_C = \mathbb{E}[C_g]$, $\mu_X = \mathbb{E}[X_g]$, $g = 1, \ldots, M$.

In the second place, $Y_{g,i}$s are assumed to be identically distributed conditionally on (X_g, C_g), with distribution function (d.f.)

$$F_g(y) = F(y|X_g, C_g) = \mathbb{P}(Y_{g,i} \leq y|X_g, C_g);\ \ g = 1, \ldots, M.$$

Unit i of cluster g is assumed to be independent of units of different clusters, but may be correlated with other units of the same cluster. More precisely, conditionally on X_g, C_g, X_h, C_h the r.v.s $Y_{g,i}$ and $Y_{h,j}$ are assumed to be independent as $h \neq g$. Furthermore, for each unit i of cluster g there exists a set L_i of $|L_i|$ units of cluster g for which

$$Corr(Y_{g,i}, Y_{g,j}|X_g, C_g) = \begin{cases} \rho_{ij} \text{ if } i \in L_i \\ 0 \text{ if } i \notin L_i \end{cases}.$$

As far as the two-stage sampling design is concerned, our assumptions are listed below.

- 1st Stage. A sample $\mathbf{g}$ of m clusters is selected according to an *high entropy* sampling design (cfr. [8], [9], [3], [2]) with first order inclusion probabilities

$$\pi_g = m\frac{X_g}{\sum_{g=1}^{M} X_g} \sim \frac{m}{M}\frac{X_g}{\mu_X}, \ g = 1, \ldots, M.$$

- 2nd Stage. From each cluster $g \in \mathbf{g}$ selected at first stage, a sample $\mathbf{s}_g$ of n_g elementary units is drawn according to simple random sampling without replacement. Samples $\mathbf{s}_g$s are independent conditionally on $\mathbf{g}$. The *total sample* is $\mathbf{s} = (\mathbf{s}_g;\ g \in \mathbf{g})$.

3 Main theoretical results

Consider the indicator function

$$I_{(y_{g,i} \leq y)} = \begin{cases} 1 \text{ if } y_{g,i} \leq y \\ 0 \text{ if } y_{g,i} > y \end{cases}; \ i = 1, \ldots, N_g, \ g = 1, \ldots, M; \ y \in \mathbb{R}.$$

The finite population distribution function (f.p.d.f.) is defined as

$$F_N(y) = \frac{1}{N}\sum_{g=1}^{M}\sum_{i=1}^{N_g} I_{(y_{g,i} \leq y)} = \sum_{g=1}^{M} w_g F_{N_g}(y) \tag{1}$$

where

$$F_{N_g}(y) = \frac{1}{N_g}\sum_{i=1}^{N_g} I_{(y_{g,i} \leq y)}$$

is the d.f. of gth cluster.

To estimate (1), we consider here the (design-based) Hájek estimator

$$\widehat{F}_H(y) = \sum_{g \in \mathbf{g}} \frac{w_g}{\pi_g}\widehat{F}_g(y) \Bigg/ \sum_{g \in \mathbf{g}} \frac{w_g}{\pi_g}$$

where

$$\widehat{F}_g(y) = \frac{1}{n_g} \sum_{i \in \mathbf{s}_g} I_{(y_{g,i} \leq y)}$$

is the empirical distribution function (e.d.f.) of cluster gth.

From now on, we will assume that the probability distribution of X_g is non-degenerate and possesses finite second moment, so that $\mathbb{E}[X_g^2] = \mu_{2x} < \infty$. As far as the population size and the sample size are concerned, our set-up is essentially similar to [2]. In detail, we will assume that

- $M \to \infty$, $m \to \infty$, with $m/M \to f \geq 0$;
- $\min_{1 \leq g \leq M} N_g \to \infty$, $\min_{1 \leq g \leq M} n_g \to \infty$.

Proposition 1. *Under the above conditions, the following results hold.*

- *The relationship*

$$\sqrt{m}(\widehat{F}_H(y) - F_N(y)) = \sqrt{m} \sum_{g \in \mathbf{g}} w_g \frac{1}{\pi_g} (\widehat{F}_g(y) - F_{N_g}(y)) + o_p(1)$$

  holds, where $o_p(1)$ tends to 0 in probability uniformly w.r.t. y.
- *Conditionally on X_gs, C_gs, $Y_{g,i}$, the sequence*

$$\sqrt{m} \sum_{g \in \mathbf{g}} w_g \frac{1}{\pi_g} (\widehat{F}_g(y) - F_{N_g}(y)); \; m \geq 1$$

  converges weakly to a Gaussian process $(W_H(y);\ y \in \mathbb{R})$, with zero mean function ($E[W_H(y)]$ and covariance kernel $K(y,t) = E[W_H(y)W_H(t)]$. Weak convergence takes place in the space $D[-\infty, +\infty]$ of cadlag functions equipped with the Skorokhod distance, and holds for a set of sequences of X_gs, C_gs, $Y_{g,i}$ having probability 1.

As a by-product of Proposition 1, we easily obtain asymptotic normality for a wide class of finite population parameters. Generally speaking, a finite population parameter is a functional $\theta : F_N(y) \to \mathbb{R}$. As an estimator of $\theta(F_N)$, it is intuitive to use a plug-in approach consisting in replacing F_N with $\widehat{F}_H$ into $\theta(\cdot)$. This would lead to the estimator $\widehat{\theta} = \theta(\widehat{F}_H)$ of $\theta = \theta(F_N)$.

The map $\theta(\cdot) : l^\infty[-\infty, +\infty] \to E$ is *Hadamard-differentiable* at F if there exists a continuous linear mapping $\theta'_F : l^\infty[-\infty, +\infty] \to E$ such that

$$\left\| \frac{\theta(F + th_t) - \theta(F)}{t} - \theta'_F(h) \right\|_E \to 0 \;\; as\, t \downarrow 0, \; for\, every\, h_t \to h. \tag{2}$$

The term $\theta'_F(\cdot)$ in (2) is the *Hadamard derivative* of θ at F (cfr. [10]).

Proposition 2. *Under the condition of Proposition* 1*, and if θ is Hadamard - differentiable at $F(y) = \mathbb{E}[F_N(y)]$ with Hadamard derivative $\theta'_F(\cdot)$, then $\sqrt{m}(\theta(\widehat{F}_H) -$*

$\theta(F_N))$ *tends in distribution to a normal random variable with zero expectation and variance* $\sigma_\theta^2 = E[\theta'_F(W_H)^2]$.

4 The resampling procedure

Although results in Propositions 1, 2, are of importance, they cannot be immediately used to construct a confidence interval for a finite population parameter θ, because the asymptotic variance σ_θ^2 generally possesses a complicate structure, depending on the superpopulation distribution of X_gs, $Y_{g,i}$s. For this reason, we resort to a resampling procedure based on a pseudo-population constructed *via* a two-stage mechanism. The construction of such a two-stage pseudo-population is described below.

1. For every sampled cluster $g \in \mathbf{g}$, expand $\mathbf{s}_g$ to a "pseudo-population for cluster g", where each unit $i \in \mathbf{s}_g$ appears $N^*_{g,i}$ times, with $N^*_{g,i} = [N_g/n_g] + \varepsilon_{g,i}$, where $\varepsilon_{g,i}$ is a Bernoulli r.v. with expectation $N_g/n_g - [N_g/n_g]$.
2. Expand each cluster $g \in \mathbf{g}$ to a "clustered pseudo-population", where each cluster $g \in \mathbf{g}$ appears $M^*_g = [1/\pi_g] + r_g$ times, where r_g is a Bernoulli r.v. with expectation $1/\pi_g - [1/\pi_g]$.

In general, the constructed pseudo-population has total size $N^* \neq N$, although it can be shown that N^*/N tends in probability to 1 as M increases. In the sequel, we will denote by $F^*_{N^*}(y)$ the d.f. of the pseudo-population.

From the pseudo-population, L independent pseudo-samples $\mathbf{s}^*_1, \ldots, \mathbf{s}^*_L$ are drawn according to a two-stage design identical to that used to select the sample $\mathbf{s}$ from the actual population. Denote further by $\widehat{F}^*_{H,l}(y)$ the Hájek estimator of $F^*_{N^*}(y)$ based on the pseudo-sample $\mathbf{s}^*_l$, and compute the corresponding estimates of $\theta(\cdot)$:

$$\widehat{\theta}^*_l = \theta(\widehat{F}^*_{H,l});\ \ l = 1, \ldots, L.$$

Next, the L quantities

$$Z^*_l = \sqrt{m}\left(\widehat{\theta}^*_l - \theta(F^*_{N^*})\right) = \sqrt{m}\left(\theta(\widehat{F}^*_{H,l}) - \theta(F^*_{N^*})\right);\ \ l = 1, \ldots, L \tag{3}$$

are computed, as well as their variance

$$\widehat{S}^{2*} = \frac{1}{L-1}\sum_{l=1}^{L}\left(Z^*_l - \overline{Z}^*_L\right)^2, \tag{4}$$

where $\overline{Z}^*_L = \sum_{l=1}^{L} Z^*_l$. Denote further by

$$\widehat{R}^*_L(z) = \frac{1}{L}\sum_{l=1}^{L} I_{(Z^*_l \leq z)},\ \ z \in \mathbb{R} \tag{5}$$

the empirical distribution function of Z_l^*s, and by

$$\widehat{R}_L^{*-1}(p) = \inf\{z : \widehat{R}_L^*(z) \geq p\}, \ 0 < p < 1 \tag{6}$$

the corresponding pth quantile.

Proposition 3. *Under the same conditions as Propositions* 1*,* 2*, the relationship*

$$\sup_z \left| P(\theta(\widehat{F}_H)) - \widehat{R}_L^*(z) \right| \to 0 \tag{7}$$

holds as $L \to \infty$, a.s. w.r.t. X_gs, C_gs, $Y_{g,i}$s, and in probability w.r.t. samples $\mathbf{s} = (\mathbf{s}_g; g \in \mathbf{g})$, and S^{*2} tends in probability to σ_θ^2.

As a consequence, the confidence intervals for $\theta_N = \theta(F_N)$

$$\left[\widehat{\theta}_H - n^{-1/2} R_L^{*-1}(1-\alpha/2),\ \widehat{\theta}_H - n^{-1/2} R_L^{*-1}(\alpha/2)\right] \tag{8}$$

$$\left[\widehat{\theta}_H - n^{-1/2} z_{\alpha/2} \widehat{S}^*,\ \widehat{\theta}_H + n^{-1/2} z_{\alpha/2} \widehat{S}^*\right] \tag{9}$$

both possess asymptotic level $1-\alpha$ as M, m, $\min_g N_g$, $\min_g n_g$, and L increase.

Acknowledgments. Thanks are due to Prof. Paola Vicard, for her suggestions and insightful remarks.

Models and methods - Theoretical Issues in Statistical Inference

A new mixture model for three-way data

Una nuovo modello mistura per dati a tre vie

Salvatore D. Tomarchio, Antonio Punzo and Luca Bagnato

Abstract In the last years, there has been a growing interest in the analysis of three-way (matrix-variate) data via mixture models. Quite often real data are affected by outliers, and this also occurs in the context of three-way data. A common solution for managing this type of data consists in fitting mixtures of heavy-tailed distributions. Unfortunately, the three-way literature is still limited, with the only matrix variate *t* mixtures recently proposed to cope with this issue. Therefore, in this work we firstly introduce a new heavy-tailed matrix-variate distribution and then we use it within the mixture model setting. The resulting mixture model is finally fitted to a real dataset for illustrative purposes.

Abstract *Negli ultimi anni, vi è stato un crescente interesse verso l'analisi di dati a tre vie (matrix-variati) per mezzo di modelli mistura. Spesso i dati reali sono affetti da osservazioni atipiche, e questo accade anche nel contesto dei dati a tre vie. Una soluzione comune per gestire questo tipo di dati consiste nell'utilizzo di misture di distributioni a code pesanti. Sfortunatamente, la letterature dei dati a tre vie è ancora limitata, con le sole misture di distribuzioni t recentemente proposte per far fronte a questo problema. Quindi, in questo lavoro innanzitutto introduciamo una nuova distribuzione matrix-variata a code pesanti e successivamente la utilizziamo all'interno di un modello mistura. Il conseguente modello mistura viene quindi utilizzato su un dataset reale a scopi illustrativi.*

1 Introduction

In the last years, there has been a growing interest in the application of model-based clustering techniques to three-way (matrix-variate) data (see, e.g. [3],[4]). Although there are countless examples of clustering for multivariate distributions via mixture models, the corresponding three-way literature is still little developed. This data structure arises when p variables are observed in r different occasions on n statistical units, so that the data can be organized in a three-way array consisting of the following three dimensions: variables (rows), occasions (columns) and units (layers). Therefore, each statistical unit is a $p \times r$ matrix.

Quite often real data are affected by outliers, and this also occurs in the context of three-way data. In this work we focus on mild outliers (see, [1] for further details) that, in the clustering context, are defined as points that deviate from the distribution within a cluster, but they would fit well if the overall within-cluster distribution had heavier tails [2]. A common solution for managing this type of data consists in fitting mixtures of heavy-tailed distributions. In fact, the matrix Gaussian mixture model (MXG-Ms), that can be considered the reference model, is unable to adequately model such data, because of the tails behavior of its mixing components. However, the three-way literature is still limited, and only the matrix t mixture model (MXt-Ms) has been proposed to deal with this issue. For this reason, in this work we firstly introduce a matrix-variate distribution whose tails are heavier than the matrix Gaussian distribution (MXG), and subsequently it used as component distribution in a finite mixture model. This new distribution, called herein matrix shifted exponential normal (MXSEN), generalizes the corresponding multivariate distribution recently introduced in [5]. To obtain the MXSEN, we use the well-known variance mixture model [6], as discussed in Section 2. Its use in model-based clustering via mixture models (MXSEN-Ms) is also illustrated. An application to a real data set is finally shown in Section 3, where the MXSEN-Ms are compared to MXG-Ms and MXt-Ms in terms of goodness of fit and classification performance.

2 Methodology

2.1 The matrix shifted exponential normal

A classical way to make heavier the tails of a Gaussian distribution is by means of the variance mixture model. In a three-way framework, a $p \times r$ random matrix $\mathbf{X}$ is said to follow a variance mixture model if its probability density function (pdf) is

$$f(\mathbf{X};\mathbf{M},\boldsymbol{\Sigma},\boldsymbol{\Psi},\boldsymbol{\theta}) = \int_{S_h} f_{\text{MXG}}(\mathbf{X};\mathbf{M},\boldsymbol{\Sigma}/w,\boldsymbol{\Psi}) h(w;\boldsymbol{\theta}) dw, \tag{1}$$

where:

1. f_{MXG} is the pdf of a matrix Gaussian distribution, that is given by

$$\frac{1}{(2\pi)^{\frac{rp}{2}}|\boldsymbol{\Sigma}|^{\frac{r}{2}}|\boldsymbol{\Psi}|^{\frac{p}{2}}}\exp\left\{-\frac{1}{2}\text{tr}\left[\boldsymbol{\Sigma}^{-1}(\mathbf{X}-\mathbf{M})\boldsymbol{\Psi}^{-1}(\mathbf{X}-\mathbf{M})'\right]\right\},$$

   with $p\times r$ mean matrix $\mathbf{M}$, $p\times p$ row covariance matrix $\boldsymbol{\Sigma}$ and $r\times r$ column covariance matrix $\boldsymbol{\Psi}$;
2. $h(w;\boldsymbol{\theta})$ is the mixing pdf, with support $S_h\subseteq\mathbb{R}_{>0}$, depending on the parameter(s) $\boldsymbol{\theta}$.

Therefore, it is a finite/continuous mixture of MXG distributions on $\boldsymbol{\Sigma}$ obtained via a convenient discrete/continuous mixing distribution with positive support. The additional parameters of the mixing distribution govern, in the variance mixture model, the deviation from normality in terms of tail weight.

If in (1), a shifted exponential distribution is chosen as mixing pdf $h(w;\boldsymbol{\theta})$, then the matrix shifted exponential normal pdf can be obtained. In formula,

$$f_{\text{MXSEN}}(\mathbf{X};\mathbf{M},\boldsymbol{\Sigma},\boldsymbol{\Psi},\boldsymbol{\theta})=\int_1^{\infty}f_{\text{MXG}}(\mathbf{X};\mathbf{M},\boldsymbol{\Sigma}/w,\boldsymbol{\Psi})h_{\text{SE}}(w;\theta)dw, \tag{2}$$

where $h_{\text{SE}}(w;\theta)=\theta\exp[-\theta(w-1)]$ denotes the pdf of a shifted exponential on $S_h=(1,\infty)$. After some algebra, the pdf in (2) can be written as

$$f_{\text{MXSEN}}(\mathbf{X};\mathbf{M},\boldsymbol{\Sigma},\boldsymbol{\Psi},\boldsymbol{\theta})=(2\pi)^{-\frac{pr}{2}}|\boldsymbol{\Sigma}|^{-\frac{r}{2}}|\boldsymbol{\Psi}|^{-\frac{p}{2}}\theta\exp\{\theta\}\,\varphi_{\frac{pr}{2}}\left(\frac{\delta(\mathbf{X};\mathbf{M},\boldsymbol{\Sigma},\boldsymbol{\Psi})}{2}+\theta\right), \tag{3}$$

where $\delta(\mathbf{X};\mathbf{M},\boldsymbol{\Sigma},\boldsymbol{\Psi})$ denotes the Mahalanobis distance from $\mathbf{X}$ to the center $\mathbf{M}$ with respect to $\boldsymbol{\Sigma}$ and $\boldsymbol{\Psi}$, and $\varphi_m(z)$ is the Misra function [7], generalized form of the exponential integral function [8]. Similarly to the corresponding multivariate distribution [5], the closer the values of θ to 0 are, the heavier the tails of MXSEN distribution with respect to the (nested) MXG distribution become.

2.2 Finite mixtures of MXSEN distributions

Clustering and classification aim at finding and analyzing underlying group structures in the data. One common method used for clustering is model-based, and generally makes use of a G-component finite mixture model. A $p\times r$ random matrix $\mathbf{X}$ arises from a parametric finite mixture distribution if its pdf can be written as

$$p(\mathbf{X};\boldsymbol{\Theta})=\sum_{g=1}^{G}\pi_g f(\mathbf{X};\boldsymbol{\Theta}_g) \tag{4}$$

where $\pi_g>0$ are the mixing proportions, such that $\sum_{g=1}^{G}\pi_g=1$, $f(\cdot)$ are the component densities and $\boldsymbol{\Theta}$ contains all the parameters of the model. If in (4) the pdf of the MXSEN distribution in (3) is chosen for all the component densities, then we

obtain MXSEN-Ms that are more flexible with respect to MXG-Ms in modeling data affected by outliers, because of their tail behavior. Parameter estimation is carried on via an ECM algorithm, a variant of the classical expectation-maximization (EM) algorithm, which is a natural approach for maximum likelihood estimation in the context of mixture models.

3 Real data application

The real dataset herein analyzed consists of $n = 75$ study programs taught in the Italian universities. There are $G = 2$ groups in the data, i.e. $n_1 = 33$ bachelor study programs and $n_2 = 42$ master study programs. For each statistical unit the following three indicators ($p = 3$) concerning the academic careers are considered: the percentage of students that continue in the second year of the study program, the percentage of students that finish their studies within the normal duration of the study program and the percentage of dropouts after $t + 1$ years, where t is the normal duration of study program. All the variables are measured for three years ($r = 3$), implying that each study program is a 3×3 matrix.

MXSEN-Ms, and for comparison purposes also MXG-Ms and MXt-Ms, are hence fitted to the data for $G \in \{1, 2, 3\}$, and their results are shown in Table 1. The Bayesian information criterion (BIC) [9], one of the most popular (likelihood-based) model selection criterion, is then used to select the number of groups G. Furthermore, the adjusted Rand index (ARI) [10] and the percentage of missclassified units (ϵ) are adopted to evaluate the classification performance. As shown in Table 1, the

Table 1 BIC values and classification performance of the competing mixture models.

Model	G	BIC	ARI	ϵ
MXG-Ms	3	-2247.253	0.7196	0.0933%
MXt-Ms	2	-2322.750	0.7953	0.0533%
MXSEN-Ms	2	**-2323.933**	**0.8443**	**0.0400%**

BIC selects $G = 3$ groups for MXG-Ms, whereas for MXt-Ms and MXSEN-Ms the correct number of groups is chosen ($G = 2$). This is an indication of the fact that the tails of each component distribution in MXG-Ms are lighter than required, implying that this model overfits the true number of clusters. Comparable issues, but in the multivariate literature, can be found for example in [11]. In any case, according to the BIC, the MXSEN-Ms are the best model in terms of fitting. From a classification point of view, similar conclusion can be drawn. In fact, MXSEN-Ms show the highest ARI and the lowest percentage of missclassified units. Finally, the estimated values of θ for the two groups are $\theta_1 = 0.25$ for the bachelor study programs and $\theta_2 = 0.10$ for the master ones. Being both close to 0, this seems to suggest the presence of mild outliers in the data, particularly for the master programs, outlying the necessity of considering distributions with heavier tails with respect to the MXG distribution.

A Sequential Test for the C_{pmk} Index

Un test sequenziale per l'indice C_{pmk}

Michele Scagliarini

Abstract We propose a sequential hypothesis test for the process capability index C_{pmk}. We compare the performance of the proposed test with the properties of the most used non-sequential test by performing a simulation study. The results indicate that the sequential test has best results in terms of power function and makes it possible to save a not negligible amount of sample size.

Abstract *Si propone un test sequenziale per la verifica d'ipotesi sull'indice di capacità C_{pmk}. Le proprietà statistiche del test proposto sono confrontate con quelle del test non sequenziale maggiormente usato in letteratura mediante simulazioni. I risultati indicano che il test sequenziale ha risultati migliori in termini di funzione di potenza e consente una non trascurabile riduzione dell'ampiezza campionaria.*

1 Introduction

Process capability indices are well known management tools used for assessing performance of manufacturing processes both at the production level and for business relationships. The index C_{pmk} has been designed by taking into account the process yield (meeting the manufacturing specifications) as well as the process loss (variation from the target). It is defined as $C_{pmk} = \left(d - |\mu - T|\right) \Big/ 3\sqrt{\sigma^2 + \left(\mu - T\right)^2} = \left(d/\sigma - |\xi|\right) \Big/ 3\sqrt{1+\xi^2}$ where μ is the process mean, σ is the process standard deviation, T is the process target, d=($USL-LSL$)/2 (LSL and USL are the specification limits), and ξ=(μ-T)/σ [4]. As a part of

[1] Michele Scagliarini, Department of Statistical Sciences, University of Bologna; michele.scagliarni@unibo.it

contractual agreement it is often necessary to demonstrate that the process capability index C_{pmk} meets or exceeds some particular target value, say C_{pmk0}. Such decision-making problem may be formulated as a hypothesis testing problem: $H_0 : C_{pmk} \le C_{pmk0}$ (the process is not capable) versus $H_1 : C_{pmk} > C_{pmk0}$ (the process is capable).

In this study, starting from some of the results obtained by [2], we propose a sequential test for the index C_{pmk}. Firstly, we review the most used non-sequential test for assessing whether a process is capable or not. Secondly, we analytically obtain the test statistic of the sequential test and describe in detail the testing procedure. Finally, we compare the sequential test properties with those of the non-sequential test by performing an extensive simulation study. The results show that the proposed sequential test has good power behavior and makes it possible to save sample size, which can be translated into reduced costs, time and resources.

2 Hypothesis testing on C_{pmk}

Assuming a normally distributed quality characteristic, $X \sim N\left(\mu, \sigma^2\right)$, [5] proposed a statistical test (PC-test) based on the distribution of the estimator: $\hat{C}_{pmk} = \min\left\{ \dfrac{USL - \bar{X}}{3\sqrt{S_n^2 + \left(\bar{X} - T\right)^2}}, \dfrac{\bar{X} - LSL}{3\sqrt{S_n^2 + \left(\bar{X} - T\right)^2}} \right\} = \dfrac{d - \left|\bar{X} - T\right|}{3\sqrt{S_n^2 + \left(\bar{X} - T\right)^2}}$ where, $\bar{X} = \sum_{i=1}^{n} X_i \Big/ n$ and $S_n^2 = \sqrt{\sum_{i=1}^{n} \left(X_i - \bar{X}\right)^2 \Big/ n}$ are the maximum likelihood estimators of μ and σ^2 respectively. For the case $T = \left(USL + LSL\right)/2$ the cumulative distribution function of $\hat{C}_{pmk}$ can be expressed as

$$F_{\hat{C}_{pmk}}(x) = 1 - \int_0^{b\sqrt{n}/(1+3x)} G\left(\frac{\left(b\sqrt{n} - t\right)^2}{9x^2} - t^2 \right) \left[\phi\left(t + \xi\sqrt{n}\right) + \phi\left(t - \xi\sqrt{n}\right) \right] dt \qquad (1)$$

for $x>0$, where $b=d/\sigma$, $G(\cdot)$ is the cumulative distribution function of the chi-square distribution χ^2_{n-1}, and $\phi(\cdot)$ is the probability density function on the standard normal distribution. The decision rule is to reject $H_0 : C_{pmk} \le C_{pmk0}$ if $\hat{C}_{pmk} > c_0$ and fail to reject H_0 otherwise. Given the values of the type-I error probability α, the capability requirement C_{pmk0}, the sample size n and the parameter ξ, the critical value c_0 can be obtained by solving the equation

$\int_0^{b\sqrt{n}/(1+3c_0)} G\left(\frac{\left(b\sqrt{n}-t\right)^2}{9c_0^2}-t^2\right)\left[\phi\left(t+\xi\sqrt{n}\right)+\phi\left(t-\xi\sqrt{n}\right)\right]dt=\alpha$. It can be noted that this function depends on the parameter ξ which in real applications is usually unknown. To eliminate the need of estimating ξ [5] studied the behaviour of the critical value c_0 as a function of ξ. The authors found that the condition $|\xi|=0.5$ should provide conservative critical values and for several combinations of α, C_{pmk0}, and *n*. The results on c_0 are reported by the authors [5] in their Tables 1-5.

3 A sequential test for C_{pmk}

Under the assumption that the data came from a multivariate distribution with density function $f(x;\boldsymbol{\theta})$, [2] proposed a general sequential testing procedure for testing $H_0: h(\boldsymbol{\theta})=\mathbf{0}$ versus $H_1: h(\boldsymbol{\theta})\neq\mathbf{0}$, where $h(\boldsymbol{\theta}):\mathbb{R}^d\to\mathbb{R}^q$, with $q\le d$, is a function with first order derivative matrix denoted by $H(\boldsymbol{\theta})$ with $\boldsymbol{\theta}$ unknown. Under the standard regularity conditions for the existence of the multivariate maximum likelihood estimators the author showed that the statistic $W_k=kh\left(\hat{\boldsymbol{\theta}}_k\right)\left[H^t(\boldsymbol{\theta})I^{-1}(\boldsymbol{\theta})H(\boldsymbol{\theta})\right]^{-1}h\left(\hat{\boldsymbol{\theta}}_k\right)^t$, where k is the sample size, $\hat{\boldsymbol{\theta}}_k$ is a consistent estimator of $\boldsymbol{\theta}$ and $I(\boldsymbol{\theta})$ is the Fisher information matrix, can be approximated by a functional of Brownian motions. The proposed test statistic is $W_k^*=kh\left(\hat{\boldsymbol{\theta}}_k\right)\left[H^t\left(\hat{\boldsymbol{\theta}}_k\right)I^{-1}\left(\hat{\boldsymbol{\theta}}_k\right)H\left(\hat{\boldsymbol{\theta}}_k\right)\right]^{-1}h\left(\hat{\boldsymbol{\theta}}_k\right)^t$ where $\hat{\boldsymbol{\theta}}_k$ is the maximum likelihood estimator of $\boldsymbol{\theta}$ [2]. The α-level sequential test procedure, truncated at the maximal allowable sample size n_0, is performed as follows:

1. for $k=2,3,...,n_0$ compute of the statistic $W_k^{*(1)}=\sqrt{k/n_0}\sqrt{W_k^*}$;
2. hypothesis H_0 is rejected the first time that $W_k^{*(1)}$ exceeds the critical value w_α;
3. if $W_k^{*(1)}$ does not exceed w_α by n_0 then do not reject H_0.

The maximal sample size n_0 can be decided on the basis of financial, ethical or statistical reasons as, for example, to achieve a desired power level. The critical value w_α, given the type I error probability α, can be obtained from [1]. Let us consider the hypothesis $H_0: C_{pmk}=C_{pmk0}$ versus $H_1: C_{pmk}\neq C_{pmk0}$ and assume that the quality characteristic is normally distributed $X\sim N\left(\mu,\sigma^2\right)$. To obtain a sequential test comparable with the PC-test we further assume the parameter ξ as known. Let us define the function $h(\boldsymbol{\theta})$ as

$h(\boldsymbol{\theta}) = \ln\left(\left(C_{pmk}\right)^2\right) - \ln\left(C_{pmk0}^2\right) = \ln\left[\left(d/\sigma - |\xi|\right)^2 \Big/ 9\left(1+\xi^2\right)C_{pmk0}^2\right]$, where $\boldsymbol{\theta} = \sigma^2$. For $C_{pmk} \geq 0$, H_0 is equivalent to $H_0 : h(\boldsymbol{\theta}) = 0$ and the alternative hypothesis is equivalent to $H_1 : h(\boldsymbol{\theta}) \neq 0$. In the case at hand the statistic W_k^* can be written as $W_k^* = kh^2\left(\hat{\boldsymbol{\theta}}_k\right)\left[H^t\left(\hat{\boldsymbol{\theta}}_k\right)I^{-1}\left(\hat{\boldsymbol{\theta}}_k\right)H\left(\hat{\boldsymbol{\theta}}_k\right)\right]^{-1}$ where $\hat{\boldsymbol{\theta}}_k = S_k^2$ with $S_k^2 = \sum_{i=1}^{k}\left(X_i - \bar{X}_k\right)^2 \Big/ k$. The function $h\left(\hat{\boldsymbol{\theta}}_k\right)$ is thus given by $h\left(\hat{\boldsymbol{\theta}}_k\right) = \ln\left[\left(d/\sqrt{S_k^2} - |\xi|\right)^2 \Big/ 9\left(1+\xi^2\right)C_{pmk0}^2\right]$ and consequently W_k^* can be written as:

$$W_k^* = \frac{k\left(\ln\left[\left(d/\sqrt{S_k^2} - |\xi|\right)^2 \Big/ 9\left(1+\xi^2\right)C_{pmk0}^2\right]\right)^2}{\dfrac{\left[d\left(\sqrt{S_k^2}\,|\xi| - d\right)\right]^2}{\left[S_k^2\left(S_k^2\xi^2 - 2d|\xi|\sqrt{S_k^2} + d^2\right)\right]^2}\,2S_k^4} \tag{2}$$

Therefore, given the value of α and the maximal allowable sample size n_0, the test is performed by computing, for k=2,3,…, n_0, the statistic $W_k^{*(1)} = \sqrt{k/n_0}\,W_k^*$.

Let n_{stop} be the first integer k=2,3,…, n_0 for which $W_k^{*(1)} > w_\alpha$: we reject H_0 if $W_{n_{stop}}^{*(1)} > w_\alpha$; we do not reject H_0 if $W_k^{*(1)}$ does not exceed w_α by n_0. In this framework n_{stop} is the stopping sample size of the test.

4 Comparisons and concluding remarks

In this Section, we investigate the performance of the sequential test and compare it with that of the PC-test. Note that the sequential test is two sided with composite alternative hypothesis ($H_1 : C_{pmk} \neq C_{pmk0}$), while the PC-test is unilateral ($H_1 : C_{pmk} > C_{pmk0}$). In order to correctly compare the statistical properties of the tests, we considered scenarios under H_1 where $C_{pmk} = C_{pmk1}$ with $C_{pmk1} > C_{pmk0}$. In such a way the sequential bilateral test with Type I error probability α can be compared with the non-sequential unilateral test with Type I error probability equal to α_u=α/2. In the research we examined several scenarios, here, for the sake of conciseness, we show the results only for the case where the capability requirement

is $C_{pmk0} = 2$. For $\alpha = 0.02(\alpha_u = 0.01)$, $C_{pmk1} = 2.1(0.05)3.0$ and $n = 50,100,200$ we analytically compute the power function of the PC-test. As far as the sequential test is concerned we considered the values of *n* as the maximal sample size n_0. Therefore, for each value of *n* and C_{pmk1} we generated 50000 replicates from a normally distributed quality characteristic. The aim of these simulations was to determine the empirical power function $\hat{\pi}_s$ of the sequential test and the average n_{avg} of the stopping sample sizes n_{stop} required for the sequential test, with maximal allowable sample size $n_0 = n$, for concluding in favor of H_1. The results are summarized in Figure 1 and Table 1. Figure 1 displays the power functions of the two tests for the values of *n* and C_{pmk1} of interest. Table 1, for some values of C_{pmk1}, contains: π_{PC} the power of the PC-test; $\hat{\pi}_s$ the estimated power of the sequential test; n_{avg} the average of the stopping sample sizes n_{stop}; $SD(n_{avg})$ the standard deviation of the stopping sample sizes n_{stop}.

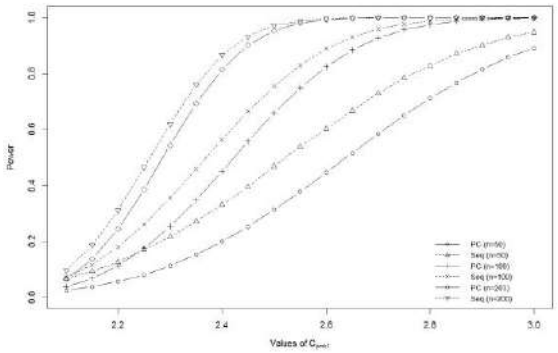

Figure 1: power functions of the PC and sequential tests

Table 1: Summary of the results under H_1 for several values of C_{pmk1} and *n*=50,100,200

C_{pmk1}	π_{PC}	$\hat{\pi}_s$	n_{avg}	$SD(n_{avg})$
		n=50		
2.20	0.0577	0.1255	48.3	5.9
2.30	0.1138	0.2159	47.1	7.3
2.40	0.1993	0.3316	45.5	8.6
		n=100		
2.20	0.1134	0.1800	95.7	11.9
2.30	0.2540	0.3565	91.0	15.9
2.40	0.4512	0.5636	84.2	19.2
		n=200		
2.20	0.2449	0.3111	184.9	29.0
2.30	0.5438	0.6194	165.2	38.4
2.40	0.8159	0.8668	140.3	40.0

From the results reported in Figure 1 and Table 1, it can be observed that the sequential test has better performance than the PC-test. As an example, when the true capability of the process is $C_{pmk} = C_{pmk1} = 2.3$ with n=50 we have that $\pi_{PC} = 0.114$ and $\hat{\pi}_s = 0.216$. When the sample size is n=100 the power functions are $\pi_{PC} = 0.254$ and $\hat{\pi}_s = 0.357$ and for n=200 are $\pi_{PC} = 0.544$ and $\hat{\pi}_s = 0.619$. By examining the averages of the final sample sizes n_{avg} the results show that the sequential test saves a not negligible amount of sample size. As an example, under $H_1 : C_{pmk} = C_{pmk1}$ with $C_{pmk1} = 2.4$ and n=100, the power of the PC-test is $\pi_{PC} = 0.4512$, while with a maximum allowable sample size equal to $n_0 = 100$ the power of the sequential test is $\hat{\pi}_s = 0.5636$, with $n_{avg} = 84.2 (\simeq 85)$. In this case the sequential test saves, on average, 15.8% of the sample size as to the PC-test. We also investigate the behavior of the sequential test under H_0. The results, obtained through a further simulation study, showed that the empirical type I error probability of the sequential test is very close to the nominal α-level. As an example when $H_0 : C_{pmk} = C_{pmk0}$ holds, with n=200 we have that the empirical type-I error probability is $\hat{\alpha} = 0.0021$. In this case $\hat{\alpha}$ is only slightly larger than the nominal level $\alpha = 0.002$.

Before concluding, we would point out some issues that deserve attention and further research. A recent study [3] argued that the PC-test might be not conservative with respect to the type I error probability since the supremum of the α-risk doesn't occur exactly at $|\xi| = 0.5$. We will study the effect of the parameter ξ on both tests in a future piece of research.

Summarizing the results shows that the proposed sequential test allows higher power levels with, on average, smaller stopping sample sizes as compared with the fixed sample size test. We consider these results as valuable, because in a highly competitive context where both cost and quality are relevant, the availability of statistical methods, which make it possible to save sampling size, can be directly translated into saved resources and reduced costs.

Probability Interpretations and the Selection of the Most Effective Statistics Method

Sul Significato della Probabilità e la Scelta del Metodo

Paolo Rocchi

Abstract A recent study shows how frequentist and subjective authors often tackle the probability interpretation using philosophical arguments. This paper recalls an attempt to explain the probability meanings by means of a purely mathematical method. Two theorems spell out the testing conditions of long-term events and the single event. Doing so the theorems define the properties of the frequentist and subjective probabilities and prove these probabilities are not irreconcilable as usually credited. Lastly, we derive a precise rule for working statisticians who are called to select the most effective statistics applicable in a project.

Abstract *Questo lavoro affronta il problema dell'interpretazione della probabilità adottando un metodo puramente matematico. Due teoremi illustrano le condizioni per verificare sperimentalmente le probabilità di eventi ripetuti e dell'evento singolo. I teoremi dimostrano che ci sono due diversi modelli di probabilità e non uno soltanto. Le probabilità frequentista e soggettiva non sono inconciliabili come si crede usualmente. Infine viene derivata una regola precisa per selezionare la statistica più efficace in un dato progetto.*

Key words: Frequentism, subjectivism, testability, selection of statistics in a project.

Introduction

Presently statisticians face issues of different weight that could be placed in a scale of severity. It may be said that specialist and minute questions regarding statistical techniques lie at one side; at the other side, there are foundational issues that deal with substantial and general aspects of statistics. This paper deals with two problems of the second group, specifically:

[1] Paolo Rocchi, IBM and Università Luiss; procchi@luiss.it

1) The *selection of the most effective statistics in a project,*
2) The *probability interpretations.*

1) - Experts have the classical and Bayesian statistics at disposal which in principle, should enhance the effectiveness of working statisticians, although the two statistics are divided by various disagreements concerning the scopes to pursue, the data to gather, the techniques to use, etc. [1] There is no shared criterion to select the most effective method in a project, and an investor who pays for a statistical study and requests for the best outcome, does not obtain univocal answers. Experts take different positions: the supporters of the classical [2] and the Bayesian statistics [3] prescribe their own methodology in any situation and do not admit exceptions. Some tend to minimize the divergence and search a common way to estimation [4], to regression [5] or propose hybrid modes [6][7].

2) - The literature usually divides the main views of probability in two. *Objective interpretations* see probability as a feature of reality independent of human cognition; *epistemic interpretations* primarily ascribe probability to human knowledge or belief [8]. The frequentist and subjective (including Bayesian) models are the most popular. The first model supported by Venn, von Mises and Reichenbach, qualifies mass random events whose results are uncertain in detail but the numerical proportion in the long run with respect to a given result can be predicted [9]. The subjective school opened by de Finetti and Ramsey, and consolidated by the Bayesians such as Savage, Schlaifer and Jeffreys, claims that probability derives from an individual's personal judgment or own experience about whether a specific outcome is likely to occur [10]. The two interpretations seem to be irreconcilable from the logical point of view, yet 'dualist' authors – Ramsey, Carnap, Popper and more recently Costantini, Lewis and others – tend to accept both the perspectives. They have devised original ideas and criteria for the comprehensive adoption, however they have not reached a conclusive frame so far.

A recent bibliographical research provides evidence of how probability theorists are strongly influenced by personal opinions and philosophical arguments [11]. In consequence of this discovery, I decided to develop a purely mathematical approach to the interpretation problem. This report recalls the main results – proved and commented in [12] – which suggest a rational criterion even for solving problem 1.

A Mathematical Pathway

Let us recall a few basic assumptions. Probability is the *measure of how likely the random result e will occur*. Given a sample space Ω and an associated sigma algebra Σ, the probability *P* is a function with domain Σ that satisfies:

1. $P(e) \geq 0$ for all $e \chi \Sigma$.
2. $P(\Omega) = 1$.

3. $\left(\bigcup_{i=1}^{\infty} e_{(i)}\right) = \sum_{i=1}^{\infty} P(e_{(i)})$ if pairwise disjoint $e_{(1)}, e_{(2)}, e_{(3)}, \ldots \chi \Sigma$ (1)

The possibility of proving or rejecting a hypothesis by means of experimental trials is inherent to genuine science, thus the probability established in abstract with axioms (1) needs to be tested. It is necessary to discuss how and when the quantity $P(e)$ can be checked. The ensuing theorems illustrate the relations between the experimental frequency F and the probability P of a random event in two distinct situations that are the sequel of repeated trials (e_∞) and the single trial (e_1) in the order.

1.1 Theorems of Large Numbers and a Single Number

Suppose e is an i.i.d variable, the *theorem of large numbers* (TLN) states that as the number of trials grows, the relative frequency almost surely gets closer to $P(e_\infty)$

$$F\left(e_n\right) \xrightarrow{a.s.} P(e_\infty), \qquad as \quad n \to \infty. \tag{2}$$

The *theorem of a single number* (TSN) demonstrates that the relative frequency unfits with the probability of a single random experiment

$$F(e_1) \neq P(e_1), \qquad n = 1. \tag{3}$$

The theorem of large numbers has a conceptual link with the law of large numbers (LLN), but a neat difference divides them.

LLN expresses the convergence of empirical random data toward an expected value. Émile Borel developed a special strong version of LLN where q is the number of empirical occurrences and P is a purely numerical value

$$\frac{q}{n} \xrightarrow{a.s.} P, \qquad as \quad n \to \infty. \tag{4}$$

The statement (4) describes the property of P whereas (2) describes the property of $P(e_\infty)$ because TLN is a theorem about testing and not a general law. In other words, LLN deals with the probability P in abstract, TLN establishes the testing condition for $P(e_\infty)$ that is a particular kind of probability. TLN proves that – at least in principle – the probability of repeated events (called *collective* by von Mises and *series* by Venn) can be verified by means of experiments, hence $P(e_\infty)$ is a parameter that exists in the real world, the *frequency probability* $P(e_\infty)$ is *an authentic physical quantity*.

TSN proves how one cannot test the probability of a single random event. It is not a question of instruments or experimental setting; never ever one can corroborate $P(e_1)$ and therefore it *is not a physical quantity*. This conclusion perfectly matches with the famous aphorism by de Finetti: “Probability does not exist”.

TSN implies that scientists should reject $P(e_1)$ because it is out of control; instead statisticians and even common people are concerned with the probability of a single result. Subjectivists and Bayesians exploit the *semantic value* of $P(e_1)$ and circumvent this obstacle caused by (3). What does 'semantic value' exactly mean?

Semiotics is the science of signs and teaches us that numbers, words, symbols etc. are items of information [13] and as such they can convey meanings. The number $P(e_1)$ does not have any physical significance nonetheless it does not lose the capability of conveying significance. Subjectivists and Bayesians use it to express a *personal credence about the occurrence of* (e_1), namely $P(e_1)$ is a *subjective probability*.

I recall in concise terms the criticism of writers against this model [14]:

1. Subjective probability expresses the personal belief which in principle can be affected by the variety of personal convictions held by an individual. The suspicions of arbitrariness have been raised since the early beginnings.

2. The betting scheme used to ensure the consistent value of $P(e_1)$ sounds somewhat strange in scientific and engineering sectors.

3. Testing is a key criterion for the scientific method but in principle subjective probability is alien to experimental validation. This turns out to be repellent to the science which investigates objective situations and strives for results independent of the observer.

In the light of statement (3), the disapprovals **1, 2** and **3** take completely different significance. In fact, TSN proves that $P(e_1)$ has no physical meaning and remark **3** can but confirm this essential property. TSN leads us to grasp how the subjectivists and Bayesians masters conducted an intelligent plan of action to recycle $P(e_1)$ as epistemic probability. Keynes teaches us how epistemic probabilities are not so easy to assess and to check, hence the manoeuvre of subjectivists and Bayesians necessarily presents the weak sides **1** and **2**. The landscape emerging from TLN and TSN shows how the most critical annotations against the subjective model decrease in importance. It may be said that the above listed remarks and even other negative commentaries give details about the price paid to reuse $P(e_1)$ that otherwise should be rejected from the scientific domain.

The Best Statistics?

1.1 Theorem of Compatibility

The results achieved by means of the theorems of large numbers and a single number can be summarized in the following way:

$$\textit{Frequentist Probability}: P(e_n) \qquad n \to \infty \qquad (7a)$$

$$\textit{Subjective Probability}: P(e_n) \qquad n = 1 \qquad (7b)$$

The *theorem of compatibility* (TC) proves that the frequentist and subjective models do not contradict

$$[P(\infty)] \text{ OR } [P(e_1)]. \quad (8)$$

The hypotheses (7a) and (7b) take two disjoint intervals for n, consequently the frequentist and subjective probabilities apply to distant situations; $P(\infty)$ and $P(e_1)$ do not overlap and thus do not contradict even if they widely differ.

The reader can note how the assumptions (7a) and (7b) play a key role; conversely, conventional constructions who do not specify the hypotheses necessary to apply each model, lead to irreconcilable positions. The founders of the frequentist and subjective schools sustain diverging models but share the same philosophy; they assume that probability has only one meaning. In the place of accurate hypotheses (7.a) and (7.b) they assume there is a sole 'authentic' probability model. This unproven precondition constitutes a sort of hidden axiom raising endless debates and preventing researchers from attacking the core of the interpretation issue. TC disproves this dogmatic assumption and shows how intrinsically probability is multifold.

1.2 How to Select the Method

TLN, TSN and TC regulate the exercise of probability and lead to the criterion for picking the most effective statistics in a given project. Specifically, one reasonably can infer the following rules:

- **a.** *If one means to investigate the long-term event (7a), the one must resort to use the classical statistics.*
- **b.** *If one means to investigate a single event (7b), he must adopt the Bayesian statistics.*

The rules **a** and **b** do have the scope of fixing the superiority of a statistical method over the other; they merely establish a criterion to use the classical and Bayesian statistics in a given project.

Assumption (7a) is consistent with the classical statistical inference that makes propositions about a population, using data drawn from that population with some form of sampling. Bayesian statistics teaches us to update our beliefs in the evidence of new data when we have to forecast a future single event. Note how the Bayesian procedures are not confined to a single observation. When a Bayesian applies to a sequel of repeated events, his conclusions regard each individual case; he addresses the situations one by one.

Comments and Conclusions

A - Gauss, Hilbert and other eminent mathematicians consider simplicity as a virtue of theoretical works, a sign of elegance and not a defect. Other experts claim

that simplicity is a characteristic of mathematics because it is easier to gain enlightenment from a simple proof compared to a complex proof. The theorems presented here sound very simple from the mathematical viewpoint; they offer concise illustrations which should not be deemed as a fault.

B - In terms of methodology, the present research suggests an innovative pathway since it examines the nature of probability by means of the mathematical method and rejects any philosophical approach.

C - Rules **a** and **b** provide a precise guideline to statisticians who are called for selecting the most appropriate methods in a project. Currently writers examine the pros and cons of classical and Bayesian methods using empirical and sometimes personal criteria, instead rules **a** and **b** descend from theorems and not from individuals' ideas.

D - The theorems presented in this paper provide new answers to knotty controversies, specifically:

D.1 TLN and TSN tackle the *problem of testability* that is a typical of science and give precise substance to the probability meanings issue.

D.2 TLN and TSN demonstrate that there are two different models of probability: $P(e_\infty)$ and $P(e_1)$, and not only one.

D.3 TSN enables us to grasp how $P(e_1)$ is reused as subjective probability and makes explicit the intellectual origin of subjectivism.

D.4 TC proves that $P(e_\infty)$ and $P(e_1)$ are not irreconcilable.

Robust Composite Inference

Inferenza composita robusta

Mameli Valentina, Musio Monica, Ruli Erlis, Ventura Laura

Abstract Likelihood analyses can be difficult to perform both when the full likelihood is too complex or even impossible to specify and when robustness with respect to data or to model misspecifications is required. To deal both with complex models and robustness, in this paper we propose to resort to a composite robust scoring rule. In particular, we focus on the Tsallis score, which allows us to deal with model misspecifications. Theory and an application are discussed.

Abstract *Le procedure di verosimiglianza possono essere complicate sia quando la verosimiglianza è troppo complessa, o impossibile da specificare, sia quando è richiesta robustezza. Per trattare contemporaneamente sia modelli complessi sia robustezza, si propone di utilizzare una regola di punteggio composita robusta. In particolare, si considera la regola di punteggio di Tsallis, che consente di trattare modelli non correttamente specificati. Teoria e una applicazione sono discusse.*

Key words: *B*-robustness; Complex models; Composite score; Tsallis score.

1 Introduction

Suppose we wish to fit a parametric model $\{F_\theta : \theta \in \Theta \subseteq \mathbb{R}^p\}$, based on a random sample $(y_1, \cdots, y_n)$ of size n. The most popular tool for inference on θ is the log-likelihood function $\ell(\theta) = \sum_{i=1}^{n} \log f(y_i;\theta)$, where $f(\cdot;\theta)$ is the density associated to F_θ. For instance, the maximum likelihood estimator (MLE) is defined as $\hat{\theta} = \arg\max_\theta \ell(\theta)$, and confidence regions with nominal coverage $1-\alpha$ can be con-

structed as $\{\theta : W(\theta) \leq \chi^2_{p;1-\alpha}\}$, where $W(\theta) = 2\{\ell(\hat{\theta}) - \ell(\theta)\}$ is the likelihood ratio statistic and $\chi^2_{p;1-\alpha}$ is the $(1-\alpha)$-quantile of the χ^2_p distribution.

However, likelihood inference can be difficult to perform when the full likelihood is too complex or even impossible to specify and, moreover, can behave quite poorly under slight model misspecifications. A possible solution is to resort to suitable pseudo-likelihood functions as a replacement of the full likelihood. Useful examples are given by *composite likelihoods* (see, e.g., [10]), when the full likelihood is computationally cumbersome or when a fully specified model is out of reach, or by *scoring rules* (see, e.g., [2], [3], [4], and references therein), to deal with complex models or model misspecifications.

The aim of this paper is to propose a general approach for dealing with complex models and robustness simultaneously. The proposal is to replace the log-likelihood function with the *scoring rule*

$$S(\theta) = \sum_{i=1}^{n} S(y_i; \theta), \tag{1}$$

where $S(y;\theta)$ is a proper scoring rule (see [4]). The scoring rule (1) yields an unbiased estimating equation for any statistical model and thus it forms a special case of M-estimation [6]. More precisely, we propose to mix the Tsallis scoring rule ([1],[9]), which presents robustness properties, with the composite likelihood, which is still a special case of scoring rule. An example is discussed.

2 Background on proper scoring rules

To deal with complex models or model misspecifications, useful surrogate likelihoods are given by proper scoring rules (see [3] and [4], and references therein). A scoring rule is a loss function which is used to measure the quality of a given probability distribution F_θ for a random variable Y, in view of the result y of Y.

An important example of proper scoring rules is the log-score, which is defined as $S^L(y;\theta) = -\log f(y;\theta)$ [5] and which corresponds to minus the log-likelihood function. In this paper we focus on the Tsallis score ([1], [9]), given by

$$S^T(y;\theta) = (\gamma - 1)\int f(x;\theta)^\gamma d\mu(x) - \gamma f(y;\theta)^{\gamma-1}, \quad \gamma > 1. \tag{2}$$

The Tsallis score gives in general robust procedures [4], and the parameter γ is a trade-off between efficiency and robustness.

Proper scoring rules can also be extended to the case of a random vector in analogy with composite likelihoods [10]. Let $\{Y_k\}$ be a set of marginal or conditional variables with associated proper scoring rule S_k. A proper scoring rule for the random vector Y may be defined as

$$S(\mathbf{y}; F) = \sum_k S_k(\mathbf{y}_k; F_k), \tag{3}$$

where $Y_k \sim F_k$ when $Y \sim F$, and $\mathbf{y}$ and $\mathbf{y}_k$ are the values assumed by Y and Y_k, respectively. Scoring rules (3) are called *composite scoring rules* [3]. Note that when each S_k is the log-score, equation (3) is a negative composite log-likelihood.

The validity of inference about θ using scoring rules can be justified by invoking the general theory of unbiased M-estimating functions, as discussed in [4]. The class of M-estimators is broad and includes a variety of well-known estimators. For example it includes the MLE, the maximum composite likelihood estimator [10], and robust estimators [6] among others.

3 Robust composite scoring rules

Consider independent observations y_i of a random vector $Y_i = (Y_{i1}, \ldots, Y_{iq})$, $i = 1, \ldots, n$, where Y_i has density $f(y_i; \theta)$, $\theta \in \Theta \subseteq \mathbb{R}^p$, $y_i \in \mathcal{Y}$. Hereafter, regularity conditions as detailed e.g. in [7] will be assumed. Since the Tsallis score (2) gives in general robust procedures, in this section we focus on this particular scoring rule. The robust composite scoring rule can be defined through K marginal or conditional events $A_k(y_i)$ on $\mathcal{Y}$, giving scoring rule contributions $S_k^T(y_i; \theta) = S^T(A_k(y_i); \theta)$. Then, the robust composite scoring rule is defined as

$$S_c^T(\theta) = \sum_{i=1}^{n} \sum_{k=1}^{K} w_k S_k^T(y_i; \theta), \tag{4}$$

where w_k, $k = 1, \ldots, K$, are positive weights. If the events are defined in terms of pairs of observations (y_{ir}, y_{is}), from the bivariate marginal density $f_{rs}(y_{ir}, y_{is}; \theta)$, $r, s = 1, \ldots, q$, $r \neq s$, the robust composite scoring rule may be called the robust pairwise scoring rule and is denoted by

$$S_p^T(\theta) = \sum_{i=1}^{n} \sum_{r,s=1, r \neq s}^{q} w_{rs} S^T(y_{ir}, y_{is}; \theta). \tag{5}$$

The validity of inference based on $S_c^T(\theta)$ and $S_p^T(\theta)$ can be justified by using the general theory of scoring rules [4]. Given a robust composite scoring rule $S_*^T(y; \theta)$, where $*$ can be c or p, let us denote by $S_*^T(\theta) = \sum_{i=1}^{n} S_*^T(y_i; \theta)$ the total empirical score (4) or (5). Moreover, let $s_*^T(y; \theta)$ be the gradient vector of $S_*^T(y; \theta)$ with respect to θ, i.e. $s_*^T(y; \theta) = \partial S_*^T(y; \theta) / \partial \theta$. Under broad regularity conditions, the robust composite scoring rule estimator $\tilde{\theta}$ is the solution of the unbiased estimating equation $s_*^T(\theta) = \sum_{i=1}^{n} s_*^T(y_i; \theta) = 0$ and it is asymptotically normal, with mean θ and covariance matrix $V(\theta) = K(\theta)^{-1} J(\theta) K(\theta)^{-\mathsf{T}}$, with $K(\theta) = E_\theta(\partial s_*^T(\theta) / \partial \theta^{\mathsf{T}})$ and $J(\theta) = E_\theta(s_*^T(\theta) s_*^T(\theta)^{\mathsf{T}})$ sensitivity and variability matrices, respectively. The matrix $G(\theta) = V(\theta)^{-1}$ is the Godambe information and its form is due to the failure of the information identity, i.e. $K(\theta) \neq J(\theta)$.

From the general theory of M-estimators, the influence function (IF) of $\tilde{\theta}$ is $IF(y; \tilde{\theta}) = K(\theta)^{-1} s_*^T(y; \theta)$. The estimator $\tilde{\theta}$ is B-robust if and only if $s_*^T(y; \theta)$ is bounded in y [6]. Note that, in general, the MLE has unbounded IF, i.e. it is not

B-robust. Sufficient conditions for the robustness of the Tsallis score are discussed in [1] and [4].

Asymptotic inference on the parameter θ can be based on the Wald-type statistic

$$w_S(\theta) = (\tilde{\theta} - \theta)^{\top} V(\tilde{\theta})^{-1} (\tilde{\theta} - \theta), \tag{6}$$

which has an asymptotic chi-square distribution with d degrees of freedom. In contrast, the asymptotic distribution of the scoring rule ratio statistic $W_S(\theta) = 2\left\{S_*^T(\theta) - S_*^T(\tilde{\theta})\right\}$ is a linear combination of independent chi-square random variables, i.e. $W_S(\theta) \dot{\sim} \sum_{j=1}^{d} \mu_j Z_j^2$, with $\mu_1, \ldots, \mu_d$ eigenvalues of $J(\theta)K(\theta)^{-1}$ and $Z_1, \ldots, Z_d$ independent $N(0,1)$ variables. Adjustments of the scoring rule ratio statistic have received consideration in [4], extending results for composite likelihoods [8]. In particular, using the rescaling factor $A(\theta) = \frac{s_*^T(\theta)^{\top} J(\theta)^{-1} s_*^T(\theta)}{s_*^T(\theta)^{\top} K(\theta)^{-1} s_*^T(\theta)}$, we have [4]

$$W_S^{adj}(\theta) = A(\theta) W_S(\theta) \dot{\sim} \chi_d^2. \tag{7}$$

Analogous limiting results can be shown to hold for inference on the scalar parameter ψ. With the partition $\theta = (\psi, \lambda)$, the scoring rule estimating function is similarly partitioned as $s_*^T(y;\theta) = (s_{*\psi}^T(y;\theta), s_{*\lambda}^T(y;\theta))$, where $s_{*\psi}^T(y;\theta) = (\partial/\partial\psi) S_*^T(y;\theta)$ and $s_{*\lambda}^T(y;\theta) = (\partial/\partial\lambda) S_*^T(y;\theta)$. Moreover, consider the corresponding partitions for K and K^{-1}, and similarly for G and G^{-1}. Finally, let $\tilde{\theta}_\psi$ be the constrained scoring rule estimate of θ for fixed ψ, and let $\tilde{\psi}$ be the ψ component of $\tilde{\theta}_\psi$. A profile scoring rule Wald-type statistic for the ψ component may be defined as $w_{Sp}(\psi) = (\tilde{\psi} - \psi)(G^{\psi\psi})^{-1/2}$, and it has an asymptotic $N(0,1)$ null distribution. Moreover, we have that the asymptotic distribution of the profile scoring rule ratio statistic $W_{Sp}(\psi) = 2\left(S_*^T(\tilde{\theta}_\psi) - S_*^T(\tilde{\theta})\right)$ is $\nu\chi_1^2$, where $\nu = (K^{\psi\psi})^{-1} G^{\psi\psi}$. In view of this, an adjusted profile scoring rule ratio statistic can be computed as [4]

$$W_{Sp}^{adj}(\psi) = \frac{W_{Sp}(\psi)}{\nu} \dot{\sim} \chi_1^2. \tag{8}$$

The adjusted profile scoring rule root can is $r_{Sp}(\psi) = \text{sign}(\tilde{\psi} - \psi) W_{Sp}^{adj}(\psi)^{1/2}$, which has an asymptotic standard normal distribution.

4 An example

We discuss inference on the correlation coefficient of an equi-correlated multivariate normal distribution. This classical example is considered, among others, by [8] and [4]; see also references teherein.

Let $Y = (y_1, \ldots, y_q)$ be a $q-$dimensional random vector with mean μ and covariance matrix Σ, with $\Sigma_{rr} = \sigma^2$ and $\Sigma_{rs} = \rho\sigma^2$ for $r \neq s$, with $r, s = 1, \ldots, q$ and $\rho \in (-1/(q-1), 1)$. The log-likelihood for $\theta = (\mu, \sigma^2, \rho)$ is given by

$$\ell(\theta) = -\frac{nq}{2}\log\sigma^2 - \frac{n(q-1)}{2}\log(1-\rho) - \frac{n}{2}\log 1+\rho(q-1) - \frac{SSW}{2\sigma^2(1-\rho)} - \frac{qSSB+nq(\bar{y}-\mu)^2}{2\sigma^2(1+\rho(q-1))}, \tag{9}$$

where $SSW = \sum_{i=1}^{n}\sum_{r=1}^{q}(y_{ir}-\bar{y}_i)^2$, $SSB = \sum_{i=1}^{n}(\bar{y}_i-\bar{y})^2$, $\bar{y}_i = \sum_{r=1}^{q} y_{ir}/q$ and $\bar{y} = \sum_{i=1}^{n}\sum_{r=1}^{q} y_{ir}/(nq)$. The Tsallis score is

$$S^T(y;\theta) = \frac{(\gamma-1)}{(2\pi)^{\gamma q/2}(\det\Sigma)^{\gamma/2}}\int_{\mathbb{R}^q} e^{-\frac{\gamma}{2}(y-\mu)\Sigma^{-1}(y-\mu)^{\mathsf{T}}}dy + \tag{10}$$

$$- \frac{\gamma}{(2\pi)^{(\gamma-1)q/2}(\det\Sigma)^{(\gamma-1)/2}} e^{-\frac{\gamma-1}{2}(y-\mu)\Sigma^{-1}(y-\mu)^{\mathsf{T}}}. \tag{11}$$

The first order consecutive pairwise Tsallis is obtained by compounding together the bivariate density for pairs of observations (y_{ir}, y_{is}), for $i = 1,\ldots,n$,

$$f(y_{ir},y_{is};\theta) = \frac{e^{-\frac{1}{2\sigma^2(1-\rho^2)}\{(y_{ir}-\mu)^2+(y_{is}-\mu)^2-2\rho(y_{ir}-\mu)(y_{is}-\mu)\}}}{2\pi(\sigma^4(1-\rho^2))^{1/2}}. \tag{12}$$

The pairwise Tsallis scoring rule (with all weights equal to 1) is then equal to $S_p^T(\theta) = \sum_{i=1}^{n}\sum_{r,s=1,r\neq s}^{q} S_p^T(y_{ir},y_{is};\theta)$, where

$$S_p^T(y_{ir},y_{is};\theta) = \frac{\left((\gamma-1)(\gamma)^{-1} - \gamma e^{-\frac{(\gamma-1)}{2\sigma^2(1-\rho^2)}\{(y_{ir}-\mu)^2+(y_{is}-\mu)^2-2\rho(y_{ir}-\mu)(y_{is}-\mu)\}}\right)}{(2\pi)^{(\gamma-1)}(\sigma^4(1-\rho^2))^{(\gamma-1)/2}}.$$

For comparison we also consider the pairwise log-likelihood for $\theta = (\mu,\sigma,\rho)$, given by (see [8])

$$S_p(\theta) = -\frac{nq(q-1)}{2}\log\sigma^2 - \frac{nq(q-1)}{4}\log(1-\rho^2) - \frac{q-1+\rho}{2\sigma^2(1-\rho^2)}SSW + - \frac{q(q-1)SSB+nq(q-1)(\bar{y}-\mu)^2}{2\sigma^2(1+\rho)}.$$

We ran a simulation experiment, with $n = 10$ and $q = 3$, in order to assess the accuracy of the pairwise estimators, when data are generated both from the equicorrelated normal model with parameter $\theta = (0, 0.5, 0.95)$, and also from the equicorrelated normal model with parameter $\theta = (0, 0.5, 0.95)$ contaminated by a uniform distribution on the interval $[1, 10]$. We compare the MLE ($\hat{\theta}$), the pairwise MLE ($\hat{\theta}_p$), the Tsallis estimate based both on the full scoring rule ($\hat{\theta}_T$) and on the pairwise scoring rule ($\hat{\theta}_{pT}$). Table 1 gives the results of the simulation study based on 10000 Monte Carlo trials. Note that, under the central model, the four estimators behave quite similarly. Under the contaminated model, the two estimators based on the Tsallis scoring rule show a reasonable behaviour, while both the estimators

based on the likelihood exhibit poor performances. The pairwise Tsallis estimator shows better performances with respect to the one based on the full scoring rule.

5 Final remarks

In this contribution we illustrate how to derive a composite robust scoring rule, in order to deal both with complex models and with model misspecifications. The behaviour of the proposed composite robust scoring rule is currently under study in other examples.

Statistical hypothesis testing within the Generalized Error Distribution: Comparing the behavior of some nonparametric techniques

Verifica d'ipotesi nell'ambito della Distribuzione degli Errori Generalizzata: Confronto dell'efficacia di alcuni test non parametrici

Massimiliano Giacalone and Demetrio Panarello[1]

Abstract This paper's goal is to deal with the issue of hypothesis testing when the errors are assumed to be distributed according to a Generalized Error Distribution. Focus is given to the central tendency parameters, validating the suitability of nonparametric methods in this respect. The present work describes a simulation study aimed at assessing the validity of the Van der Waerden and Wilcoxon tests in the case of data coming from a G.E.D.; in order to compare the statistical power of such tests, we proceed to calculate the usual empirical significance level. The use of test statistics obtained by means of a Van der Waerden test generalized by considering the G.E.D.'s shape parameter provides better results, in terms of statistical power, compared to the Wilcoxon and the classic Van der Waerden tests.

Abstract *Questo lavoro si propone di trattare il problema della verifica di ipotesi nel caso in cui si supponga che gli errori si distribuiscano secondo una Generalized Error Distribution. Si focalizza l'attenzione sui parametri di tendenza centrale, verificando l'opportunità dell'uso di metodi non parametrici. Viene descritto uno studio di simulazione per stabilire la validità dei test di Van der Waerden e Wilcoxon nel caso di dati provenienti da una G.E.D.; per il confronto della potenza di tali test, si procede al calcolo classico del livello di significatività empirico. L'uso di statistiche test ottenute da un test di Van der Waerden generalizzato tenendo conto del parametro di forma della G.E.D. fornisce risultati migliori, in termini di potenza statistica, rispetto al test di Wilcoxon e al Van der Waerden classico.*

1 Introduction

There is a great need for determining how well a model fits the sample data, in various research contexts.

Historically, the first problem of model fitting dates back to the attempt by Galileo Galilei, in the 1600s, of predicting the orbit of a celestial body, with the aim of building a mathematical model and estimate its parameters [1]. In 1806, Carl Friedrich Gauss developed the first method for studying accidental errors, based on the principle of arithmetic mean, known as the Least Squares Method. The axiomatic setting that the Gauss method is based on was slightly modified by the Soviet astronomer Mikhail Subbotin [5], who obtained a more general error distribution law, which best lends itself to describing the majority of phenomena that are observable in reality.

It is very common in Statistics to assume normality of the data, even though this hypothesis is not always fully supportable. Indeed, the normality assumption is definitely restrictive, as it limits the scope of operational situations in which statistical hypothesis testing tools can be used. Nonparametric techniques, on the other hand, are "distribution-free" and can be applied independent of the statistical nature of the data. Indeed, as the actual distribution of any sample is, at best, only partly known, nonparametric tests, despite being less statistically powerful (i.e., they are more likely to lead to Type II errors, thus making the null hypothesis more likely to be accepted), are in fact more appropriate than the parametric ones as they do not require knowledge about the distribution's density function. Nonparametric techniques date back to the introduction of the X^2 test by Karl Pearson, in 1900.

The aim of this paper is to deal with the issue of nonparametric hypothesis testing when assuming that the errors are distributed according to the Subbotin distribution, also known as Generalized Error Distribution (G.E.D.), which constitutes a valid generalization of the Gaussianity assumption [2]. Its density function is:

$$f_p(z) = \frac{1}{2p^{\frac{1}{p}}\sigma^p\Gamma(1+\frac{1}{p})}\exp\left(-\frac{1}{p}\left|\frac{z-M_p}{\sigma_p}\right|^p\right),$$

where $M_p = E(z)$ is the location parameter, $\sigma_p = E\left(|z-M_p|\right)^{\frac{1}{p}}$ is the scale parameter, and p>0 is the shape parameter.

Literature has proposed several nonparametric procedures for testing hypotheses about the centrality parameter. In the following Section, we will introduce three nonparametric tests (Wilcoxon, Van der Waerden, and generalized Van der Waerden test), with the aim of comparing the behavior of such procedures when the sample observations are extracted from a random variable that is distributed according to a law belonging to the Generalized Error Distribution density family.

2 Nonparametric mean hypothesis testing

Let $X_1, X_2, \dots, X_m$ and $Y_1, Y_2, \dots, Y_n$ denote two independent samples extracted from continuous populations. Under the null hypothesis H_0 that the distribution functions coincide, while remaining unspecified, we can count on a single set of random observations, of cardinality $N = n + m$, extracted from the common – though unknown – population. The alternative hypothesis is that the populations are of the same shape but with different measures of central tendency.

Nonparametric tests of this kind are based on ranks, since the ranks of the X's, compared to those of the Y's, contain a piece of information regarding the relative measure of the population's median. The ranks of the X sample observations, in the ordered combination of the two considered samples, would generally be larger than the Y ranks if the population's median of X exceeds the population's median of Y.

Wilcoxon [8] proposed a test in which the unilateral alternative hypothesis $H_1{:}\Theta < 0$ on the centrality parameter is accepted if the rank sum of the X's exceeds the acceptance region, determined based on sample size and significance level; $H_1{:}\Theta > 0$ is accepted if this rank sum is below the acceptance region; and the bilateral hypothesis $H_1{:}\Theta \neq 0$ is accepted when the rank sum is between its smallest and highest values. Therefore, the test can be expressed as:

$$W_N = \sum_{i=1}^{N} iZ_i ,$$

where the Zi's are random variables indicating whether the distributions belong to one sample or the other.

Mean and variance of W_N, under the null hypothesis that refers to the event in which the two distributions are equal, can be calculated as follows:

$$E(W_N) = \frac{m(N+1)}{2} \qquad var(W_N) = \frac{mn(N+1)}{12} .$$

The Van der Waerden [7] test combines the concept of normal scores and the rank sum criterion used in the Wilcoxon test [3]. The classic version of this test allows us to make a generalization of it, suitable when the samples are generated by a Generalized Error Distribution. The X_N test by Van der Waerden is:

$$X_N = \sum_{i=1}^{N} \Phi^{-1}\left(\frac{i}{N+1}\right) Z_i ,$$

where Φ denotes the cumulative distribution function of the standard normal.

The X_N statistics is symmetric with respect to zero and its variance is:

$$var(X_N) = mn \sum_{i=1}^{N} \frac{\left[\Phi^{-1}\left(\frac{i}{N+1}\right)\right]^2}{N(N-1)} .$$

For large samples of N>50, the distribution under the null hypothesis of the standardized X_N can be approximated by the standard normal. Starting from this consideration, it is possible to put, within the computation of the test statistic,

weights reflecting the Generalized Error Distribution percentiles. Such percentiles are known and tabulated, so that this combination feels somehow natural.

That said, it can be interesting to investigate the performance of the test statistic

$$X_{NP} = \sum_{i=1}^{N} \Psi^{-1}\left(\frac{i}{N+1}\right) Z_i$$

,

where Ψ denotes the Generalized Error Distribution's cumulative distribution function, in the event in which the sample observations belong to a G.E.D. population with known shape parameter.

It is possible to notice that the last equation is very similar to the one of the classic Van der Waerden test, except for the rank weighting system, which employs the G.E.D. percentiles rather than the Gaussian ones.

3 Statistical power estimation

As proposed by [6], we estimate the tests' statistical power by means of simulations made on very small samples (N=12, n=m=6) and a dense d_j shifts' set. The simulations are repeated for three different nominal significance levels. We assume p and σ to be known; for the sake of simplicity, we will assume σ to be always equal to 1. All the calculations have been implemented and processed in the statistical environment R, with the aid of the normalp package [4]. From the results (Table 1), it is possible to notice that, especially as the significance level increases, the statistical power of the generalized Van der Waerden test is always equal or higher than the one of the classic Van der Waerden test.

4 Conclusions

The Generalized Error Distribution introduces an extension of the classical theory which is of particular importance in order to analyze the behavior of particular estimators on small samples, and in order to avoid the inaccuracy of reducing any empirical distribution to the normal distribution, regardless of the determination of the p parameter. Until now, the theory relating to the Generalized Error Distribution does not provide adequate and dedicated hypothesis testing tools. With this paper, we aim at paving the way for tackling this central aspect.

It can definitely be concluded that the use of test statistics formulated by considering the value of the data's p parameter represents an improvement in the quality of any statistical study. The results obtained by generalizing the van der Waerden test encourage the deepening of this matter and allow us to glimpse the opportunity of studying test statistics which are suitable for the investigation of other statistical hypotheses.

Stochastic dependence with discrete copulas

Dipendenza stocastica con copule discrete

Fabrizio Durante and Elisa Perrone

Abstract We here discuss the role of discrete copulas in dependence modeling. We analyze the relationships between copulas and discrete copulas, thereby drawing connections to the popular doubly stochastic matrices and their geometric interpretation. We inquire into the properties of discrete copulas under the assumption of negative dependence constraints. Finally, we discuss how these properties can be exploited to obtain an inferential procedure to detect special dependence properties.
Abstract *Si presenta l'uso di copule discrete nei modelli di dipendenza. Inoltre, si analizza la relazione tra copule e copule discrete, evidenziando legami con matrici doppiamente stocastiche e la loro interpretazione geometrica. Inoltre si studiano le proprietà delle copule discrete aventi un vincolo di dipendenza negativa. Infine, si discute su come tali proprietà possano essere impiegate per ottenere una procedura inferenziale che individui alcuni aspetti di dipendenza stocastica.*

1 Introduction

Copulas are powerful mathematical tools for constructing marginal-free distributions for multivariate phenomena [2, 4, 10]. The cornerstone of the copula theory is *Sklar's Theorem*, which states that the joint distribution function $F_{\mathbf{X}}$ of a d-dimensional random vector $\mathbf{X} = (X_1, \ldots, X_d)$ in $\mathbb{R}^d$ with univariate margins

$F_{X_1},\ldots,F_{X_d}$, can be written as

$$F_{\mathbf{X}}(x_1,\ldots,x_d) = C(F_{X_1}(x_1),\ldots,F_{X_d}(x_d)), \tag{1}$$

where the function $C : [0,1]^d \to [0,1]$ is a *d-dimensional copula* [18], which is uniquely identified on the set $\mathrm{Range}(F_{X_1}) \times \cdots \times \mathrm{Range}(F_{X_d}) \subseteq [0,1]^d$. As a result of Sklar's Theorem, when accurate marginal estimates can be obtained, copulas can be used to join them and obtain flexible multivariate statistical models for the data at hand.

In the case of discrete random variables, various copulas can be associated to the same random vector, and Sklar's theorem only identifies the associated *discrete copula*, i.e., the restriction of these copulas on uniform grid domains [5, 8, 9]. Any discrete copula can be extended to a full-domain copula by redistributing the discrete probability mass on each rectangle of the grid [1]; but, obviously, this extension is generally not unique. This well-known identifiability issue suggests caution while bringing copulas into a discrete framework [3]. In spite of this, discrete copulas are useful tools in dependence modeling, and they deserve the attention of the research community.

First, discrete copulas are strictly related to the so-called *empirical copulas*, which are the foundation of rank-based multivariate statistics analysis [14]. This makes them key tools in several applications, such as weather forecasting, where recovering the rank structure of a given multivariate sample is crucial [7, 15, 16]. Besides, the space of discrete copulas admits a representation as a convex polytope, i.e., a bounded convex body which consists of all the points satisfying a list of affine inequalities. As a result, the selection of discrete copulas is amenable to techniques from convex geometry and linear optimization.

Recent progress takes advantage of this polytopal representation to find simple copula models which maximize the entropy and match a prescribed Spearmans ρ [12]. For example, such models have been used in hydrology to generate synthetic data of rainfall totals when missing values occur in the observational data [13]. In [11], the authors introduce the polytopal representations of sub-families of discrete copulas with desirable stochastic properties. These representations are used to adjust the entropy-copula optimization problem to include negative dependence constraints.

In this work, we present recent advances in the study of polytopes of discrete copulas with desirable negative dependence properties, and we discuss their use to detect negative dependence of a multivariate dataset.

2 Discrete copulas and negative dependence constraints

We now assume $p \in \mathbb{N}$, and $I_p := \left\{0, \frac{1}{p}, \ldots, \frac{p-1}{p}, 1\right\}$. A $(p \times p)-$*discrete copula* is a function $C_p : I_p^2 \to [0,1]$ that satisfies the following conditions:

(c1) for all $i \in \{0,\dots,p\}$

$$C_p\left(\tfrac{i}{p},0\right) = C_p\left(0,\tfrac{i}{p}\right) = 0; \;\; C_p\left(\tfrac{i}{p},1\right) = C_p\left(1,\tfrac{i}{p}\right) = \tfrac{i}{p};$$

(c2) for all $i,j \in \{0,\dots,p-1\}$

$$C_p\left(\tfrac{i}{p},\tfrac{j}{p}\right) + C_p\left(\tfrac{i+1}{p},\tfrac{j+1}{p}\right) \geq C_p\left(\tfrac{i+1}{p},\tfrac{j}{p}\right) + C_p\left(\tfrac{i}{p},\tfrac{j+1}{p}\right).$$

As shown in [5], there is a one-to-one correspondence between the discrete copulas and the doubly stochastic matrices, which are matrices with non-negative entries and row and column sums equal to one. Hence, the space of discrete copulas corresponds to the well-known Birkhoff polytope [19]. This correspondence is obtained via a linear transformation: for all $i,j \in \{1,\dots,p\}$, the doubly stochastic matrix $B_p = (b_{i,j})$ associated with a discrete copula C_p is defined as follows:

$$b_{i,j} := p\left(C_p\left(\tfrac{i-1}{p},\tfrac{j-1}{p}\right) + C_p\left(\tfrac{i}{p},\tfrac{j}{p}\right) - C_p\left(\tfrac{i-1}{p},\tfrac{j}{p}\right) - C_p\left(\tfrac{i}{p},\tfrac{j-1}{p}\right)\right). \qquad (2)$$

The entries of the doubly stochastic matrix associated with the discrete copula C_p correspond to the probability mass induced by C_p in each sub-square of the grid. The following example illustrates this property.

Example 1. We now consider the independence copula $C(u,v) = u \cdot v$ for any u,v in the unit interval, which describes the behavior of independent random variables. Assuming $p = 4$, the corresponding discrete copula C_4 is a (5×5)-matrix, whose entries are the values of C in each point of the grid $I_4 \times I_4$. In particular, C_4 and its associated doubly stochastic matrix B_4 are as follows:

$$C_4 = \begin{pmatrix} 0 & 0 & 0 & 0 & 0 \\ 0 & \frac{1}{16} & \frac{1}{8} & \frac{3}{16} & \frac{1}{4} \\ 0 & \frac{1}{8} & \frac{1}{4} & \frac{3}{8} & \frac{1}{2} \\ 0 & \frac{3}{16} & \frac{3}{8} & \frac{9}{16} & \frac{3}{4} \\ 0 & \frac{1}{4} & \frac{1}{2} & \frac{3}{4} & 1 \end{pmatrix}, \quad B_4 = \begin{pmatrix} \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} \\ \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} \\ \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} \\ \frac{1}{4} & \frac{1}{4} & \frac{1}{4} & \frac{1}{4} \end{pmatrix} \qquad (3)$$

We note that the independence copula spreads the probability mass uniformly on the unit square. Thus, the entries of the doubly stochastic matrix B_4 are all equal. □

As mentioned in the introduction, there are infinite ways to obtain a full domain copula from a discrete one. A popular approach is through *checkerboard extension techniques*, that is by spreading the probability mass of C_p uniformly in each sub-square of $I_p \times I_p$. The full domain copula obtained in this way is called *checkerboard copula*. The density function of such a copula is a step-wise function whose values are given by the entries of the doubly stochastic matrix associated to C_p. This connection allows for selecting suitable checkerboard copulas by solving simply a convex optimization problem on the Birkhoff polytope [12]. Though, a natural question is how to incorporate desirable dependence properties in the optimization problem by means of suitable constraints.

This question is addressed in [11] through the introduction and study of novel polytopes relevant to copula modeling and discrete geometry. In particular, the authors analyze discrete versions of the *ultramodular copulas*, which represent a form of negative dependence property for bivariate random vectors known as *stochastic decreasingness*.

This negative dependence property is often observed in applications. Indeed, several parametric copulas widely used in finance, hydrology, and environmental sciences, belong to the class of ultramodular copulas. Examples are the Gaussian, Clayton, Ali-Mikhail-Haq, Frank, and Farlie-Gumbel-Morgenstern copula families.

In [11], the authors provide (1) a geometric description of the convex space of discrete ultramodular copulas, and (2) an extension result that shows that ultramodularity is preserved through checkerboard extensions. The combination of (1) and (2) allows for formulating a new class of convex optimization problems for the selection of ultramodular checkerboard copulas in hydrology. In the next session, we discuss how (1) and (2) can be used to develop novel statistical tools for detecting negative dependence of multivariate data.

3 Detecting dependences through discrete copulas

We now consider a bivariate random sample $(X_k, Y_k)_{k=1,\dots,n}$ from the continuous random pair (X,Y). We assume that the underlying distribution of (X,Y) is stochastically decreasing, i.e. $x \mapsto \mathbb{P}(Y > y \,|\, X = x)$ and $y \mapsto \mathbb{P}(X > x \,|\, Y = y)$ are decreasing functions. This condition can be expressed in terms of the copula C_{XY} and is equivalent to the fact that C_{XY} is ultramodular, i.e., it has convex sections in each variable.

In principle, we expect that the stochastic decreasingness of the random vector (X,Y) should be encoded in the discrete copula associated with the sample. In particular, from a geometric perspective, we would expect (X,Y) to be mutually stochastically decreasing if and only if the discrete copula corresponding to the sample is "close enough" to the polytope of ultramodular discrete copulas defined in [11]. Given a sample of size n, we can proceed as follows:

1. Compute the empirical copula EC from the sample;
2. Evaluate the empirical copula on a square grid of fixed partition size $p \times p$ (this results in a discrete copula EC_p) with $p = p(n) < n$;
3. Find the doubly stochastic matrix B_p associated with EC_p by using the linear transformation of Equation (2);
4. Evaluate the distance between B_p and the space of all densities of ultramodular checkerboard copulas of step p (UDC_p), by also matching the value of the empirical Spearman's ρ of the sample:

$$\begin{array}{ll} \text{minimize} & \mathrm{dist}(B_p - U_p) \\ \text{subject to} & U_p \in \mathrm{UDC}_p;\ \rho_{U_p} = \tilde{\rho} \end{array} \tag{4}$$

Intuitively, the smaller the distance, the higher the chance that the random vector (X,Y) is stochastically decreasing. As a consequence, the distance computed in Equation (4) can be used as a test statistic for a significance test whose null hypothesis is *"The given random sample is associated with a ultramodular copula"*. Various tests have been developed in the literature to check stochastic monotonicity [6, 17]. However, to the best of our knowledge, a significance test built on this idea has never been considered. We now present a simulation study to evaluate the performance of the proposed testing procedure.

We consider a distance based on the Frobenius norm, which is the discrete analogous of the L^2-distance often used in Cramér-von Mises-type tests for copulas. The data are simulated from a Gaussian copula, which is ultramodular for negative values of the parameter ρ. We assume a finer partition grid p as the strength of the correlation increases. This adjustment is required since the associated doubly stochastic matrices B_p become sparser. We use a bootstrap approach to compute the p-value of the test by assuming a bootstrap sample of size 1000 and a resampling scheme from a copula in the ultramodular class.

Table 1 shows the percentage of the rejection of the null hypothesis for different significant levels α. The rejection rate is computed over $N = 1000$ independent samples of size $n = 500$, drawn from a Gaussian copula with parameter ρ.

The results are promising and suggest that the presented approach can be used to detect stochastic decreasing properties of a random sample. We are currently working on a follow-up paper where we study the performance of the test under other copula assumptions and settings for the convex optimization problem, alongside further analysis of the power of the test.

p	ρ	$\alpha = 0.1$	$\alpha = 0.05$	$\alpha = 0.01$
15	-0.38	10.9 %	6.8 %	0.8 %
25	-0.70	11.5 %	6.0 %	1.6 %

Table 1 The table presents the percentage of the rejection of the null hypothesis over 1000 $N = 1000$ independent samples of size $n = 500$. The samples are drawn from a Gaussian copula with parameter ρ. The test is performed assuming two values of the partition grid p.

Models and methods - Time Series and Longitudinal Data

Bootstrap test in Poisson–INAR models

Bootstrap test in modelli INAR con innovazioni Poisson

Lucio Palazzo and Riccardo Ievoli

Abstract In this paper we exploit bootstrap–based specification test on the autoregressive coefficient in INteger–AutoRegressive models (INAR) considering the case of homoskedastic Poisson innovations. Performance of four unrestricted bootstrap methods are analyzed through a small–scale Monte carlo exesercise.
Abstract *In questo lavoro si sono indagate le potenzialità di tecniche bootstrap per la verifica di ipotesi sul coefficiente autoregressivo dei modelli INAR, nel caso innovazioni omoschedastiche distribuite come delle v.c. Poisson. Le performance di quattro metodi sono state valutate attraverso uno studio di simulazione.*

Key words: Integer-valued time series, bootstrap methods, specification test

1 Introduction

INteger AutoRegressive models (INAR), introduced in [1], became very popular to model non–negative integer time series. INAR with Poisson innovations (P–INAR) represents one of the most applied version of this model. Moreover, a drawback can be found in the poor performance of asymptotic approximation, requiring large samples to ensure negligible bias of conventional estimators, correct coverage rates and avoid over–rejections in hypothesis testing. Bootstrap methods in INAR have been recently introduced by [3] to obtain more reliable inference in point estimation and confidence bounds.

In this paper we study, through a simulation study, if and how the bootstrap can improve inference in testing the coefficient of P–INAR(1) model. To the best of our knowledge, this is the first work that analyses the potential of bootstrap in testing P–INAR coefficients especially in small samples which is a common issue in real data.

The paper is organized as follows: Section 2 presents the P–INAR(1) model and its associated specification test. Section 3 introduces the bootstrap schemes while results of a small–scale Monte Carlo simulation are shown in Section 4. Finally, Section 5 concludes with some remarks and possible advances.

2 Testing Coefficient in P–INAR(1)

Consider the following stable P–INAR(1) model, introduced in [1] and defined as

$$X_t = \alpha * X_{t-1} + \varepsilon_t \tag{1}$$

where X is a non–negative (integer valued) random variable, $\alpha \in [0,1)$ and $\{\varepsilon_t\}$ is i.i.d $Pois(\lambda)$ with $\lambda < \infty$. The symbol $*$, i.e. the *binomial thinning* operator is defined as a random sum of i.i.d. random variables $\{Y_i\}$, with $Y_i \sim \text{Ber}(\alpha)$, independent of X_t, such that $\text{E}(Y_i) = \alpha$ and $\text{Var}(Y_i) = \alpha(1-\alpha)$. Aside from the thinning parameter α, the parameter λ in P–INAR(1) λ is the Poisson mean. Conventional MM estimator for α in Equation 1, denoted also as Yule–Walker (YW), is defined as

$$\hat{\alpha}_T = \frac{\sum_{t=2}^{T}(X_t - \overline{X})(X_{t-1} - \overline{X})}{\sum_{t=1}^{T}(X_t - \overline{X})^2} \tag{2}$$

The test statistic, here denoted as τ_{obs}, for the null hypothesis $H_0 : \alpha = \alpha_0$ against the alternative $H_1 : \alpha > \alpha_0$, is

$$\tau_{obs} = \frac{\hat{\alpha}_T - \alpha_0}{\left[\hat{V}(\hat{\alpha}_T)\right]^{1/2}} \tag{3}$$

where $\hat{\alpha}_T$ is defined in expression (2) and $\hat{V}(\hat{\alpha}_T) = T^{-1}[1 - \hat{\alpha}_T^2 + \hat{\alpha}_T \hat{\lambda}_T^{-1}(1-\hat{\alpha}_T)^2]$, with $\hat{\lambda}_T = \hat{\lambda}_T^{MM} = T^{-1}\sum_{t=1}^{T}\hat{\varepsilon}_t$ is the MM (or YW) estimator for λ and $\hat{\varepsilon}_t = x_t - \hat{\alpha}_T\, x_{t-1}$. In stable P–INAR(1) normalized MM estimators are asymptotically normal. Without loss of generality we consider the case of $\alpha_0 = 0$.

3 Bootstrap Algorithm for testing INAR

Here we present four Bootstrap algorithms in order to test the null hypothesis $H_0 : \alpha = 0$ against the alternative $H_1 : \alpha > 0$. These methods, where we do not impose the null hypothesis (i.e. $\alpha = 0$) in the bootstrap DGP, are suitable to obtain the

distribution of a bootstrap test statistic τ^*, can be classified in two groups. The former is defined as "direct", because sampling (with replacement) from the observed data, while the latter, called "indirect", requires estimation of model parameters and residuals. Two procedures are summarized in the following schemes.

Algorithm 1 (Direct Procedure)**.**
Given a random sample $x_1,\dots,x_T$ of size T, then

Step 1. Sample data randomly with replacement, obtaining the pseudo–sample $x_1^*,\dots,x_T^*$;
Step 2. Compute the bootstrapped test statistic τ^*;
Step 3. Repeat steps 1–2, with $b = 1,\dots,B$ to obtain $\tau_1^*,\dots,\tau_B^*$.

Algorithm 2 (Indirect Procedure)**.**
Given a random sample $x_1,\dots,x_T$ of size T and estimates of the parameter $(\hat{\alpha},\hat{\lambda})$:

Step 1. Sample from bootstrap pseudo–residuals, namely $\varepsilon_1^*,\dots,\varepsilon_T^*$;
Step 2. Create $x_1^*,\dots,x_T^*$ plugging pseudo residuals and estimated parameters in the bootstrap DGP.
Step 3. Repeat B times steps 1–2 producing $\tau_1^*,\dots,\tau_B^*$.

We firstly consider a direct non–parametric approach, denoted as Circular Block Bootstrap (CBB) [5]. Sample is split into overlapping blocks of fixed length, then bootstrapped series are produced drawing resulting blocks at random with replacement. Finally the pseudo–series are circularized including an additional set blocks generated combining initial and final values of the series.

Furthermore, three different methods are illustrated, starting from the general procedure explained in Algorithm 2. A naive approach is to apply an AutoRegressive Bootstrap (ARB) procedure. ARB is very easy to implement because AR and INAR models share the same autocorrelation structure, and ARB usually outperforms asymptotic approximations in finite samples [4]. In order to apply ARB with discrete–valued data, the following rounding scheme is necessary to discretize the bootstrap series: $\tilde{x}_t^{*b} = 0$ if $x_t^* \leq 0.5$ and $\tilde{x}_t^{*b} = \lceil \tilde{x}_t^{*b} \rceil$ otherwise.

Since ARB neglects the discrete nature of data, a possible more efficient approach is given by two methods introduced in [3], which essentially differs in the generation of ε_t^*. The first method is the Parametric Bootstrap (PB) and requires a) the estimation for the thinning parameter and b) the assumption of parametric distribution (i.e. Poisson) depending on a set of parameters used to estimate the true innovations' distribution ε_t from the INAR data. The replicated series are generated as follows:

$$x_t^* = \hat{\alpha} \tilde{*} x_{t-1}^* + \varepsilon_t^*, \quad \forall t = 2,\dots,n \tag{4}$$

Since PB is based on strictly assumptions, a more suitable method is the Semiparametric Bootstrap (SPB). SPB use the estimated P–INAR(1) coefficients, derived by using the same approach introduced in PB, but a nonparametric estimation of the innovations distribution. There are several ways to compute nonparametric estimates ε_t^* of equation (4), we follow [3] adopting the procedure introduced in [2]. Improvements in terms of performances of semi–parametric methods in this framework are

still under debate, although they have some advantages. For instance they can be valid even if some model assumptions, such as normality of residuals, do not hold.

For all considered methods the statistic of interest is computed as follows:

$$\tau^* = \frac{\hat{\alpha}_T^* - \hat{\alpha}_T}{\left[\hat{V}^*(\hat{\alpha}_T)\right]^{1/2}} \tag{5}$$

where $\hat{\alpha}_T^*$ is the bootstrap counterpart of $\hat{\alpha}_T$ obtained through equation (1) and bootstrapped data $x_1^*, \ldots, x_T^*$. Finally, the bootstrap p–value is computed through $\tau_1^*, \ldots, \tau_B^*$ as:

$$p^* = 2 \cdot \min \left\{ B^{-1} \sum_{b=1}^{B} I(\tau_b^* < \tau_{obs}), B^{-1} \sum_{b=1}^{B} I(\tau_b^* > \tau_{obs}) \right\} \tag{6}$$

this is the so–called equitail bootstrap p–value and is more appropriate than the symmetric counterpart, obtaining as $p^* = B^{-1} \sum I\left(|\tau_b^*| > |\tau_{obs}|\right)$, especially when the test statistic of interest is not always nonnegative.

4 Montecarlo Simulation

In order to analyze the behavior of four bootstrap methods, illustrated in Section 3, we generate $M = 2000$ samples following equation (1) and with following DGP: $\varepsilon_t \sim Pois(\lambda)$ with $\lambda = (1,5)$ and increasing sample length. The selected nominal level is equal to 0.05. Empirical size of bootstrapped t statistic is reported fixing $\alpha = 0$, while we choose the following values for the P–INAR(1) coefficient: $\alpha = \{0, 0.05, 0.1, \ldots, 0.8\}$ to evaluate the empirical power. Number of bootstrap replication is set equal to $B = 999$. We compute rejection frequencies for the asymptotic statistic as a benchmark, generating $M = 10000$ dataset under the previously introduced DGP.

Table 1 presents results in terms of empirical size: asymptotic rejection frequencies are often quite far from the nominal level equal, especially when $\lambda = 1$. As expected, ARB and CBB are dramatically ovesized, performing considerably worse than asymptotic approximation, due to their inadequacy in reproduce the real dependency of data in the bootstrap sample. Nevertheless, PB and SPB present rejections which are very closer to the nominal level even in moderately small samples. In particular, SPB seems to outperform PB in most parameter settings. Moreover, when $\lambda = 5$ rejection frequencies of asymptotic approximation are comparable to PB and SPB

In Figure 1 we plot the logit of the rejection frequencies under two different sample sizes ($T = 50, 250$). We found that empirical power associated to PB and SPB always outperform asymptotic approximation under moderately small sample size ($T = 50$). Moreover, when the sample size is moderately large ($T = 250$), empirical power of asymptotic approximation in two considered scenarios is comparable with

the PB and SPB. Surprisingly, only when T is small the ARB presents the same behavior of PB.

5 Conclusions

Resampling methods as PB and SBP can outperform asymptotic approximation in testing P–INAR(1) coefficient, even if the sample size is small. PB and SPB can be generalized to the case of more lagged regressors. Proposed bootstrap test may be also exploited considering different INAR marginal distribution, i.e. the Negative Binomial or Geometric, and their associated estimators. On the other hand, conventional methods (CBB and ARB), which not take into account of the discreteness and positiveness of the data, are confirmed unreliable in the context of hypothesis testing. To improve bootstrap inference, some possible extensions can be exploited. First of all, resampling methods involving the null hypothesis in the bootstrap DGP can be exploited. Secondly, other estimators can be implemented in the bootstrap procedure such as conditional least squares and maximum likelihood.

Continuous Time-Interaction Processes for Population Size Estimation

Processi autointerattivi in tempo continuo per la stima della dimensione di una popolazione

Linda Altieri, Alessio Farcomeni, Danilo Alunni Fegatelli and Francesco Palini

Abstract This work presents time-interacting temporal point processes for capture-recapture data with behavioural responses. The proposed model is able to provide unbiased estimates of the population size for both self-exciting and self-correcting behaviours.

Abstract *Questo studio presenta processi di punto temporali autointerattivi. Il modello proposto fornisce una stima non distorta della dimensione di una popolazione sia in caso di processi auto-eccitanti che di processi auto-correggenti.*

Key words: self-exciting process, self-correcting process, time-interaction, behavioural response, population size, capture-recapture data

1 Introduction

A continuous time point process is a stochastic process modelling a list of times of event $\{t_1,\ldots,t_S\}$. The temporal process is associated to a counting process $N(t)$ for the number of events in the interval $(0,t)$, with $N(t) \sim Poisson(\lambda(t))$. The process conditional intensity function is given by

$$\lambda(t) = \lim_{h\to 0} \frac{E[N(t+h) - N(t)|\mathscr{H}(t)]}{h} \tag{1}$$

where $\mathscr{H}(t)$ is the history of event times up to t.

Different processes may be defined by modelling $\lambda(t)$. In this work, we combine the so-called *self-exciting* [1] and *self-correcting* [2] processes, where the occurrence of an event at time t affects the probability of occurrence of another event after t. We apply the resulting general formulation to capture-recapture data [3], based on repeatedly observing subjects over time. The objective is to obtain an estimate of the overall size of the catchable population, including subjects with zero captures.

In continuous time, each subject is at risk of capture in any moment of a fixed-length period, say $(0,T)$. In general, the expected number of captures per subject in the interval $(0,T)$ can be expressed as $E[N(T)] = \int_0^T \lambda(t)\, dt$. It is straightforward to check that $E[n] = N \cdot P(N(T) > 0)$, where n is the number of captured subjects and N is the total amount of subjects in the population, including the unobserved ones. The general form for the Horvitz-Thompson type estimator for N is then $\widehat{N} = \sum_{i=1}^{n} \frac{1}{P(N_i(T)>0)}$ where the probability $P(N_i(T) > 0)$ of observing a subject i in the interval of interest $(0,T)$ depends on the chosen model.

In a generic self-exciting process, the occurrence of an event at time t causes the conditional intensity function to increase. In capture-recapture contexts, a self-exiciting kernel allows events to trigger other events in the short term, the so called *trap-happiness* effect. The intensity is modeled as

$$\lambda_{SE}(t) = \eta + \sum_{k:t_k<t} g(t-t_k), \tag{2}$$

for some smooth self-exciting kernel $g(\cdot)$, where t_k is an event time in $(0,t)$. A standard choice is the exponential kernel $g(t) = \sum_{j=1}^{J} \alpha_j e^{-\beta_j t}$, for some $J \geq 1$. A stationarity condition for the exponential kernel is that $\sum_j \alpha_j/\beta_j < 1$, to avoid explosion of the intensity function. In practice, the exponential kernel with $J = 1$ is often flexible enough to provide good fit in self-exciting patterns.

Assumption (2), though, is not flexible enough to take *trap-shyness* into account, i.e. to consider situations where the conditional intensity function drops after an event. This can be captured by self-correcting kernels, where the intensity increases over time in absence of events, and is decreased by each event. The conditional intensity of a self-correcting process may be expressed as

$$\lambda_{SC}(t) = \eta \exp(-\theta(N(t) - \eta t)),$$

where θ is a parameter controlling the degree of trap-shyness and ηt is a target for the number $N(t)$ of events at time t.

In the following, we combine self-exciting and self-correcting processes. We derive the conditional likelihood for the biased samples obtained with population size experiments, where only units with at least one event are recorded. We then use the resulting parameter estimates within the Horvitz-Thompson estimator to obtain population size estimates.

2 Time-interaction processes

We propose a unified model which extends both self-exciting and self-correcting processes to a general time-interaction process. In the simplest case, we model the conditional intensity of a time-interaction process as

$$\lambda(t) = \alpha \sum_{k:t_k<t} \exp(-\beta(t-t_k)) + \eta \exp\left(-\theta(N(t)-\eta t)\right), \tag{3}$$

where $\alpha, \beta, \eta, \theta > 0$ and $\alpha < \beta$ to avoid explosion. Note that the intensity is not differentiable, but it is continuous in all parameters.

Model estimation relies on the conditional likelihood; the estimated parameters are then used for a Horvitz-Thompson estimator for N, the total population amount. In a generic temporal point process, the log-likelihood for a subject i with capture times $\{t_{i1}, \ldots, t_{ik}, \ldots, t_{iK_i}\}$ in an interval of interest $(0,T)$ is

$$l_i(\lambda) = \sum_{k=1}^{K_i} \log(\lambda(t_{ik})) - \int_0^T \lambda(t)\, dt \tag{4}$$

where $K_i = N_i(T)$ and we assume $t_{i0} = 0$ and $t_{i(K_i+1)} = T$.

For the time-interaction process, the log-likelihood becomes

$$\begin{aligned} l_i(\psi) = \textstyle\sum_{k=1}^{K_i} \log\left[\alpha \sum_{s:t_{is}<t_{ik}} \exp(-\beta(t_{ik}-t_{is})) + \eta \exp\left(-\theta(N(t_{ik})-\eta t_{ik})\right)\right] \\ + \tfrac{\alpha}{\beta} \textstyle\sum_{k=1}^{K_i} \left[\exp(-\beta(T-t_{ik})) - 1\right] \\ - \tfrac{1}{\theta} \textstyle\sum_{k=0}^{K_i} \exp(-\theta k) \left[\exp(\theta\eta t_{ik+1}) - \exp(\theta\eta t_{ik})\right] \end{aligned} \tag{5}$$

where $\psi = (\alpha, \beta, \eta, \theta)$ is a short-hand notation for the parameters of interest.

In absence of selection bias, the log-likelihood for n observed subjects over the interval $(0,T)$, is given by

$$l_n(\psi) = \sum_{i=1}^{n} \left(\sum_{k=1}^{K_i} \log(\lambda(t_{ik})) - \int_0^T \lambda(t)\, dt \right). \tag{6}$$

Naturally, we can only sample subjects with $K_i > 0$. The likelihood above is therefore misspecified, and we resort to the conditional likelihood, which conditions on the event that there are one or more measurements. Because of the Poisson distribution of $N_i(t)$, the probability of observing a subject is

$$\Pr(K_i > 0) = 1 - \exp\left(- \int_0^T \eta \exp(\theta\eta t) dt \right) = 1 - \exp\left[- \frac{\exp(\theta\eta T) - 1}{\theta} \right]. \tag{7}$$

Note that, in this model, $\Pr(K_i > 0) = \Pr(K > 0)$ is the same for all subjects.

Hence, the conditional log-likelihood for n observed subjects is given by

$$l_n^*(\psi) = l_n(\psi) - n\log\left\{1 - \exp\left[-\frac{\exp(\theta\eta T) - 1}{\theta}\right]\right\}. \tag{8}$$

This approach allows not only to estimate the vector of parameters of interest ψ, but also to evaluate the total number of subjects $N = n + n_0$, where n_0 is the number of unobserved individuals belonging to the population of interest.

In order to maximize the conditional log-likelihood, the gradient is needed, which can be derived in closed form; then, the Hessian can be obtained numerically. A Newton-Raphson method proceeds after operating a change of variables so that positive parameters $\psi = (\alpha, \beta, \eta, \theta)$ are replaced by real-valued parameters $\psi' = (\alpha', \beta', \eta', \theta')$, where $\alpha = \exp(\alpha')$, $\beta = \exp(\alpha') + \exp(\beta')$, $\eta = \exp(\eta')$ and $\theta = \exp(\theta')$.

The Horvitz-Thompson type estimator for N in the current model, where the probability of no captures is the same for all subjects, is

$$\widehat{N} = \frac{n}{Pr(K > 0)} = \frac{n}{1 - \exp\left[-\frac{\exp(\theta\eta T) - 1}{\theta}\right]}. \tag{9}$$

2.1 Time-interaction processes with heterogeneity

In addition to behavioural effects, general models for closed population size estimation must consider three further sources of variation in capture rates: time-dependent effects, observed and unobserved heterogeneity ([8, 6]). The most general model is named M_{hotb}, where h stands for the unobserved heterogeneity, o for the observed heterogeneity, t for the time-heterogeneity and b for the behavioral response to capture. Under such model, the intensity function for a generic subject i is:

$$\lambda_i(t) = \alpha_i \sum_{k:t_{ik}<t} \exp(-\beta_i(t - t_{ik})) + \eta t^{\eta-1} \exp\left(X_i'\gamma + \mu_i - \theta_i(N_i(t) - \eta t^{\eta-1})\right), \tag{10}$$

where X_i is a $P \times 1$ vector of subject-specific covariates associated to P regression coefficients γ to capture the observed heterogeneity, while μ_i is a subject-specific random effect measuring the unobserved heterogeneity. The effects α, β, θ and μ may be thought of as following latent class models: they can take values in a discrete set of C latent classes subjects may belong to, with $C < n$. Therefore, $\alpha_i \in \widetilde{\alpha} = (\widetilde{\alpha}_1, \ldots, \widetilde{\alpha}_C)$, $\beta_i \in \widetilde{\beta} = (\widetilde{\beta}_1, \ldots, \widetilde{\beta}_C)$, $\theta_i \in \widetilde{\theta} = (\widetilde{\theta}_1, \ldots, \widetilde{\theta}_C)$ and $\mu_i \in \widetilde{\mu} = (\widetilde{\mu}_1, \ldots, \widetilde{\mu}_C)$. For identifiability reasons, we assume the latter vector $\widetilde{\mu}$ is in increasing order and that it sums to zero. The parameter η is under the constraint of being positive as for the simple model (2), called M_b model.

Maximum likelihood estimates for ψ are obtained via an EM algorithm, where starting values are provided for all parameters, respecting the constraints and identifiability. The last step consists in estimating N with a Horvitz-Thompson estimator, that takes random effects into account. Firstly, each subject is assigned to the latent class c with the greatest estimated probability $\widehat{\pi}_c$; such class is denoted as c_i^*.

Other estimated parameters $\widehat{\psi}_i^*$ are selected accordingly. Consequently, the probability $P(K_i > 0)$ is derived for each subject, and the estimator is

$$\widehat{N} = \sum_{i=1}^{n} \frac{1}{P(K_i > 0)} = \sum_{i=1}^{n} \frac{1}{1 - \exp\left[-e^{X_i'\widehat{\gamma}+\widehat{\widetilde{\mu}}_{c_i^*}} \int_0^T t^{\widehat{\eta}+1} e^{\widehat{\widetilde{\theta}}_{c_i^*}} \widehat{\eta} t^{\widehat{\eta}-1} \, dt\right]}. \quad (11)$$

3 Simulation study

We conducted a simulation study to validate the goodness of fit of our model. As competitors, we considered the lower bound nonparametric estimator of Chao (*Ch*) [4], the generalized Zelterman and Chao estimator (*GF*) which also includes time varying covariates and a behavioral effect [5, 7] and model M_t and M_{th} developed in the R package `ctime` [9]. In order to verify the performance of our estimator in different situations, eighty different simulation settings were proposed. For all simulations, we considered two latent classes; the vector parameter $\mu = (\mu_1, \mu_2)$ was fixed to (-7.5,0). For each combination of model parameters, K=1000 datasets were analyzed. Table 3 reports the empirical coverage and the root mean square error (RMSE) for all estimators evaluated for each scenario. As one can see, in almost all cases our estimator (N_{TI}) provides a smaller RMSE. We obtained a higher RMSE only in seven settings in which the impact of the behavioral effect is minor compared to the heterogeneity effect and a parsimonious model was preferred.

4 Conclusions

We proposed a general framework for estimating the population size in closed populations with capture-recapture of subjects in continuous time. Our model, named time-interaction process, applies to situations where a behavioural effect may be assumed, and extends both self-exciting and self-correcting processes. The estimator for the population size is associated to a smaller root mean square error in a variety of situations compared to standard estimators in the literature of capture-recapture data.

Longitudinal data analysis using PLS-PM approach

Analisi dei dati longitudinali attraverso l'approccio PLS-PM

Rosanna Cataldo, Corrado Crocetta, Maria Gabriella Grassia, Marina Marino

Abstract Longitudinal data over the past 20 years have seen a greater diffusion in the social sciences. Accompanying this growth was an interest in the methods for analyzing such data. Structural Equation Modeling (SEMs) and especially Partial Least Squares Path Modeling (PLS-PM) are a valuable way to analyze longitudinal data because it is both flexible and useful for answering common research questions. The aim of this paper is to demonstrate how PLS-PM can help us to analyze longitudinal data.

Abstract *I dati longitudinali degli ultimi 20 anni hanno visto una maggiore diffusione nelle scienze sociali. Ad accompagnare questa crescita è stato un interesse per i metodi di analisi di tali dati. I modelli ad equazioni strutturali (SEM) ed in particolare il metodo Partial Least Squares- Path Modeling (PLS-PM) sono un prezioso metodo di analizzare i dati longitudinali perché è sia flessibile che utile per rispondere a domande di ricerca comuni. Lo scopo di questa ricerca è di dimostrare come questo approccio può aiutarci ad analizzare i dati longitudinali.*

Key words: Partial Least Squares - Path Modeling, Longitudinal study

1 Introduction

A longitudinal study refers to an investigation where participant outcomes are collected at multiple times. Longitudinal data are difficult to collect, but longitudinal research is popular. And this popularity seems to be growing. With this comes the subsequent need for good data analysis methods to analyze these special kinds of data. The analysis of change in longitudinal data has attracted considerable attention over past decades in behavioral research [1]; [3]. Researchers have proposed a number of advanced and sophisticated quantitative approaches to address the stability and change of variables over time [5]; [17]. A broad range of statistical methods exists for analyzing data from longitudinal designs. Each of these methods has specific features and the use of a particular method in a specific situation depends on such things as the type of research, the research question, and so on. The central concern of longitudinal research, however, revolves around the description of patterns of stability and change, and the explanation of how and why change does or does not take place [11]. A common design for longitudinal research in the social sciences is the panel or repeated measures design, in which a sample of subjects is observed at more than one point in time. If all individuals provide measurements at the same set of occasions, we have a fixed occasions design. When occasions are varying, we have a set of measures taken at different points in time for different individuals. Such data occur, for instance, in growth studies, where individual measurements are collected for a sample of individuals at different occasions in their development. The model on longitudinal data can be approached from several perspectives, and the model can be constructed as a Structural Equation Model (SEM). According to Baltes and Nesselroade [2], SEM is a valuable way to analyze longitudinal data because it is both flexible and usefulfor answering common research questions. The explicit invocation of latent variables (LVs) afforded by the SEM makes this framework the one most commonly used to implement and analyze longitudinal data [18]; [23]. The SEM framework is often used to study change processes because this framework provides an opportunity to specify multiple latent variables as predictors and outcomes. SEM techniques include two main methods: covariance-based SEM (CB-SEM), represented by LISREL [14] and component-based SEM, with Partial Least Square-Path Modeling (PLS-PM) [9]; [24]. PLS-PM can be used to implement and to analyze the longitudinal data.

2 Longitudinal data analysis with PLS-PM approach

Recently, Roemer [20] has proposed using the component-based approach to SEM - PLS-PM in a longitudinal study [7]; [24]. In accordance with Roemer [20], we posit that PLS path modeling is highly appropriate for an analysis of the development and change in constructs in longitudinal studies, since it offers three favorable methodological characteristics. First, constructs often need to be predicted in evolutionary models [12]; [22]. Secondly, model complexity quickly increases when

development and change need to be analyzed in longitudinal studies. This is due to the larger number of constructs that are measured at different points in time and the respective effects between those constructs [12]. PLS-PM is well suited to dealing with such complex models [8]; [28]. Thirdly, sample sizes can become quite small in longitudinal studies [13]. PLS path modeling is particularly appropriate in such cases [10]; [15]. In Wold's original design of PLS-PM [27] it was expected that each construct would necessarily be connected to a set of observed variables. On this basis, Lohmöller [16] proposed a procedure to treat hierarchical constructs, the so-called hierarchical component model. There are several main reasons for the inclusion of a Higher-Order Construct Model: Higher-Order Construct Models prove valuable if the constructs are highly correlated; the estimations of the structural model relationships may be biased as a result of collinearity issues, and a discriminant validity may not be established. In situations characterized by collinearity among constructs, a Second-Order Construct can reduce such collinearity issues and may solve discriminant validity problems. PLS path modeling allows for the conceptualization of a hierarchical model, through the use of three main approaches existing in the literature: the Repeated Indicators Approach [16], the Two Step Approach [19] and the Mixed Two Step Approach [4]. The Repeated Indicators Approach is the most popular approach when estimating Higher-Order Constructs in PLS-PM [25]. We propose using a Higher Order Model to analyze longitudinal data. An example, with three points in time, is presented in Fig. 1.

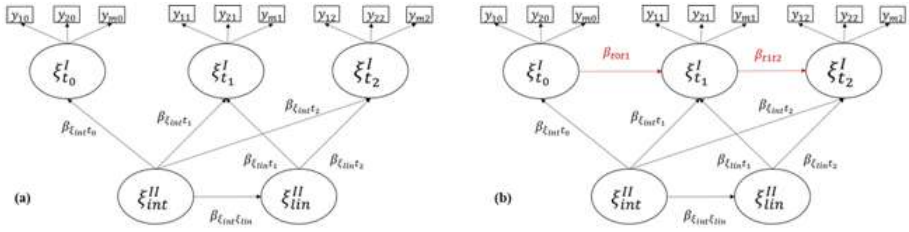

Fig. 1 (a) PLS-PM model - three times with m indicators in each n times; (b) PLS-PM model - three times with m indicators in each n times, with $\xi^I_{t_{i-1}}$ that impact on $\xi^I_{t_i}$

The Higher Order LV ξ^{II}_{int} describes the mean growth, and the LV ξ^{II}_{lin}.the mean slope. ξ^{II}_{int} is reflected in the construct of first order $\xi^I_{t_0}$, $\xi^I_{t_1}....\xi^I_{t_n}$. The construct of second order ξ^{II}_{lin} is reflected in the construct of first order $\xi^I_{t_1}....\xi^I_{t_n}$, The equations of the inner model are:

$$\begin{aligned}
\xi_{lin}^{II} &= \beta_{0lin} + \beta_{\xi_{int}\xi_{lin}}\xi_{int}^{II} + \zeta_{lin} \\
\xi_{t_0}^{I} &= \beta_{0t_0} + \beta_{\xi_{int}t_0}\xi_{int}^{II} + \zeta_{t_0} \\
\xi_{t_1}^{I} &= \beta_{0t_1} + \beta_{\xi_{int}t_1}\xi_{int}^{II} + \beta_{\xi_{lin}t_1}\xi_{lin}^{II} + \zeta_{t_1} \\
&\ldots \\
\xi_{t_i}^{I} &= \beta_{0t_i} + \beta_{\xi_{int}t_i}\xi_{int}^{II} + \beta_{\xi_{lin}t_i}\xi_{lin}^{II} + \zeta_{t_i} \\
\xi_{t_n}^{I} &= \beta_{0t_n} + \beta_{\xi_{int}t_n}\xi_{int}^{II} + \beta_{\xi_{lin}t_1}\xi_{lin}^{II} + \zeta_{t_n}
\end{aligned} \tag{1}$$

where $\beta_{\xi_{int}\xi_{lin}}$ is the strength and sign of the relations between construct ξ_{lin}^{II} and the predictor construct ξ_{int}^{II}; $\beta_{\xi_{int}\xi_{lin}}$ representing the growth mean rate; $\beta_{\xi_{int}t_i}$ is the strength and sign of the relations between construct $\xi_{t_i}^{I}$ and the predictor construct ξ_{int}^{II}; $\beta_{\xi_{lin}t_i}$ is the strength and sign of the relations between construct $\xi_{t_i}^{I}$ and the construct ξ_{lin}^{II}. They indicate how both intercept and slope factors contribute to explaining each time. β_0 is just the intercept term and ζ accounts for the residuals. The intercept term β_0 of each equation should always be non-significant. If we introduce the impact of the LV at i-1 time ($\xi_{t_{i-1}}^{I}$) on the LV at i time ($\xi_{t_i}^{I}$), for its better prediction ($\xi_{t_0}^{I} \rightarrow \xi_{t_1}^{I}$; $\xi_{t_1}^{I} \rightarrow \xi_{t_2}^{I}$;...; $\xi_{t_{n-1}}^{I} \rightarrow \xi_{t_n}^{I}$) as in Fig. 1 (b), the equations of the inner model become:

$$\begin{aligned}
\xi_{lin}^{II} &= \beta_{0lin} + \beta_{\xi_{int}\xi_{lin}}\xi_{int}^{II} + \zeta_{lin} \\
\xi_{t_0}^{I} &= \beta_{0t_0} + \beta_{\xi_{int}t_0}\xi_{int}^{II} + \zeta_{t_0} \\
\xi_{t_1}^{I} &= \beta_{0t_1} + \beta_{\xi_{int}t_1}\xi_{int}^{II} + \beta_{\xi_{lin}t_1}\xi_{lin}^{II} + \beta_{t0t1}\xi_{t_0}^{I} + \zeta_{t_1} \\
&\ldots \\
\xi_{t_i}^{I} &= \beta_{0t_i} + \beta_{\xi_{int}t_i}\xi_{int}^{II} + \beta_{\xi_{lin}t_i}\xi_{lin}^{II} + \beta_{t_{i-1}t_i}\xi_{t_{i-1}}^{I} + \zeta_{t_i} \\
\xi_{t_n}^{I} &= \beta_{0t_n} + \beta_{\xi_{int}t_n}\xi_{int}^{II} + \beta_{\xi_{lin}t_1}\xi_{lin}^{II} + \zeta_{t_n}
\end{aligned} \tag{2}$$

where $\beta_{t_{i-1}t_i}$ that represent the carry-over effects [12]; [6]. A sizeable positive effect means that the individuals' estimations of the construct remain stable over time [6]. In contrast, a small effect means that there has been a substantial reshuffling of the individuals' standings on the construct over time [21]. Finally, a sizeable negative effect means that there has been a reversal of the position of individuals on the structure over time. $\beta_{t_{i-1}t_i}$ contributes to explaining the variability at t time.

As in the CB-SEM framework, the model must be evaluated: first the measurement model and then the structural model. For the measurement model the Dillon-Goldstein's Rho, the mean of communalities and the mean redundancies must be examined. The structural model quality of the inner model must be assessed by examining the following indices: the regression weights, the coefficient of determination (R^2), the redundancy index, and the goodness-of-fit (GoF) statistics [24]. If the structural model quality is well assessed, but one or more *carry-over effects* are negative, this means there are two or more subsamples, with different growth curves. In this case, we suggest splitting the sample into two or more subsamples.

Subsequently, multi-group comparisons could be used to test any differences in the structural path estimates.

3 Conclusions

In this paper we have showed how the PLS-PM approach can be successfully used to analyze longitudinal data. Using PLS-PM we have the best estimation of the measurement model without any problem concerning its identification. The choice of using the PLS-PM is particularly useful for several reasons. First of all, this approach is applicable to small samples and it is capable of estimating rather complex models (with many latent and observable variables) with less restrictive requirements concerning normality and variable and error distributions [10]. Furthermore, PLS-PM approach provides the possibility of working with missing data and in the presence of multi-collinearity. Another advantage of this approach, as compared to other multivariate techniques, is that it examines simultaneous a series of dependence relationship, using a single statistical approach to test the full scope of projected relations [10].

Long-memory models for count time series
Modelli a memoria lunga per serie di dati di conteggio

Luisa Bisaglia, Massimiliano Caporin and Matteo Grigoletto

Abstract In this paper we analyze two different approaches for modeling dependent count data with long-memory. The first model we consider explicitly takes into account the integer nature of data and the long-range correlation, while the second model is a count-data long-memory model where the distribution of the current observation is specified conditionally upon past observations. We compare these two different models by looking at their estimation and forecasting performances.
Abstract *In questo lavoro analizziamo due diversi approcci per modellare la dipendenza di lungo periodo in serie storiche di dati di conteggio. Il primo modello considera esplicitamente la natura dei dati e la correlazione di lungo periodo, mentre il secondo è un modello a memoria lunga per dati di conteggio in cui la distribuzione dell'osservazione attuale viene specificata condizionatamente alle osservazioni passate. Il confronto fra questi due approcci è fatto tramite uno stidio Monte Carlo che confronta le performance di stima e previsione.*

Key words: count time series, long-memory, GLM, estimation, forecasting

1 Introduction

Recently, there has been a growing interest in studying nonnegative integer-valued time series and, in particular, time series of counts. In some cases, the discrete values of the time series are large numbers and may be analyzed using continuous-valued models such as ARMA with Gaussian errors. However, when the values are small,

M. Grigoletto
Dept. Statistical Sciences, University of Padova e-mail: matteo.grigoletto@unipd.it

as in the case of counting processes, the usual linear ARMA processes become inappropriate for modeling and forecasting purposes since they would invariably produce non-integer forecast values. One of the most common approaches to build an integer-valued autoregressive (INAR) process is based on a probabilistic operator called binomial thinning, as reported in Al-Osh and Alzaid (1987) and McKenzie (1985) who first introduced INAR processes. A different approach is based on the generalized linear models (GLM) advanced by Nelder and Wedderburn (1972) and McCullagh and Nelder (1989). This framework generalizes the traditional ARMA methodology allowing for more flexible dynamics also coherent with count data time series (for details and references, see, for example, Fokianos, 2016).

Long-memory (LM) processes have proved to be useful tools in the analysis of many empirical time series. One of the most popular processes that takes into account this particular behavior of the autocorrelation function is the AutoRegressive Fractionally Integrated Moving Average process (ARFIMA(p,d,q)), independently introduced by Granger and Joyeux (1980) and Hosking (1981). This process generalizes the ARIMA(p,d,q) process by relaxing the assumption that d is an integer. In particular, when $d \in (0,0.5)$ the autocorrelation function of the process decays to zero hyperbolically at a rate $O(k^{2d-1})$, where k denotes the lag. If $p = q = 0$, the process $\{X_t,\, t = 0,\pm 1,\ldots\}$ is called Fractionally Integrated Noise, FI(d). In the following we will concentrate on FI(d) processes with $d \in (0,0.5)$.

Persistent count time series occur for example in finance when modeling stock market daily trading volumes (e.g. Palma and Zevallos, 2011).
In this work, we analyze two different approaches for modeling dependent count data with long-memory. The first model we consider takes explicitly into account the integer nature of data and the long-range correlation, mixing the INteger AutoRegressive (INAR) model proposed by Al-Osh and Alzaid (1987) and McKenzie (1985) with the Fractionally Integrated (FI) model introduced by Granger and Joyeux (1980) and Hosking (1981). The second model, introduced by Palma and Zevallos (2011), builds on a conditional distribution for count data where the parameters' dynamic is characterized by long-memory. We compare estimation and forecasting performances of the two models by Monte Carlo simulations.

2 LM models for count time series data

2.1 GLM approach

Palma and Zevallos (2011) introduce a model for count time series characterized by long-range dependence. They propose a new class of conditional long-memory models (CLMs), where the conditional distribution of the data, given a data-driven parameter, is explicitly specified. The conditional long-memory process, X_t, can be defined as follows:

$$X_t \mid \mathscr{F}_{t-1} \sim G(\lambda_t, g(\lambda_t)), \quad \text{with} \quad \lambda_t = \mu \sum_{j=0}^{\infty} \pi_j - \sum_{j=1}^{\infty} \pi_j X_{t-j} \tag{1}$$

where $\mathscr{F}_t$ is the $\sigma-$field generated by the information up to instant t, $\{X_t, X_{t-1}, \ldots\}$, $G(\alpha, \beta)$ is a distribution corresponding to a continuous or discrete nonnegative random variable with mean α and variance β, both finite, $g(\cdot)$ is a positive function, μ is a constant and $\{\pi_j\}_{j>0}$ is an absolutely summable sequence of real numbers such that $\pi_0 = 1$ and $\pi_j \approx C j^{-d-1}$ for large positive j and some $d < 0.5$. Therefore, given the information $\mathscr{F}_{t-1}$, X_t has distribution G with conditional mean λ_t and conditional variance $g(\lambda_t)$. Obviously, if G is a distribution corresponding to a discrete nonnegative random variable, we obtain a LM model for count time series data. Even if, from a theoretical point of view, this setup is general enough to allow for the use of different integer distributions, in practice only a Poisson has been used by Palma and Zevallos (2011).

It can be shown (Palma and Zevallos, 2011) that model (1) has a non-Gaussian ARFIMA(p,d,q) representation. In particular, for the ARFIMA$(0,d,0)$ case we have $\pi_0 = 1$ and $\pi_j = \Gamma(j-d)/[\Gamma(j+1)\Gamma(-d)]$, for $j \geq 1$.

For further details about CLM-ARFIMA processes see Palma and Zevallos (2011). In particular, it is shown that CLM-ARFIMA and standard ARFIMA processes share the same correlation structure.

The CLM approach allows using all the tools available for GLM models (see, for instance, Liboschik et al., 2017).

2.2 Models based on the thinning operator

Integer-valued autoregressive (INAR) processes, initially proposed by Al-Osh and Alzaid (1987) and McKenzie (1985), in their most basic form follow the recursion:

$$X_t = \alpha \circ X_{t-1} + \varepsilon_t$$

where '$\circ$'is the thinning operator, defined by $\alpha \circ X = \sum_{i=1}^{X} Y_i$ with $X \in \mathbb{N}$, $\alpha \in [0,1]$ and Y_i is a sequence of i.i.d. count random variables, typically Ber(α), independent of X with common mean α. Hence, α plays the role of thinning probability. Moreover, ε_t is a sequence of i.i.d. discrete random variables with mean μ_ε and variance σ_ε^2. While the INAR(1) and INMA(1) models are defined univocally, for the INAR(p) and INMA(q) models there are additional complexities and different types of INAR(p) and INMA(q) processes might be considered (see Weiss, 2018 for a recent review on this topic). Recently, Weiss (2019) developed the INARMA(p,q) process:

$$X_t = \alpha_1 \circ X_{t-1} + \ldots + \alpha_p \circ X_{t-p} + \beta_1 \circ \varepsilon_{t-1} + \ldots + \beta_q \circ \varepsilon_{t-q} + \varepsilon_t$$

where, to obtain feasible stochastic properties, he assumed independence among all thinnings, independence from the innovations, and independence from $(X_s)_{s<t}$

for the thinning at time t. Combining the ideas of the INARMA model with the fractional integration of Granger and Joyeux (1980) and Hosking (1981), Quoreshi (2014) introduce the INARFIMA model based on the following INMA(∞) representation:

$$X_t = \sum_{i=0}^{\infty} \psi_i \circ \varepsilon_{t-i} \tag{2}$$

where $\psi_0 = 1$ and $\psi_i = \Gamma(i+d)/[\Gamma(i+1)\Gamma(d)]$, for $i \geq 1$, and d is the long memory coefficient. Since the ψ_i in (2) are considered thinning probabilities, then $d \in [0,1]$. Quoreshi (2014) proposes different estimation methods, based on conditional least squares, feasible generalized least squares and the generalized method of moments. In his paper Quoreshi (2014) does not consider the problem of forecasting with the INARFIMA model.

In the present paper, differently from Quoreshi (2014), who adopts the MA(∞) representation, to take into account the long memory and integer nature of data, we propose to consider the INAR(∞) recursion:

$$X_t = \sum_{i=1}^{\infty} \pi_i \circ X_{t-i} + \varepsilon_t \tag{3}$$

that is:

$$\sum_{i=0}^{\infty} \pi_i \circ X_{t-i} = (1 - B^{\circ})^d X_t = \varepsilon_t \tag{4}$$

where $\pi_0 = 1$ and $\pi_j = \Gamma(j-d)/[\Gamma(j+1)\Gamma(-d)]$ for $j \geq 1$, with $d \in (0, 0.5)$. As in Du and Li (1991) the ε_t constitutes a sequence of i.i.d. discrete random variables independent of all counting series, and all thinning operations are mutually independent. The conditional mean of process (3) is given by:

$$E[X_t \mid X_{t-1}, \ldots] = \mu_\varepsilon + \sum_{i=1}^{\infty} \pi_i X_{t-i}$$

and thus the autocorrelation function of X_t is the same of an I(d) process. Moreover, the conditional variance is:

$$V[X_t \mid X_{t-1}, \ldots] = \sigma_\varepsilon^2 + \sum_{i=1}^{\infty} \pi_i (1 - \pi_i) X_{t-i} \, .$$

In practice, only $X_1, \ldots, X_n$, are available, but X_t depends on the infinite past of the process. Therefore, we must approximate X_t with an AR(p), taking p large enough so that $\sum_{i=p+1}^{\infty} \pi_i \circ X_{t-i}$ in (3) is negligible. In our applications, all the available past observations are used.

2.3 Forecasting LM models for count time series

For CLM-ARFIMA models the natural one-step predictor of λ_{n+1} conditional on the past information, $\mathscr{F}_n$, is based on (1) and can be written as: $\hat{\lambda}_{n+1} = \hat{\mu}\sum_{j=0}^{n}\hat{\pi}_j - \sum_{j=1}^{n}\hat{\pi}_j X_{n+1-j}$ where each $\hat{\pi}_j$ depends on the long-memory parameter estimate, $\hat{d}$ (and other parameters, if present). Hence, the predicted conditional distribution is

$$\hat{X}_{n+1} \mid \mathscr{F}_n \sim G(\hat{\lambda}_{n+1}, g(\hat{\lambda}_{n+1}))$$

and the construction of conditional prediction intervals for one-step forecasts is a simple task. For k-step forecasts, with $k > 1$, we have to recursively use previous forecast values, for example: $\hat{\lambda}_{n+2} = \hat{\mu}\sum_{j=0}^{n+1}\hat{\pi}_j - \hat{\pi}_{n+1}\hat{X}_{n+1} - \sum_{j=2}^{n+1}\hat{\pi}_j X_{n+2-j}$ and the predicted conditional distribution is

$$\hat{X}_{n+2} \mid \mathscr{F}_n \sim G(\hat{\lambda}_{n+2}, g(\hat{\lambda}_{n+2}))\ .$$

In this case, the construction of conditional prediction intervals is not immediate and we obtain prediction intervals via computational methods. Forecasting with INARFIMA models is very simple too. Using (3), we have:

$$\hat{X}_{n+k} = \sum_{i=1}^{\infty}\hat{\pi}_i \circ \hat{X}_{n+k-i}\ ,$$

with $\hat{X}_j = X_j$ for $j \leq n$. Also in this case, prediction intervals cannot be directly recovered and we must resort to computational methods.

3 Some simulation results

In this section we provide the results of some Monte Carlo experiments we carried out to asses the estimation performance of different long-memory parameter estimators. Count time series of lengths $n = 500$ and $n = 1000$ were generated from models (1) and (3). The Poisson and Negative Binomial distributions were used for the conditional distribution G in (1) (models CP and CNB) and for ε_t in the INAR model (3) (models PI and NBI). The distribution parameters were chosen so that the amount of over-dispersion in the different cases is comparable. The functions we use are written in the `R` language and are available upon request from the authors. Table 1 shows the average estimates (and their standard deviations, in parentheses) over 1000 Monte Carlo replications. The estimation methods considered are maximum likelihood (ML), Geweke and Porter-Hudak (GPH) and Whittle (WH). Simulation results show how the long memory parameter d is, for all models, correctly estimated on average, with the ML and WH methods yielding comparable standard deviations, while the GPH method performs considerably worse.

Combining multiple frequencies in Realized GARCH models

Combinazione di frequenze in modelli Realized GARCH

Naimoli Antonio and Storti Giuseppe

Abstract This paper proposes extensions of the Realized GARCH model of Hansen et al. (2012) by incorporating information from multiple realized volatility measures computed at different sampling frequencies to achieve an optimal trade-off between bias and efficiency. Future volatility forecasts are determined by a weighted average of the considered realized measures, where the weights are time-varying and adaptively determined according to the estimated amount of noise and jumps. This specification aims to reduce bias effects related to the different sampling frequencies at which the realized measure are computed.

Sommario *L'obiettivo di questo lavoro è quello di estendere il modello Realized GARCH di Hansen et al. (2012) incorporando informazioni provenienti da molteplici misure di volatilità realizzate calcolate a diverse frequenze di campionamento al fine di raggiungere un trade-off ottimale tra distorsione ed efficienza. La volatilità futura viene determinata come media ponderata delle misure realizzate considerate, usando pesi variabili nel tempo e determinati in modo adattivo in base all'errore di misura stimato. Questa specificazione mira a ridurre gli effetti della distorsione legati alla frequenza di campionamento con cui vengono calcolate le misure realizzate.*

1 Introduction

Accurate estimation of volatility is of crucial importance in investment and risk management activities. The wide dissemination of high-frequency financial data has inspired researchers to develop ex-post volatility estimators to measure the quadratic variation of asset prices. It is well recognized that the use of intra-day data in dynamic models for forecasting volatility allows for more accurate forecasts.

In the absence of microstructure noise and measurement errors, Andersen et al. (2003) show that the Realized Variance (RV), using all available data, produces a consistent estimate of the latent Integrated Variance.[1] This suggest that the RV should be computed by using tick-by-tick data or intra-daily returns sampled at the highest possible frequency. However, due to market microstructure frictions, RV tends to be biased as the intra-daily sampling frequency increases. This implies a trade-off between bias and variance related to the working sampling frequency used.[2] This trade-off is the reason why realized volatility measures are often based on intraday returns sampled at a frequency ranging from 5 to 30 minute. However, although in most settings the 5-minute aggregation is sufficient to control the effects of microstructure noise, it may not be sufficient to filter out the effect of jumps. This leads to the use of jump-robust estimators[3] or to aggregate intra-daily returns at lower frequencies in computing realized measures. The drawback of using these solutions is a substantial loss of efficiency on days when the jumps are negligible or not present at all. This emphasizes the duality between variability, maximized at higher sampling frequencies, and bias, due to microstructure noise and jumps, vanishing at lower frequencies.

This paper proposes dynamic models for forecasting daily volatility based on the combination of realized volatility measures computed at different frequencies aiming to achieve an optimal "compromise" between bias and efficiency. In particular, in our approach, future volatility forecasts are driven by the variation of a weighted average of multiple realized measures, where the weights vary over time depending on the estimated amount of noise and jumps. The proposed modelling approach is developed on the basis of the Realized GARCH (RGARCH) (Hansen et al., 2012). Here, we focus on models that include two realized variances based on different discretization grids, and therefore the proposed specification is called the *Mixed Frequency* Realized GARCH (MF-RGARCH). The model includes separate measurement equations for each of the realized measure considered. We also develop a variant of the MF-RGARCH characterized by a single measurement equation, the SMF-RGARCH model, in which the dependent variable is a time-weighted average of the "raw" realized measures.

---

[1] The Realized Variance is given by $RV_t = \sum_{i=1}^{M} r_{t,i}^2$, where $r_{t,i} = p_{t-1+i\Delta} - p_{t-1+(i-1)\Delta}$ is the i-th Δ-period intraday return, with p_t the logarithmic price process of a financial asset and $M = 1/\Delta$ the sampling frequency.

[2] See, for example, Aït-Sahalia et al. (2005), Zhang et al. (2005) and Bandi and Russell (2008), among others.

[3] See, among others, Barndorff-Nielsen and Shephard (2004b) and Andersen et al. (2012).

2 Mixed Frequency models

In this section, we present extensions of the standard RGARCH aiming to achieve an optimal trade-off between bias and variability by exploiting the information of realized measures based on different sampling frequencies. In our modelling approach, volatility dynamics are given by a time-weighted average of realized measures and, as in Hansen and Huang (2016), models also include different measurement equations for each realized measure considered. Therefore, the resulting model specification is denoted as Mixed Frequency Realized GARCH (MF-RGARCH) model. In particular, the MF-RGARCH is specified as

$$r_t = \sqrt{h_t} z_t \tag{1}$$

$$log(h_t) = \omega + \beta\, log(h_{t-1}) + \gamma log(\tilde{x}_{t-1}) \tag{2}$$

$$log(\tilde{x}_t) = \alpha_t\, log\left(x_t^{(H)}\right) + (1-\alpha_t)\, log\left(x_t^{(L)}\right) \tag{3}$$

$$log\left(x_t^{(j)}\right) = \xi_j + \varphi_j\, log(h_t) + \tau_j(z_t) + u_t^{(j)} \qquad j = H, L \tag{4}$$

where r_t is the daily open-to-close log-return at time t, $x_t^{(H)}$ and $x_t^{(L)}$ denote realized measures computed at a higher and a lower frequency, respectively, h_t is the conditional variance of returns, $z_t \overset{iid}{\sim} (0,1)$ and $u_t^{(j)} \overset{iid}{\sim} (0, \sigma^2_{u,j})$. Consequently, $\log(\tilde{x}_t)$ is a time-weighted average of two log-realized measures based on different sampling frequencies, where the weight α_t is given by:

$$\alpha_t = \alpha_0 + \alpha_1 R_t \text{ and } R_t = \left(RQ_t^{(L)} / RQ_t^{(H)}\right)^{0.5}.$$

Therefore, α_t is a linear function of the ratio between the Realized Quarticity (RQ) measures computed at low and high frequency respectively.[4] The ratio R_t plays the role of a state variable whose impact is related to the level of bias due to noise and jumps. As discussed in Barndorff-Nielsen and Shephard (2004a) and Bandi and Russell (2008), among others, the RQ highlights the sensitivity of fourth moment of returns to outliers and market microstructure noise. They found that these effects tend to be reduced as the returns sampling frequency shrinks. Being the ratio between RQs computed at different frequencies, R_t has the function of correcting for upward and downward bias eventually affecting the involved realized measures.

Furthermore, by collapsing the two measurement equations into one single equation in which the dependent variable is given by the weighted average $log(\tilde{x}_t)$ we obtain the *Single* equation Mixed Frequency Realized GARCH (SMF-RGARCH). Namely, equation (4) is replaced by: $log(\tilde{x}_t) = \xi + \varphi\, log(h_t) + \tau(z_t) + \tilde{u}_t$.

[4] The Realized Quarticity is defined as $RQ_t^{(j)} = \frac{M}{3}\sum_{i=1}^{M} r_{t,i}^4, j = H, L$.

3 Empirical Application

In order to assess the relative merits of the proposed modelling approach, we present an empirical application on a set of 4 German stocks: Bayerische Motoren Werke (BMW), Daimler (DAI), Deutsche Telekom (DTE) and Metro Group (MEO). Namely, we consider daily open-to-close log-returns and daily realized variances and quarticities based on 30 second, 1, 5, 10, 15 and 30 minute frequencies. The sample period spans a total of 2791 trading days ranging from 02/01/2002 to 27/12/2012. The raw data have been filtered according to the procedure described in Brownlees and Gallo (2006), where only continuous trading transactions within the regular market hours 9:00 am - 5:30 pm have been used to build the variables of interest. In the following, we refer to $m = minutes$ and $s = seconds$ to denote the sampling frequency of the realized measures employed in our analysis.

The out-of-sample predictive ability of the fitted models has been assessed by means of a rolling window forecasting exercise using a window of 1500 days, where the model parameters are recursively re-estimated every day. Also, we assume a Gaussian specification of z_t and the measurement error of the high and low realized measure, such that $z_t \overset{iid}{\sim} N(0,1)$, $u_t^{(H)} \overset{iid}{\sim} N(0,\sigma^2_{u,H})$ and $u_t^{(L)} \overset{iid}{\sim} N(0,\sigma^2_{u,L})$. The forecasting exercise covers the 2008 credit crisis and the turmoil period related to the instability of the Euro area in the late 2011, ranging from 15 November 2007 to 27 December 2012 for a total of 1298 days.

We consider the standard RGARCH as a benchmark, taking the 5-minute *RV* as volatility measure. Also, we set the 5-minute *RV* as the base frequency in the (S)MF-RGARCH models, then mixed with realized measures computed at higher frequencies of 30 second and 1 minute, and lower frequencies of 10, 15 and 30 minute.[5] The forecast accuracy has been evaluated by the QLIKE loss function, assessing the significance of differences in forecasting performance across different models by the Model Confidence Set (MCS) of Hansen et al. (2011) considering the confidence levels of 75% and 90%. We refer to the QLIKE loss function since it is more powerful in rejecting poorly performing predictors (see e.g. Patton (2011) and Liu et al. (2015) among others), among the class of robust loss functions for volatility forecast evaluation. The QLIKE loss function is given by

$$QLIKE = T^{-1} \sum_{t=1}^{T} \left(log(\hat{h}_t) + RV_t / \hat{h}_t \right). \tag{5}$$

The left panel of Table 1 shows that the QLIKE loss function, using the 5-minute realized variance as volatility proxy, is always minimized by the MF-RGARCH models mixing the 5-minute *RV* with realized measures based on intra-daily returns sampled at lower frequencies. Furthermore, the results of the MCS point out that the MF-RGARCH$^{(5_m,10_m)}$ is the only model that always falls into the MCS at

[5] This choice is due to the fact that it has been provided empirical evidence that, in most settings, the 5-minute frequency ensures better performance in terms of fitting and forecasting than realized measures computed at different frequencies (Liu et al., 2015).

Table 1: Average values of QLIKE loss using 5-min *RV* as volatility proxy (left) and MCS p-values (right). For each stock: in **boldface**: minimum loss; in box models $\in$ 90% MCS and in box models $\in$ 75% MCS.

the confidence level of 75%. The MF-RGARCH models based on the $(5_m, 15_m)$ and $(5_m, 30_m)$ frequency combinations still provide a good performance always entering the MCS at the considered confidence levels, with the exception of the MF-RGARCH$^{(5_m,15_m)}$ for DAI. In contrast, the MF-RGARCH models combining the 5-minute *RV* with realized volatility measures computed at higher frequencies are overall characterized by a lower predictive accuracy since they are only included in the MCS in some isolated cases. On the other hand, the predictive performance of models that include a single measurement equation, the SMF-RGARCH, is not as satisfactory. Finally, even the standard RGARCH never enters in the set of superior models. It is close in entering the 90% MCS for the stock DAI, but it is clearly outperformed by its mixed frequency counterparts.

4 Conclusions

We propose flexible generalizations of the Realized GARCH model of Hansen et al. (2012), where the dynamics of the conditional variance are driven by a weighted average of realized variances computed using intra-daily information at different frequencies. The coefficients of the weighted average are time-varying and adaptively estimated in order to guarantee, in a fully data driven fashion, an optimal bias-variance trade-off. The proposed approach can be used to generate improved conditional variance forecasts and, in an ex-post framework, also to compute an optimized volatility measure. The out-of-sample forecasting exercise shows that the mixed-frequency models can allow for substantial improvements

in terms of forecasting accuracy over the standard Realized GARCH as measured by the QLIKE loss function. The only models entering MCS at the considered confidence levels, for all the analyzed assets, are of the MF-RGARCH type, thus confirming the good predictive power of this class of models.

Models with Time-Varying Parameters for Realized Covariance

Modelli con Parametri Variabili per la Realized Covariance

Luc Bauwens and Edoardo Otranto

Abstract Several recent contributions in econometrics and statistics deal with the dynamic modelling of conditional covariance matrices. To guarantee the positive definiteness of the estimated covariance matrices and to obtain parsimonious models, most of the models proposed use scalar parameterizations that involve a small number of parameters, but have the drawback to impose constraints that may strongly restrict the flexibility of the dynamics of the conditional covariance or correlation process. Using the properties of the Hadamard exponential functions, we develop parsimonious but flexible models, which provide positive definite covariance matrices with different and time varying coefficients for each element of the covariance matrix. Their properties are verified with an empirical exercise, using realized covariance daily data for 29 assets.

Abstract *Vari contributi nell'ambito della letteratura statistica ed econometrica riguardano la modellistica dinamica di matrici di covarianze condizionate. Per ottenere matrici di covarianze stimate definite positive e nello stesso tempo modelli parsimoniosi, la maggior parte delle proposte è basata su parametrizzazioni scalari, che rendono poco flessibile la dinamica dei processi che generano le covarianze o le correlazioni. In questo lavoro vengono sviluppati modelli, basati sulle proprietà della funzione esponenziale di Hadamard, molto flessibili e parsimoniosi, che producono matrici di covarianze definite positive con differenti parametri (variabili nel tempo) per ogni elemento delle matrici. Le proprietà di questi modelli sono verificate con una applicazione empirica su un data set di 29 serie finanziarie.*

1 Introduction

The dynamic modelling of conditional covariance matrices is the topic of a large number of contributions in financial modelling. The literature started by extending the univariate GARCH model to the multivariate case, developing progressively the family of MGARCH models. Due to the availability of intraday prices and the development of realized volatility measures, attention shifted to the dynamic modelling of realized covariances and correlations. This has resulted in new classes of models for positive definite matrices, such as the Conditional Autoregressive Wishart (CAW) models proposed by Golosnoy et al. (2012). When the number of financial series (n hereafter) is not small (say, more than ten), the estimation of MGARCH and CAW models is difficult due to two problems: 1) the requirement of a parameterization of the dynamic process for the covariance matrix which guarantees its positive definiteness; 2) the "curse of dimensionality" problem (meaning that the number of parameters of such models tends to be large, increasing at least quadratically with n).

A turning point in MGARCH models was signed by the introduction of the DCC model of Engle (2002), who proposed a two-step specification and estimation procedure. The log-likelihood function based on the assumption of multivariate normality can be maximized in two steps. The first step provides the estimation of n univariate GARCH models for the conditional variances of the n series, whereas in the second step, the targeting of the constant matrix term is used before the correlation process parameters are estimated conditionally on the estimates of the first step. The advantage is not only in computational easiness, but also in goodness of fit: the possibility to adopt different parameters to modelize each variance increases the fit of this part (with respect to scalar BEKK), whereas for the correlation part, an assumption of common dynamics (scalar DCC) fixes the number of parameters to two. On the other hand the two-step procedure involves a loss of statistical efficiency because both sets of parameters are estimated using a limited information approach. The previous considerations are valid also for CAW models that use the DCC formulation, as proposed by Bauwens et al. (2016). The desire to modelize large dimensional covariance matrices has favoured the success of the two-step DCC formulation based on variances and correlations, at the expense of the direct joint modeling of the variances and covariances.

Our main contribution is a set of new parameterizations of the CAW model family, extending the existing BEKK-type formulation of Golosnoy et al. (2012) and the DCC-type formulation of Bauwens et al. (2016). The proposed new parameterizations imply a specific impact parameter of the lagged realized covariance (or correlation) on the next conditional covariance (or correlation) for each asset pair; moreover these impact parameters are time-varying. They nevertheless guarantee the positive definiteness of the conditional covariance (or correlation) matrix with simple parametric restrictions, while keeping the number of parameters fixed or at most near to n. In brief, they are more flexible than existing scalar or rank-1 BEKK and DCC versions, while adding a single scalar parameter to these models, hence, they remain parsimonious. This proposed parameterizations use the element–by–

element (Hadamard) exponential function of a matrix to define the impact parameter matrix of the lagged realized covariances (or correlations) of the conditional process. The model proposed is more general than the one proposed in Bauwens and Otranto (2020); it deals with realized volatility, uses different parameterizations involving the Hadamard exponential operator and extends the previous approach to the modelization of covariance matrices in a 1-step estimation framework.

2 A class of new models

Let $\mathbf{C}_t$ denote the $(n \times n)$ realized covariance matrix of day t ($t = 1, \ldots, T$), and $\mathscr{I}_t$ the information set at time t, consisting of the past values of $\mathbf{C}_t$. In the CAW framework, the conditional distribution of $\mathbf{C}_t$ is a $n-$dimensional central Wishart with $\nu (> n)$ degrees of freedom; in symbols:

$$\mathbf{C}_t | \mathscr{I}_{t-1} \sim W_n (\nu, \mathbf{S}_t / \nu) \tag{1}$$

where $\mathbf{S}_t$, of dimension $n \times n$, is the (positive semidefinite) expected value of the conditional distribution of $\mathbf{C}_t$. There is a large set of options to specify $\mathbf{S}_t$, inspired by the MGARCH literature; for example, Golosnoy et al. (2012) adopt a BEKK model. The diagonal BEKK-CAW model is the following process:

$$\mathbf{S}_t = \left(1 - \bar{a} - \bar{b}\right) \bar{\mathbf{C}} + \mathbf{A} \odot \mathbf{C}_{t-1} + \mathbf{B} \odot \mathbf{S}_{t-1} \tag{2}$$

where $\mathbf{A}$ and $\mathbf{B}$ are unknown positive semidefinite symmetric matrices of parameters, $\bar{a}$ and $\bar{b}$ are the averages of the elements of $\mathbf{A}$ and $\mathbf{B}$ respectively, and $\bar{\mathbf{C}}$ is the sample mean of the realized covariances $\mathbf{C}_t$. We call the models belonging to this family the *COV* models. Bauwens et al. (2016) specify $\mathbf{S_t}$ in the CAW framework using the DCC approach of MGARCH. They name the model "Re–cDCC". It consists of n univariate models for the conditional variances, and a scalar DCC model for the realized correlation matrix. Denoting with $\mathbf{D}_t$ a diagonal matrix with elements given by the diagonal elements of $\mathbf{S}_t$, and $\mathbf{R}_t = \mathbf{D}_t^{-1} \mathbf{S}_t \mathbf{D}_t^{-1}$, the Re–cDCC model is defined as the following set of equations:

$$\begin{aligned}
&\mathbf{R}_t = \tilde{\mathbf{Q}}_t^{-1/2} \mathbf{Q}_t \tilde{\mathbf{Q}}_t^{-1/2}, \\
&\mathbf{Q}_t = \left(1 - \bar{a} - \bar{b}\right) \bar{\mathbf{R}} + \mathbf{A} \odot \left(\tilde{\mathbf{Q}}_{t-1}^{1/2} \mathbf{D}_{t-1}^{-1} \mathbf{C}_{t-1} \mathbf{D}_{t-1}^{-1} \tilde{\mathbf{Q}}_{t-1}^{1/2} \right) + \mathbf{B} \odot \mathbf{Q}_{t-1}, \\
&\tilde{\mathbf{Q}}_t = \text{diag}(\mathbf{Q}_t),
\end{aligned} \tag{3}$$

where for any square matrix $\mathbf{X}$, $\text{diag}(\mathbf{X})$ is the diagonal matrix obtained by setting to zero all the off-diagonal elements of $\mathbf{X}$; $\bar{\mathbf{R}}$ is the sample correlation matrix, computed from the realized correlations. We call the models belonging to this family the *COR* models.

Bauwens and Otranto (2020), in the framework of MGARCH conditional correlation models, provide extensions of the scalar DCC model of Engle (2002), where

the elements of $\mathbf{A}$ depend in a nonlinear way on the lagged conditional correlations. In particular, in their model, called NonLinear AutoRegressive Correlation (NLARC) model, the effect of the lagged conditional correlations enters through the element–by–element (Hadamard) exponential function, denoted by $\exp^{\odot}$. The objective of adding flexibility in models (2) and (3), while maintaining a parsimonious parameterization, can be obtained by extending and generalizing the Bauwens and Otranto (2020) NLARC parameterization to the CAW model family. The matrix $\mathbf{A}$ becomes time-varying and is denoted by $\mathbf{A}_t$ in the sequel. Three parameterizations of the time-varying matrix $\mathbf{A}_t$ for (2) and of (3) are introduced below. Similar versions can be adopted for $\mathbf{B}$. The three proposed parameterizations are:

$$\begin{array}{ll} S(Scalar): & \mathbf{A}_t = a\exp^{\odot}(\phi_A\mathbf{M}_t) = a\mathbf{J}_n \odot \exp^{\odot}(\phi_A\mathbf{M}_t) \\ R1(Rank-1): & \mathbf{A}_t = \mathbf{a}\mathbf{a}' \odot \exp^{\odot}(\phi_A\mathbf{M}_t) \\ EO(Equal \quad Off-diagonal): & \mathbf{A}_t = \mathbf{A}_v \odot \exp^{\odot}(\phi_A\mathbf{M}_t), \end{array} \tag{4}$$

where $\phi_A \geq 0$, $\mathbf{M}_t$ is a positive definite symmetric matrix known at date t, $a \in (0,1)$ is a scalar in the first parameterization, and in the second one, $\mathbf{a}$ is an n-dimensional vector in which each element is in $(0,1)$, $\mathbf{J}_n$ is a matrix of ones. In the third parameterization, $\mathbf{A}_v$ is a matrix with diagonal elements $a_1,\ldots,a_n$, and equal off-diagonal (EO) elements, all equal to a_c, with $0 \leq a_c \leq a_i < 1$ for each $i = 1,...n$. This constraint provides a sufficient condition for $\mathbf{A}_v$ to be positive semidefinite. Notice that if $\phi_A = 0$, $\exp^{\odot}(\phi_A\mathbf{M}_t)$ is equal to $\mathbf{J}_n$, so that $\mathbf{A_t}$ is constant, being equal to $a\mathbf{J}_n$ (scalar model), $\mathbf{a}\mathbf{a}'$ (rank-1 model), or $\mathbf{A}_v$ (EO model). Two time-varying versions of $\mathbf{M}_t$ are used in the Hadamard exponential function of $\mathbf{A}_t$ when $\phi_A > 0$:

$$\begin{array}{l} Pt: \mathbf{M}_t = \mathbf{P}_{t-1} - \mathbf{J}_n, \\ Rt: \mathbf{M}_t = \mathbf{R}_{t-1} - \mathbf{J}_n, \end{array} \tag{5}$$

where $\mathbf{P}_{t-1}$ is the realized correlation matrix obtained by transforming the realized covariance matrix $\mathbf{C}_{t-1}$ into a correlation matrix, and $\mathbf{R}_{t-1}$ is the conditional correlation matrix. In the *COV* models, the latter is obtained by transforming $\mathbf{S}_{t-1}$ into a correlation matrix, and in the *COR* models, it is the matrix defined in the first line of (3). Each matrix $\mathbf{A}_t$ obtained by combining (4) and (5) is the Hadamard product of a positive definite (S case) or semidefinite matrix ($R1$ and EO) with strictly positive diagonal entries and a positive definite matrix ($\exp^{\odot}(\phi_A\mathbf{M}_t)$), so that it is a positive definite matrix (see Lemma 3 in Bauwens and Otranto, 2020).

3 Empirical application

High-frequency data for 29 stocks of the Dow Jones Industrial Average (DJIA) index have been used to compute a time-series of daily realized covariance matrices; the 30th stock was dropped since it is not permanently in the index during the sam-

ple period. The data source is the TAQ database. The sample period is 3 January 2001 to 16 April 2018, resulting in 4319 observations.[1]

Seventeen models have been estimated: nine COR and nine *COV* models in the *S*, *R*1 and *EO* parameterizations, each one with $\mathbf{M}_t = \mathbf{0}$ and the two other specifications in (5); the $COV-EO-Pt$ model, after estimation, is equal to the $COV-EO$ model, so we will not consider it longer. For the non-scalar models, we reduce the number of coefficients applying the grouping algorithm described in Bauwens and Otranto (2020). Details about estimates and grouping are available on request. Here we comment only the evaluation of models in terms of loss functions based on the comparison of fitted and realized covariance matrices. The losses adopted are the Quasi-Likelihood loss (QLIK), the Frobenius loss function (FL) and Global Minimum Variance Portfolio (GMVP) (see Bauwens and Otranto, 2020). Figure 1 shows the values of the three losses for all models, calculated for the full covariance matrix, only for the variances, only for the correlations. The points circled in green identify the models belonging to the MCS with non significant differences of the losses at the 5% nominal size of the tests. Some comments:

1. QLIK loss indicates that the Exponential Hadamard extension provides, in general, significant improvements in the models.
2. COR models shows a better performance than COV models, but this depends essentially on the better fitting of the variance part.
3. Applying the MCS only on the correlation part, COV models perform better in terms of GMVP (which is a financial loss) and sometimes also in terms of MSE.

4 Concluding remarks

We have proposed a new class of models for the realized covariance matrix, with the characteristics of a great flexibility with respect to previous models, providing the possibility, with a few set of parameters, to estimate different dynamics for each element of the realized covariance matrix. This is obtained thanks to the particular parameterization of the coefficients, based on the Hadamard exponential function, which possesses the nice property to guarantee the positive definiteness of the matrix of parameters. The models proposed belong to the family of CAW models for realized covariances and show a better performance with respect to the classical CAW models. We have performed also some out–of–sample analysis (not reported here) with similar results. We have proposed several parameterizations to estimate the new models, but they are not exhaustive; each positive definite matrix $\mathbf{M}$ in (4) is a potential solution to parameterize the model. One of the main advantages of this model is the possibility to consider different dynamics for each element of the co-

[1] Thanks to Professors Lyudmila Grigoryeva (University of Konstanz) and Juan-Pablo Ortega (University of St.Gallen) for providing the datasets for the DJIA companies and to Oleksandra Kukharenko (University of Konstanz) for handling the data and computing the realized covariance matrices from the TAQ data.

variance matrix with a few set of parameters. The approach can be easily extended to the Multivariate GARCH case.

Pitman-Yor mixture models for survival data stratification

Modelli mistura basati sul processo di Pitman-Yor per stratificazione di tempi di sopravvivenza

Riccardo Corradin, Luis Enrique Nieto Barajas & Bernardo Nipoti

Abstract Stratification of survival data is a convenient tool to account for heterogeneity across groups. While strata are usually determined through a categorical covariate, the resulting definition of a stratum might not be supported by the data. Here we propose a way of detecting the best possible stratification via a nonparametric mixture model defined by means of a Pitman-Yor process and a logistic kernel. The performance of our proposal is investigated with a simulation study.

Abstract *La stratificazione di dati è uno strumento utile ad introdurre eterogeneità in un modello di analisi della sopravvivenza. Sebbene solitamente gli strati siano definiti tramite una covariata categorica, la stratificazione che ne risulta potrebbe non essere supportata dai dati. Proponiamo qui un modo per definire la miglior stratificazione possibile, tramite un modello mistura nonparametrico definito da un processo di Pitman-Yor e un kernel logistico. Uno studio di simulazione permette di valutare l'efficacia della nostra proposta.*

1 Introduction

When modelling the hazard function of time-to-event data, stratification is a convenient tool to account for heterogeneity across groups. While strata are usually determined through a categorical/discrete covariate, it might be possible that the resulting definition of a stratum is not supported by the data. In addition, the best stratification might be the result of a combination of several covariates. Here we propose a way of defining the best possible stratification via a nonparametric mixture model. The nonparametric literature for this type of problems is, to the best of our knowledge, rather scarse with two notable exceptions being [6] and [1].

Modelling properties of nonparametric mixture models have been extensively investigated and their application has proved successful in many fields (see, e.g., [5]). In this work we consider a nonparametric mixture with mixing measure distributed as a Pitman-Yor (PY) process ([8, 9]). Our choice was motivated by the balance the Pitman-Yor process nicely strikes between modelling flexibility and tractability, in both mathematical and computational terms (see [3]).

The rest of the paper is organised as follows. In Section 2 we define the notation and introduce our model. A simulation study is presented in Section 3, while some concluding remarks are made in Section 4.

2 Pitman-Yor mixture for survival data

Let $\boldsymbol{T} = (T_1, \ldots, T_n)$ be a vector of time-to-event observations defined on some space $\mathscr{T} \subseteq \mathbb{R}^+$, and denote by $\boldsymbol{\delta} = (\delta_1, \ldots, \delta_n)$ the set of corresponding censoring random variables, defined so that $\delta_i = 1$ if the i-th event is observed exactly and $\delta_i = 0$ if it is right-censored. That is, $\delta_i = 1$ indicates that i-th event has occurred at time T_i, while $\delta_i = 0$ means that the i-th event has not occurred before T_i. We further assume that individual information is available and summarised by a d-dimensional set of covariates, denoted by $\boldsymbol{x}_i = (x_1, \ldots, x_d)$ for the i-th individual, and defined on some space $\mathscr{X} \subseteq \mathbb{R}^d$.

We consider an accelerated failure time framework, that is we assume that for each observation the effect of the covariates is multiplicative in the lifetime (see, e.g. [2]). If we denote by h_0 the baseline hazard function, common across different observations, then the accelerated failure time assumption allows us to write the individual hazard, for any $i = 1, \ldots, n$, as

$$h_i(t \mid \boldsymbol{x}_i) = \mathrm{e}^{\boldsymbol{\theta}_i^\intercal \boldsymbol{x}_i} h_0\left(\mathrm{e}^{\boldsymbol{\theta}_i^\intercal \boldsymbol{x}_i} t\right). \tag{1}$$

Moreover, if we consider the positive random variables T_0 and T_i, with $i = 1, \ldots, n$, with distributions respectively characterized by the hazard functions h_0 and h_i, then (1) implies that that $T_i = T_0/\mathrm{e}^{\boldsymbol{\theta}_i^\intercal \boldsymbol{x}_i}$. A logarithmic transformation allows us to write $Y_i = \log T_i = \mu_i + \boldsymbol{\theta}_i^\intercal \boldsymbol{x}_i + \zeta_i Y_0$, where $\mu_i = \mathbb{E}[\log T_i]$ and Y_0 is a random variable with zero-mean and unit variance. In this work we further assume that Y_0 has log-logistic

distribution, which implies that also Y_i is log-logistic, and that T_i is distributed according to a logistic accelerated failure time. Henceforth we denote by $f(y;\mu,\boldsymbol{\theta},\zeta)$ and $S(y;\mu,\boldsymbol{\theta},\zeta)$, respectively, the density and the survival functions of a random variable $Y = \mu + \boldsymbol{\theta}^\intercal \boldsymbol{x} + \zeta Y_0$, with Y_0 being a log-logistic distributed random variable with zero-mean and unit variance.

We consider a nonparametric mixture model with mixing measure distributed as a PY process, characterized by a discount parameter $\sigma \in [0,1)$, a strength parameter $\vartheta > -\sigma$, and a diffuse probability measure P_0 defined on $\Gamma = \mathbb{R}^{d+1} \times \mathbb{R}^+$, space where the individual vectors of latent parameters $\gamma_i = (\mu_i, \boldsymbol{\theta}_i, \zeta_i)$ live. The mixture model can then be expressed as

$$\tilde{f}(y) = \int_\Gamma f(y;\gamma,\boldsymbol{x})^\delta S(y;\gamma,\boldsymbol{x})^{1-\delta} \tilde{p}(\mathrm{d}\gamma) \tag{2}$$

where $\tilde{p} \sim PY(\sigma,\vartheta;P_0)$. Model (2) can be equivalently written in hierarchical form as

$$\begin{aligned} Y_i \mid \gamma_i, \boldsymbol{x}_i, \delta_i &\overset{\text{ind}}{\sim} f(y_i \mid \gamma_i, \boldsymbol{x}_i)^{\delta_i} S(y_i \mid \gamma_i, \boldsymbol{x}_i)^{1-\delta_i}, && i = 1,\dots,n \\ \gamma_i \mid \tilde{p} &\overset{\text{iid}}{\sim} \tilde{p}, && i = 1,\dots,n \\ \tilde{p} &\sim PY(\sigma,\vartheta;P_0). \end{aligned} \tag{3}$$

The model specification is completed by defining P_0 as the independent product of a Gaussian distribution for μ, a d-dimensional multivariate Gaussian distribution for $\boldsymbol{\theta}$, and inverse-gamma distribution for ζ.

The almost sure discreteness of the PY process induces ties between the individual latent variables γ_i, with positive probability. We denote by $(\gamma_1^*,\dots,\gamma_k^*)$ the set of $k \leq n$ distinct values appearing in $\boldsymbol{\gamma} = (\gamma_1,\dots,\gamma_n)$ and by $(n_1,\dots,n_k)$, with $\sum_{j=1}^k n_j = n$, their frequencies. This property can be conveniently exploited to identify homogeneous strata within the data: observations sharing the same latent value γ_j^* can be interpreted as belonging to the same stratum. A simulation scheme for the posterior distribution can be obtained by marginalizing out the distribution of $\tilde{p}$ from model (3), as displayed in the next proposition, which we state after introducing the notation $\boldsymbol{x}_{1:n} = (\boldsymbol{x}_1,\dots,\boldsymbol{x}_n)$.

Proposition 1. *Let $\boldsymbol{Y} = (Y_1,\dots,Y_n)$ be a set of observable random variables from model* (3)*. Then the joint density of $(\boldsymbol{\gamma},\boldsymbol{Y})$, conditionally on $\boldsymbol{x}_{1:n}$ and $\boldsymbol{\delta}$, is given by*

$$\frac{\prod_{j=1}^{k-1}(\vartheta + j\sigma)}{(\vartheta+1)_{n-1}} \prod_{j=1}^{k} (1-\sigma)_{n_j-1} \prod_{i \in C_j} \left[f(y_i \mid \gamma_j^*, \boldsymbol{x}_i)\right]^{\delta_i} \left[S(y_i \mid \gamma_j^*, \boldsymbol{x}_i)\right]^{1-\delta_i},$$

where the sets $C_j = \left\{ i \in \{1,\dots,n\} : \gamma_i = \gamma_j^* \right\}$, for $j = 1,\dots,k$.

Proposition 1 represents the building block for devising a Gibbs sampling algorithm analogous to those presented in [4, 7] for non-conjugate mixture models. Inference on the stratification of the survival times can be carried out based on the

posterior sample generated via MCMC, and a point estimate can be obtained by following the variation of information criterion of [10].

3 Simulation study

We carried out an extensive simulation study to evaluate the ability of our model to correctly detect the partition of a simulated dataset, thus providing a useful stratification. To this end we considered three different specifications of model (3), which were used for both generating and analysing the data. Namely:

1. model with all regression coefficients equal to 0 (special case of model (3)),
2. model with common regression coefficients across groups (modification of (3)),
3. model with group-specific regression coefficients, that is model (3).

We considered three different sample sizes, $n \in \{90, 180, 270\}$, and for each n we generated 50 datasets from each one of the three models. For each considered scenario, survival times were generated from a mixture composed by three components, and thus with a known partition of the data. All the generated datasets were analysed by implementing the same three models. Models' performance was then assessed by comparing the true partition with the estimated stratification. Such comparison was made by using the RAND index as a measure of similarity between partitions.

Figure 1 summarises the results we obtained. Each panel refers to one of the nine considered combinations between data generating processes and models implemented to estimate the stratification. In each panel, the sample size is on the x-axis while on the y-axis is the value taken by the RAND index. Some comments are in order. Whenever the data are simulated from model 3 (that is with group-specific regression coefficients), model 1 (null regression coefficients) and model 2 (common regression coefficients) are unable to correctly estimate the partition of the data. On the other hand, model 3 seems to perform well for every considered data generating process. At the same time, it is interesting to observe that when data are simulated from model 1 (or model 2), the increased flexibility of model 3 results in a slightly worse performance if compared to that one of model 1 (or model 2).

4 Discussion

We proposed a Bayesian nonparametric approach for stratifying survival data and ran a simulation study where three different specifications of the proposed model were compared. The results of our study indicate that, at least for the scenarios considered, the more flexible model performs uniformly well. On the contrary, the simpler models, with common regression coefficients, should be considered for applications only in presence of prior evidence supporting this assumption. While we presented a mixture model based on the PY process and a logistic kernel, the same

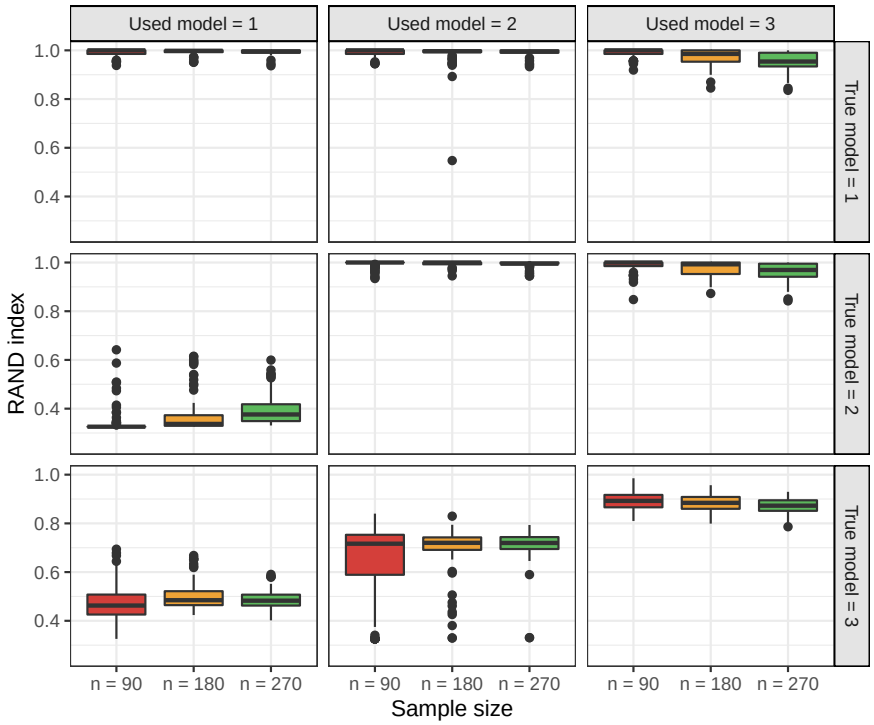

Fig. 1: Boxplots for the values taken by the RAND index, based on 50 replicates per scenario. The study considered three sample sizes $n \in \{30, 60, 90\}$, three data generating processes (one per row) and three fitted models (one per column).

approach can be investigated in greater generality by considering other families of discrete nonparametric priors, such as normalized random measures and Gibbs type priors, and by choosing a different baseline distribution. Moreover, the robustness of the proposed stratification procedure to data censoring is of prominent interest when real-world applications are considered. All these research directions are currently the subject of ongoing work.

Prediction is not everything, but everything is prediction

La previsione non è tutto, ma tutto è previsione

Leonardo Egidi

Abstract Prediction is an unavoidable task for data scientists, and over the last decades statistics and machine learning became the most popular 'prediction weapons' in many fields. However, prediction should always be associated with a measure of uncertainty, because from it only we can reconstruct and falsify the model/algorithm decisions. Machine learning methods offer many point-predictions, but they rarely yield some measure of uncertainty, whereas statistical models usually do a bad job in communicating predictive results. According to the Popper's falsificationism theory, natural and physical sciences can be falsified on the ground of wrong predictions: though, for social sciences this is not always true. We move then to a weak instrumentalist philosophy: predictive accuracy is not always constitutive of scientific success, especially in social sciences.

Abstract *La previsione è un compito inevitabile per gli scienziati dei dati e nel corso degli ultimi decenni statistica e metodi di apprendimento automatici sono diventate le più popolari 'armi di previsione di massa' in molti ambiti. Tuttavia, la previsione dovrebbe sempre essere associata a una misura di incertezza, poiché solo da essa possiamo ricostruire e falsificare le decisioni dell'algoritmo. I metodi di apprendimento automatico offrono molte previsioni puntuali, ma raramente producono qualche misura di incertezza, mentre i modelli statistici di solito comunicano male i risultati predittivi. Secondo la teoria della falsificazione di Popper, le scienze naturali e fisiche possono essere falsificate sulla base di previsioni errate: tuttavia, per le scienze sociali ciò non è sempre vero. Passiamo quindi a una debole filosofia strumentalista: l'accuratezza predittiva non è sempre costitutiva del successo scientifico, specialmente nelle scienze sociali.*

1 Introduction

As motivated by the falsificationism approach (Popper, 1934) and many philosophers of science, prediction has a primary role in the progress of science; however, this is often a controversial argument—see Kuhn (1962) and Lakatos (1976) for some criticisms. Popper argues that theories, in order to be scientific, must be falsifiable on the ground of their predictions: wrong predictions should perhaps push the scientists to reject their theories or to re-formulate them, conversely exact predictions should corroborate a scientific theory. Popper's philosophy is instrumentalist in a strong sense (Hitchcock and Sober, 2004) when applied to physical and natural sciences: predictive accuracy is constitutive of scientific success, not only symptomatic of it, and prediction works as a confirmation theory tool for science.

Since the 1940s, with the growing availability of fast computers and the use of simulation routines, science expanded its boundaries and extended the existing frameworks in new directions; think, for instance, at the Manhattan project in Los Alamos, when the problem of neutron diffusion in fissionable material allowed Stanislaw Ulam and Nicholas Metropolis to invent and develop Markov Chain Monte Carlo Methods through the ENIAC computer. Over the last decades, statistics and machine learning became the most popular 'prediction weapons' for both social and natural sciences, including frameworks such as weather's forecasting, presidential elections, planets' motions, global warming, Gross Domestic Product, etc. However, there is often a clear separation between these two fields: statistics is usually seen as a discipline which extracts information from the current data, whereas machine learning is usually designed to predict new events. Though, many times the right weapons are embraced by the wrong people. The predictive power in statistics is an elegant small gun, with good properties and small bullets, whereas in machine learning is a bazooka, with devastating effectiveness and big bullets.

The main novelty of this paper is the introduction of the *weak instrumentalist* position for prediction, under which predictive accuracy is constitutive of scientific success only when the underlying statistical methods are falsifiable and transparently designed to predict out-of-sample events. In other way said, there are many contexts, especially in social sciences, where falsification through the prediction's fallacy should be replaced by a more consistent idea of falsification. We believe this position may be beneficial for the so-called 'hard sciences' as well.

In Section 2 we state the steps required to formulate a scientific theory and review the role of prediction for science. In Section 3 we focus on prediction for statistics and machine learning, and we introduce the weak instrumentalist philosophy.

2 It is prediction part of the scientific design? Prediction as a confirmation theory approach

The main stages required to formulate a scientific law are summarized by Russell (1931) as follows: (1) observation of some relevant facts; (2) formulation of a hypothesis underlying and explaining the facts above; (3) deduction of some consequences from this hypothesis. In his opinion, the modern scientific method is born with Galileo Galilei, father of the law of falling bodies, and with Johannes Kepler, who discovered the three laws of planetary motion. Then, the law of universal gravitation of Isaac Newton embodied the two previous theories, whereas the theory of the general relativity of Albert Einstein generalized the Newton's theory. Thus, in the last 500 years, physics—and, more generally, science—advanced by falsification and generalization of the previous theories, by providing new and more exciting theories to predict new natural facts and highlighting the confirmation nature of prediction. In general, as Hitchcock and Sober (2004) argue, mathematical descriptions of the invariant behaviour of a physical phenomenon are essentially predictive: further experiments and observations can validate these theories.

However, the link of prediction with the scientific laws is in our opinion more ambiguous than what people are usually inclined to think. The following questions arise: is prediction a central step in science? Is prediction a relevant aim of science? A negative answer to the first question could be seen in disagreement with some *instrumentalist* scientists, who would claim that, from an instrumental perspective, predictive success is not merely *symptomatic* of scientific success, but it is also *constitutive* of scientific success (Hitchcock and Sober, 2004). A more sophisticated answer could be: prediction is not explicitly part of the formulation of a scientific hypothesis (1)–(3) *at the time the law is posed*, but it becomes relevant and relevant as science advances.

Steps (1)–(3) are widely used by social scientists and statisticians to build consistent theories about human and social behaviours: recently, it emerged clearly the need to build quantitative population's laws with the aim to mimic the physical nature's laws. However, the role played by prediction in social sciences is more obscure (Popper, 1944) and much controversial than for natural sciences, though data scientists are every day more and more asked to build 'weapons of mass prediction' in many social contexts. Perhaps, the actual outcome may be far away from the predictions: Trump's win in the 2016 US Presidential Elections, Brexit, and Leicester's Premier League's win were very low-probability events, but they all occurred during 2016. Can all of these rare events falsify the finest algorithms and models designed to not predict their occurrence? Our naive and tentative answer is no, they can't.

3 The role of prediction in statistical learning

3.1 From the observed to the observable

Statistics has always been thought as the *science of inference*, or *science of estimates*, and inference is always seen as a separate task from prediction. As statisti-

cians, we are often faced with a double task: first, creating a sound mathematical model to accomodate the data and retrieve useful inferences for our parameters—at the time being, we make no distinction here between classical and Bayesian statistics; second, using this model to make predictions, but this is rarely accounted by the statisticians in a transparent way.

Prediction moves from the observed to the unobserved, being the action designed to forecast future events without requiring a full understanding of the data-generation process. Each person is more or less confident with the weather's predictions or with presidential election predictions, but rarely that person is aware of the underlying statistical model required to produce that forecast, unless he is a statistician/data scientist. In such a view, inference seems hard and obscure, and prediction easy and close to the people. This is often a paradoxical argument, since the inference is often associated with the *explanation* of the problem, and should be relevant and available to the majority of the population. However, parameters do not exist in the real life, they are some fictitious and technical devices to explain and approximate the complexity. Rather, only prediction links the observed with the observable and is accessible to the people: it is not a matter of parameters' interpretation, but a check of the discrepancy between observed and future events. This is the reason why we provocatively claim that *prediction is not everything, but (almost) everything, in the real life, could be the object of a predictive action.*

In our practice, prediction should not be assimilated to 'take a rabbit out of a hat', but looking at its inherent uncertainty. If we are framed in a Bayesian context, we intend the unobserved and future values to come from a posterior predictive distribution, which incorporates the intrinsic uncertainty propagating from the parameters—summarized by the posterior distribution—to the observable future values. In the same spirit, when comparing models we support predictive information criteria which provide a measure of predictive accuracy based on the posterior predictive accuracy, such as the Watanabe Information Criterion (WAIC) and Leave-one-out Information Criterion (LOOIC).

3.2 The two cultures

As brilliantly argued by Breiman et al (2001), there are two cultures in the use of statistical modeling to reach conclusions from data: a stochastic data model consisting of predictors, parameters and random noise to explain the response variable is adopted by the data modeling culture; whereas a function of the predictors to predict the response variable is assumed by the algorithmic modeling culture, also named machine learning (ML) culture. The two approaches strongly differ in their validation: goodness-of-fit tests vs. predictive accuracy on out-of-sample data. It is evident that the data modeling culture—linear regression, generalized linear models, Cox model, etc.—is aimed at extracting some information about how nature is associating the response variable to the dependent variable, whereas the algorithmic

culture—decision and classification trees, neural nets—is more oriented to predict future values of the response variable given the values of the predictors.

Data scientists are used to train their procedures on the *training set*, which is chosen at the beginning in many possible ways. However, a small change in the dataset can cause a large change in the final predictions, and some adjustments are often required to increase the algorithm's robustness. To alleviate this lack of robustness, in the mid-1990s some data scientists argued that by aggregating many algorithms and perturbing the training set, using bagging (Breiman, 1996), boosting (Freund et al, 1996) or random forests (Ho, 1995), dramatically increased the predictive accuracy of the trees, by decreasing the variance.

3.3 ML scientists are strong instrumentalist, statisticians are weak instrumentalist

As emerges from this quick overview, the only rationale to evaluate the goodness of an algorithmic modeling procedure is to look at its predictive accuracy on out-of-sample/future data. 'Shaking the training set' became popular to ensure lower variance and higher accuracy, with the data scientist apparently ready to do 'whatever it takes' to improve over the previous methods. From a philosophical and scientific point of view, algorithmic modelers are *strong instrumentalist*, since for them the predictive accuracy carried out by their algorithms is constitutive—and not only symptomatic—of the broader scientific success.

Evaluating a model/algorithm in light of its ability to predict future data is not shameful at all; conversely, it is beneficial in many areas where a parametric stochastic model failed to be really generative and useful. However, even if predictions of future data are good tools to falsify a posed theory, many times ML techniques lack of a general and valid theoretical framework. For instance, the number of predictors at each split of a random forest is a tuning parameters, but in practice the best values for these parameters will depend on the problem. Predictions should corroborate or reject an underlying theory, but if the method (the theory) is tuned and selected on the ground of its predictive accuracy, the theory to be falsified is bogus, and not posed in a transparent way.

As statisticians and (data) scientists, our efforts should be addressed to produce good, transparent and well posed algorithms/models, and make them falsifiable upon a strong check (Gelman and Shalizi, 2013). Our skepticism regards the role of prediction in falsifying our models, for such a reason we would claim to be *weak instrumentalists*: predictions and predictive accuracy are central tasks of science, but only sometimes they are constitutive of scientific success.

To summarize the above discussion and other arguments not directly treated in this paper, we collect in Table 1 the main points which follow from the weak instrumentalist philosophy.

Table 1: Weak instrumentalism summary

General science
1. Predictive accuracy is not always constitutive of scientific success
2. Scientific falsification on the ground of wrong predictions is sometimes misleading, especially in social sciences (Trump's election, Leicester win, Brexit)
3. Supposedly valid scientific theories should exist before the future data have been revealed
4. Prediction is not explicitly part of the formulation of a scientific hypothesis at the time the law is posed, but it becomes relevant and relevant as science advances
Statistics
5. Take care of variability in the statistical predictions
6. If necessary, go beyond the distinction between inference and prediction, and consider a joint model for data, parameters and future data (falsificationist Bayes)
7. Rather than reasoning in terms of variance and bias, reason more in terms of predictive information criteria and posterior predictive distribution
Machine Learning
8. 'Shaking the training set' to improve predictive accuracy is an obscure step
9. Avoid to tune the algorithm with the only task to improve predictive accuracy
10. To be falsifiable, ML techniques need to be transparently posed

The Generalized Dynamic Mixtures of Factor Analyzers for clustering multivariate longitudinal data

Misture dinamiche di modelli fattoriali generalizzate per la classificazione di dati longitudinali

Francesca Martella, Antonello Maruotti, Francesco Tursini

Abstract This work introduces the Generalized Dynamic Mixtures of Factor Analyzers (GDMFA) approach for clustering high-dimensional longitudinal data. The proposed model can be seen as an extension of the Gaussian mixture model where individuals are allowed to move between components over time and, within each component, local dimensional reduction is performed. Temporal dependence is modelled through a first-order finite-state Markov chain. The model parameters have been estimated through an Alternating Expected Conditional Maximization (AECM) algorithm and the performance of the GDMFA model is discussed on the equitable and sustainable well-being (BES) of Italian territories data set. The results are encouraging and would deserve further discussion.

Abstract *In questo lavoro vengono introdotte le Misture Dinamiche di Modelli Fattoriali Generalizzate (GDMFA) per la classificazione di dati longitudinali. Il modello proposto puó essere visto come un'estensione del modello mistura Gaussiano dove simultaneamente gli individui possono muoversi tra le componenti durante il periodo di osservazione, e all'interno di ogni componente, viene effettuata una riduzione dimensionale locale. Inoltre, per catturare la dipendenza temporale, le componenti sono associate attraverso un processo di Markov. I parametri del modello vengono stimati attraverso un algoritmo AECM mentre l'utilitá e la validitá del modello GDMFA é discussa su dati relativi il benessere equo e sostenibile dei territori Italiani (BES). I risultati sono incoraggianti e meritano ulteriori sviluppi.*

1 Dynamic Mixtures of Factor Analyzers

The key idea of the Dynamic Mixtures of Factor Analyzers (DMFA) introduced by [4] consists of assuming that the joint distribution of a multivariate time series can be approximated by a dynamic mixture of lower-dimensional Gaussian densities in the factor space, and that, the mixture parameters evolve according to a latent homogeneous Markov chain. In details, let $\{\mathbf{Y}_t, t = 1,\ldots,T\}$ be a sequence of multivariate continuous observations, where $\mathbf{Y}_t = \{Y_{t1},\ldots,Y_{tP}\}$ and Y_{tp} represents the p-th response variable at time t ($p = 1,\ldots,P; t = 1,\ldots,T$). Moreover, let $\{S_t, t = 1,\ldots,T\}$ be a unobservable (hidden) process defined on the state space $\{1,\ldots,K\}$ following a first-order Markov chain, that is:

$$\Pr(S_t \mid S_1,\ldots,S_{t-1}) = \Pr(S_t \mid S_{t-1}) \tag{1}$$

characterized by

- the time-homogeneous $(K \times K)$-dimensional transition probability matrices Π containing the time-varying transition probabilities $\{\pi_{k|j}\}$ defined as

$$\pi_{k|j} = \Pr(S_t = k \mid S_{t-1} = j) \qquad t = 2,...,T,; j,k = 1,...,K \tag{2}$$

  where k and j refers to the current and previously visited state, respectively;
- the initial probabilities $\pi = \{\pi_k\}$ defined as:

$$\pi_k = Pr(S_1 = k) \qquad k = 1,...,K. \tag{3}$$

The DMFA model assumes that $\{\mathbf{Y}_t, t = 1,\ldots,T\}$ is a state-dependent process for which the conditional independence property holds, that is:

$$f(\mathbf{Y}_t|\mathbf{Y}_1,\ldots,\mathbf{Y}_T,S_1,\ldots,S_T) = f(\mathbf{Y}_t|S_t) \tag{4}$$

and where

$$f(\mathbf{Y}_t \mid S_t) = \mathrm{N}_P(\mu_k, \Lambda_k\Lambda_k' + \Psi_k), \tag{5}$$

i.e. the conditional distribution of $\mathbf{Y}_t \mid S_t$ is a multivariate Gaussian distribution with state-dependent mean vector μ_k and covariance matrix $\Lambda_k\Lambda_k' + \Psi_k$, where Λ_k is a $P \times q$ nonsparse real matrix of state-specific factor loadings, and $\Psi_k = \mathrm{diag}(\psi_{k1},\ldots,\psi_{kP})$ represents a positive definite matrix containing the error variances ($k = 1,\ldots,K$). The above specification implies that conditional on the state k, $\mathbf{Y}_t$ is specified by a factor analysis model as follows:

$$\mathbf{Y}_t = \mu_k + \Lambda_k\mathbf{f}_{tk} + \mathbf{e}_{tk} \tag{6}$$

where $\mathbf{f}_{tk}$ is a q-dimensional vector of state-specific latent factors drawn from $\mathrm{N}_P(\mathbf{0}, \mathbf{I}_q)$, and $\mathbf{e}_{tk}$ is a p-dimensional vector of state-specific error terms drawn from $\mathrm{N}_P(\mathbf{0}, \Psi_k)$, that is assumed to be independent of $\mathbf{f}_{tk}$. The model parameters are esti-

mated through an ML approach using a three-step Alternating Expectation Conditional Maximization (AECM) algorithm [5].

1.1 Extension to multivariate longitudinal data

To deal with multivariate longitudinal sequences, the DMFA approach introduced in the previous section needs to be extended to accommodate the peculiarities of such kind of data. These come in the form of three-way data: the first dimension identifies individuals, the second dimension identifies variables and the third one identifies time occasions. In this respect, we propose the Generalized Dynamic Mixtures of Factor Analyzers (GDMFA), where the parsimonious HMM is now defined by:

- an observed process $\{\mathbf{Y}_{it}, i = 1,\ldots,n; t = 1,\ldots,T\}$ where $\mathbf{Y}_{it} = \{Y_{it1},\ldots,Y_{itP}\}$ and Y_{itp} represents the p-th response variable given by the i-th individual at time t $(i = 1,\ldots,n; p = 1,\ldots,P; t = 1,\ldots,T)$ such that the following property holds:

$$f(\mathbf{Y}_{it}|\mathbf{Y}_{i1},\ldots,\mathbf{Y}_{iT},S_{i1},\ldots,S_{iT}) = f(\mathbf{Y}_{it}|S_{it}) \tag{7}$$

- a hidden state-dependent process $\{S_{it}, i = 1,\ldots,n; t = 1,\ldots,T\}$ defined on the state space $\{1,\ldots,K\}$ such that the following property holds:

$$\Pr(S_{it} \mid S_{i1},\ldots,S_{it-1}) = \Pr(S_{it} \mid S_{it-1}). \tag{8}$$

Moreover, as before, we defined the initial probabilities $\pi_k = Pr(S_{i1} = k)$ $(i = 1,...,n; k = 1,...,K)$ and the transition probability matrix $\Pi = \{\pi_{k|j}\}$, where $\pi_{k|j} = Pr(S_{it} = k \mid S_{it-1} = j)$ $(i = 1,...,n; t = 1,...,T,; j,k = 1,...,K)$. In line with the DMFA, we assume that conditionally to the k-th state, the random vector $\mathbf{Y}_{it}$ is modelled as

$$\mathbf{Y}_{it} = \mu_k + \Lambda_k \mathbf{f}_{itk} + \mathbf{e}_{itk} \tag{9}$$

where $\mathbf{f}_{itk}$ is a q-dimensional vector of state-specific latent factors drawn from $\mathrm{N}_P(\mathbf{0}, \mathbf{I}_q)$, and $\mathbf{e}_{itk}$ is a p-dimensional vector of state-specific error terms drawn from $\mathrm{N}_P(\mathbf{0}, \Psi_k)$, where $\Psi_k = \mathrm{diag}(\psi_{k1},\ldots,\psi_{kP})$, which is assumed to be independent of $\mathbf{f}_{itk}$. In other words, an observation i in state k follows a multivariate Gaussian density with state-dependent mean vector μ_k and covariance matrix $\Lambda_k\Lambda_k' + \Psi_k$. Note that, following the idea of [1], constraints across clusters on the Λ_k and Ψ_k matrices provide a class of 8 different models which will be presented.

In order to perform maximum likelihood estimation of the model parameters on the basis of the response vector $\mathbf{Y}_{it} = \{Y_{it1},\ldots,Y_{itP}\}$, we propose to use the same AECM algorithm as for DMFA. Specifically, this algorithm is a variant of the classical Expectation-Maximization (EM) algorithm [3] using different definitions of missing data at different stages. It is based on the complete-data log-likelihood, i.e., the log-likelihood of the observations (the incomplete data) plus the states (the missing data). Thus, we introduce two indicator variables $\mathbf{z}_{it} = (z_{it1},\ldots,\ldots,z_{itK})$ e $\mathbf{w}_{it} = (w_{it11},\ldots,\ldots,w_{itKK})$ such that $z_{itk} = 1$ if unit i is in state k at time t

and 0 otherwise, and $w_{itjk} = 1$ if individual i is in to state j at time $t-1$ and in state k at time t, 0 otherwise. Moreover, we partition the set of unknown parameters $\Theta = \{\mu_k, \pi_k, \pi_{k|j}, \Lambda_k, \Psi_k, j,k = 1,\ldots,K\}$ into two disjoint subsets $\Theta_1 = \{\mu_k, \pi_k, \pi_{k|j}, j,k = 1,\ldots,K\}$ and $\Theta_2 = \{\Lambda_k, \Psi_k, k = 1,\ldots,K\}$. One iteration of the AECM algorithm consists of two cycles; one E-step and one CM- step (one for each sub-vector of Θ) for each cycle. At the first cycle, we define the state labels as missing data, and the complete data log-likelihood function has the following form:

$$l_{c_1}(\mathbf{y},\mathbf{z},\mathbf{w}) = \sum_{i=1}^{n}\sum_{k=1}^{K} z_{i1k}\log(\pi_k) + \sum_{i=1}^{n}\sum_{j=1}^{K}\sum_{k=1}^{K}\sum_{t=2}^{T} w_{itjk}\log(\pi_{k|j}) + \sum_{i=1}^{n}\sum_{k=1}^{K}\sum_{t=1}^{T} z_{itk}\log(f(\mathbf{y}_{it} \mid S_{it} = k)). \tag{10}$$

where

$$f(\mathbf{y}_{it} \mid S_{it} = k) = \frac{\exp\left[-\frac{1}{2}(\mathbf{y}_{it}-\mu_k)'(\Lambda_k\Lambda_k' + \Psi_k)^{-1}(\mathbf{y}_{it}-\mu_k)\right]}{(2\pi)^{P/2} \mid \Lambda_k\Lambda_k' + \Psi_k \mid^{1/2}}. \tag{11}$$

The expected value of the complete-data log-likelihood is therefore

$$\begin{aligned} H_1(\Theta_1, \Theta_1^{(m)}) = &\sum_{i=1}^{n}\sum_{k=1}^{K} \hat{z}_{i1k}\log(\pi_k) + \sum_{i=1}^{n}\sum_{j=1}^{K}\sum_{k=1}^{K}\sum_{t=2}^{T} \hat{w}_{itjk}\log(\pi_{k|j}) \\ &- \frac{1}{2}\sum_{i=1}^{n}\sum_{k=1}^{K}\sum_{t=1}^{T} \hat{z}_{itk}\log(|\Lambda_k\Lambda_k' + \Psi_k|) \\ &- \frac{1}{2}\sum_{i=1}^{n}\sum_{k=1}^{K}\sum_{t=1}^{T} \hat{z}_{itk}\mathrm{tr}\left\{(\tilde{\Sigma}_k(\Lambda_k\Lambda_k' + \Psi_k)^{-1}\right\}, \end{aligned} \tag{12}$$

where

$$\tilde{\Sigma}_k = \frac{\sum_{i=1}^{n}\sum_{t=1}^{T} \hat{z}_{itk}(\mathbf{y}_{it}-\mu_k)(\mathbf{y}_{it}-\mu_k)'}{\sum_{i=1}^{n}\sum_{t=1}^{T} \hat{z}_{itk}}. \tag{13}$$

is the state-specific sample covariance matrix for all $k = 1,\ldots,K$. Thus, the E-step of the first cycle consists of calculating the conditional expectations $\hat{z}_{itk} = \mathrm{E}(z_{itk} \mid \mathbf{y}_{i1},\ldots,\mathbf{y}_{iT})$ and $\hat{w}_{itjk} = \mathrm{E}(w_{itjk} \mid \mathbf{y}_{i1},\ldots,\mathbf{y}_{iT})$ given the current values of the parameters and the observed data. On the other hand, at the first CM-step, maximizing the expected complete-data log-likelihood with respect to μ_k, π_k and $\pi_{k|j}$, we obtain, respectively:

$$\hat{\mu}_k = \frac{\sum_{i=1}^{n}\sum_{t=1}^{T} \hat{z}_{itk}\mathrm{y}_{it}}{\sum_{i=1}^{n}\sum_{t=1}^{T} \hat{z}_{itk}}, \tag{14}$$

$$\hat{\pi}_k = \frac{\sum_{i=1}^{n} \hat{z}_{i1k}}{n}, \tag{15}$$

and

$$\hat{\pi}_{k|j} = \frac{\sum_{i=1}^{n}\sum_{t=2}^{T}\hat{w}_{itjk}}{\sum_{i=1}^{n}\sum_{k=1}^{K}\sum_{t=2}^{T}\hat{w}_{itjk}}. \tag{16}$$

At the second cycle of the algorithm, we consider the state labels and the factors as missing data, therefore the complete-data log-likelihood is now as follows:

$$\begin{aligned} l_{c_2}(\mathbf{y},\mathbf{z},\mathbf{f}) = C + \sum_{i=1}^{n}\sum_{k=1}^{K}\Bigg[& -\frac{\sum_{t=1}^{T} z_{itk}}{2}\log(|\Psi_k^{-1}|) - \frac{\sum_{t=1}^{T} z_{itk}}{2}\mathrm{tr}(\Psi_k^{-1}\hat{\Sigma}_k) \\ & + \sum_{t=1}^{T} z_{itk}(\mathbf{y}_{it}-\mu_k)'\Psi_k^{-1}\Lambda_k\mathbf{f}_{itk} - \frac{1}{2}\mathrm{tr}(\Lambda_k'\Psi_k^{-1}\Lambda_k\sum_{t=1}^{T} z_{itk}\mathbf{f}_{itk}\mathbf{f}_{itk}')\Bigg] \end{aligned} \tag{17}$$

where C is a constant. The expected complete-data log-likelihood is then given by

$$\begin{aligned} H_1(\Theta_2,\Theta_2^{(m)}) = C & + \sum_{i=1}^{n}\sum_{k=1}^{K}\sum_{t=1}^{T}\frac{\hat{z}_{itk}}{2}\log(|\Psi_k^{-1}|) \\ & - \sum_{i=1}^{n}\sum_{k=1}^{K}\sum_{t=1}^{T}\frac{\hat{z}_{itk}}{2}\mathrm{tr}(\Psi_k^{-1}\tilde{\Sigma}_k) \\ & + \sum_{i=1}^{n}\sum_{t=1}^{T}\hat{z}_{itk}(\mathbf{y}_{it}-\mu_k)'\Psi_k^{-1}\Lambda_k\mathrm{E}(\mathbf{u}_{itk}\mid\mathbf{y}_{it},\mu_k,\Lambda_k,\Psi_k) \\ & - \frac{1}{2}\mathrm{tr}\left(\Lambda_k'\Psi_k\Lambda_k\sum_{i=1}^{n}\sum_{t=1}^{T}\hat{z}_{itk}\mathrm{E}(\mathbf{u}_{itk}\mathbf{u}_{itk}'\mid\mathbf{y}_{it},\mu_k,\Lambda_k,\Psi_k)\right). \end{aligned} \tag{18}$$

The estimates of Λ_k and Ψ_k matrices can easily be derived from (18). In the most general case, i.e. without any constraints on Λ_k and Ψ_k, we have

$$\hat{\Lambda}_k = \tilde{\Sigma}_k\gamma_k'\Delta_k^{-1}, \qquad \hat{\Psi}_k = \mathrm{diag}(\tilde{\Sigma}_k - \hat{\Lambda}_k\gamma_k\tilde{\Sigma}_k) \tag{19}$$

where

$$\gamma_k = \Lambda_k'(\Lambda_k\Lambda_k'+\Psi_k)^{-1}, \qquad \Delta_k = \mathbf{I}_q - \gamma_k\Lambda_k + \gamma_k\tilde{\Sigma}_k\gamma_k'. \tag{20}$$

In a similar manner, the estimates of Λ_k and Ψ_k can be easily derived under the different imposed constraints (not shown here for sake of brevity). The AECM algorithm iteratively updates the parameters until convergence to maximum likelihood estimates of the parameters. Note that the quantities $\hat{z}_{itk}$ and $\hat{w}_{itjk}$ can be computed recursively ([2]) by defining the forward variable $\alpha_{itk} = f(\mathbf{y}_{i1},\ldots,\mathbf{y}_{it},S_{it}=k)$, which represents the probability of the individual i of seeing the partial sequence ending in state k at time t, and the corresponding backward variable $\beta_{itk} = f(\mathbf{y}_{it+1},\ldots,\mathbf{y}_{iT} \mid S_{it}=k)$. Thus, we can express $\hat{z}_{itk}$ and $\hat{w}_{itjk}$ in terms of forward and backward variables by

$$\hat{z}_{itk} = \frac{\alpha_{itk}\beta_{itk}}{\sum_{k=1}^{K}\alpha_{itk}\beta_{itk}}, \tag{21}$$

and

$$\hat{w}_{it\,jk} = \frac{\pi_{k|j}\alpha_{it-1,k}f(\mathbf{y}_{it} \mid S_{it}=k)\beta_{itk}}{\sum_{j,k=1}^{K}\pi_{k|j}\alpha_{it-1,k}f(\mathbf{y}_{it} \mid S_{it}=k)\beta_{itk}}. \tag{22}$$

As a by-product of the estimation procedure, we classify the i-th individual to the k-th cluster if $\hat{z}_{itk} = \max(\hat{z}_{it1}, \ldots, \hat{z}_{itK})$.

2 Conclusions

A new model-based Gaussian clustering for multivariate longitudinal data is presented. Specifically, the proposed model allows individuals to move between clusters during the period of observation as well as local dimensional reduction within each cluster. In this way, the proposed approach is particularly suitable for high-dimensional data where parsimonious models should be used in order to reduce the general (heteroscedastic) model and, accordingly, the number of parameters to be estimated. We describe an AECM algorithm for estimating model parameters and we discuss the performance of the proposed model on the equitable and sustainable well-being of Italian territories dataset (BES dei territori, ISTAT). It is well known the importance of measuring equitable and sustainable well-being to evaluate the progress of a society not only from an economic, but also from a social and environmental point of view. In this prospective, from 2018 ISTAT provides a system of 55 BES indicators at local level illustrating the 12 domains relevant for the measurement of well-being: Health, Education and training, Work and life balance, Economic well-being, Social relationships, Politics and Institutions, Security, Subjective well-being, Landscape and cultural heritage, Environment, Innovation, research and creativity and Quality of services. Our aim will be to identify how evolve distinctive characteristics of well-being in various territories during a relatively long time period. The results are interesting and like in other studies, not always consistent with the stereotype of the rich North vs poor South.

Trends and long-run relations in cointegrated time series observed with noise

Trends e relazioni di lungo periodo in serie storiche cointegrate osservate con rumore

Angelica Gianfreda, Paolo Maranzano, Lucia Parisio and Matteo Pelagatti

Abstract Classic tests for stationarity of time series and of cointegration may fail when data are observed with dominant noise. We show that results of standard ADF are biased towards more stationarity, while the Johansen's test cointegration test may produce unrealiable results and generate false long-run signals. We show that data filtering improves the performance of standard tests and so it should become a good practice when dealing with very noisy datasets. We prove the effectiveness of different filtering strategies using simulated series.

Abstract *I test classici per stazionarietà e cointegrazione di serie storiche possono portare a conclusioni errate quando i dati sono nascosti da rumore dominante. In questo paper mostriano come i test ADF e Johansen siano distorti in presenza di tali caratteristiche. In particolare il test ADF segnala in modo eccessivo la stazionarietà delle serie, mentre il test di Johansen evidenzia un eccesso di relazioni di lungo periodo rispetto a quelle che realmente costituiscono il processo. Applicare tecniche di filtraggio migliora le performance dei tests e pertanto dovrebbero diventare buona prassi quando si affrontano situazioni simili. I risultati teorici sono validati tramite simulazioni Monte Carlo.*

1 Introduction

Many applied papers study the dynamics of multivariate time series with the aim of finding some long-run relationship governing the behavior of the observed variables. In this stream of research cointegration among time series and mean reversion are very useful and common tools to design

analysis strategies when dealing with data characterized by significant uncertainty. In this paper we stress that tests for stationarity of time series and of cointegration may fail when data show some unpleasant characteristics like high variability, leptokurtosis and extreme values. In particular, we show that results of standard ADF and Johansen's tests are biased towards more stationarity. In these cases cointegration analysis may produce unrealiable results and generate false lung-run signals. It is therefore extremely important to treat data appropriately when the scope of the analysis is to retrieve long run components governing the behavior of the series. We show that data filtering improves the performance of standard tests and so it should become a good practice when dealing with very noisy datasets. We prove the effectiveness of different filtering strategies using simulated series.

2 Why the ADF and related tests fail when integrated time series are observed with strong noise

Let us consider a simple random walk plus white noise model:

$$y_t = \mu_t + \varepsilon_t, \quad \varepsilon_t \sim \mathsf{WN}(\sigma_\varepsilon^2) \qquad \mu_t = \mu_{t-1} + \eta_t, \quad \eta_t \sim \mathsf{WN}(\sigma_\eta^2), \tag{1}$$

where the notation $\varepsilon_t \sim \mathsf{WN}(\sigma_\varepsilon^2)$ is to be read as "ε_t is a white noise sequence with variance σ_ε^2". Moreover, let $\lambda = \sigma_\eta^2/\sigma_\varepsilon^2 \geq 0$ be the *signal-to-noise ratio*. It is straightforward to prove that the process y_t has the reduced ARIMA$(0,1,1)$ form

$$\Delta y_t = \eta_t + \varepsilon_t - \varepsilon_{t-1} = \zeta_t - \theta\zeta_{t-1}, \qquad \zeta_t \sim \mathsf{WN}(\sigma^2) \tag{2}$$

with $\theta = 1 + \frac{\lambda - \sqrt{\lambda^2+4\lambda}}{2}$ and $\sigma^2 = \frac{\sigma_\varepsilon^2}{\theta}$.

When the signal-to-noise ratio is zero the MA coefficients is $\theta = 1$, the unit root operator cancels out with the MA operator and y_t turns out to be just a white noise sequence.

When λ is close to zero, the MA coefficient approaches 1 from below. In this case, the exact cancellation does not take place, however in small samples the process y_t is almost indistinguishable form a white noise. Such a MA process still has the purely AR representation $\Delta y_t = \zeta_t + \theta\Delta y_{t-1} + \theta^2\Delta y_{t-2} + \theta^3\Delta y_{t-3} + \ldots$, however, this representation cannot be well approximated by an AR(p) process with small p because θ^j approaches zero very slowly. Now, most unit root tests deriving from the Dickey-Fuller test such as ADF [6], ADF-GLS [2], Johansen [4] are based on autoregressive approximations and, if the y_t is generated as above with λ close to zero, then they are severely over-sized [3].

3 Filtering

We propose two types of time series filters that can improve the performance of unit root and cointegration tests:

1. reducing the frequency of the time series by taking averages, for instance by working on weakly means of daily or hourly electricity prices;

2. extracting the level component using the smoother in an unobserved component model (UCM) containing trend, noise and, possibly, seasonal components.

3.1 Frequency reduction by averaging

For $t = 1, 2, \ldots$, let y_t be defined as in (1) and let

$$\bar{y}_t = \frac{1}{m}\sum_{i=0}^{m-1} y_{t-i}, \qquad \bar{\eta}_t = \frac{1}{m}\sum_{i=0}^{m-1} \eta_{t-i}, \qquad \bar{\varepsilon}_t = \frac{1}{m}\sum_{i=0}^{m-1} \varepsilon_{t-i}, \tag{3}$$

where $\bar{y}_t$ is sampled over the set of time points $t \in \mathcal{T} := \{m, 2m, 3m, \ldots\}$. Then, over the time+ set $\mathcal{T}$

$$\bar{y}_t - \bar{y}_{t-m} = \bar{\eta}_t + \bar{\varepsilon}_t - \bar{\varepsilon}_{t-m},$$

with $\bar{\varepsilon}_t$ white noise sequence with variance σ_ε^2/m and $\bar{\eta}_t$ MA(1) process with $\mathsf{VAR}(\bar{\eta}_t) = \sigma_\eta^2\left[\frac{(m-1)(2m-1)}{3m} + 1\right]$, $\mathsf{COV}(\bar{\eta}_t, \bar{\eta}_{t-m}) = \sigma_\eta^2 \frac{(m-1)(m+1)}{6m}$ and $\mathsf{COR}(\bar{\eta}_t, \bar{\eta}_{t-m}) = \frac{(m-1)(m+1)}{2(m-1)(2m-1)+3m}$.

Moreover, the process $\bar{y}_t$ is ARIMA(0, 1, 1) for $t \in \mathcal{T}$ with moving average coefficient given by $\frac{-1+\sqrt{1-4\rho^2}}{2\rho}$ where the first-order autocorrelation is given by $\rho = \frac{\lambda\frac{(m-1)(m+1)}{6m} - \frac{1}{m}}{\lambda\left(\frac{(m-1)(2m-1)}{3m}+1\right)+\frac{2}{m}}$

3.2 Signal extraction in a unobserved component model

An alternative way to reduce the noise in the process y_t defined in Equation 1 is by estimating the random walk component μ_t by projecting it on the linear span of $y_0, y_1, \ldots, y_s$ where s is either equal to t or to $n-1$. This operation can be easily carried out by stating the model in state-space form and running the Kalman filter (for $s = t$) and smoother (for $s = n-1$) on the level component μ_t [1, 5]. The Kalman filter and smoother for μ_t are a linear filters whose weights are different for every t: the former is only backward looking,

$$\mu_{t|t} = \sum_{i=0}^{t} w_{ti} y_{t-i}, \qquad t = 0, 1, \ldots, n-1, \tag{4}$$

while the latter is two-sided,

$$\mu_{t|n-1} = \sum_{i=t}^{t-n+1} \tilde{w}_{ti} y_{t-i}, \qquad t = 0, 1, \ldots, n-1. \tag{5}$$

Nonetheless, when t is not too close to 0, the Kalman filter for the RW plus noise model can be well approximated by its steady state version, say $\tilde{\mu}_t$, given by the recursive filter

$$\tilde{\mu}_t = \gamma y_t + (1-\gamma)\tilde{\mu}_{t-1}, \qquad t = 0, 1, \ldots, n-1, \tag{6}$$

where $\gamma = \frac{\sqrt{\lambda^2+4\lambda}-\lambda}{2}$.

Similarly, when t is not too close to 0 or $n-1$, the smoother can be well approximated by its steady-state version, say $\hat{\mu}_t$, which is given by the backward recursion on $\tilde{\mu}_t$

$$\hat{\mu}_t = \gamma\tilde{\mu}_t + (1-\gamma)\hat{\mu}_{t+1}, \qquad t = n-1, n-2, \ldots, 0. \tag{7}$$

Assume that the variances σ^2_ε and σ^2_η of the process defined in equation (1) are known and $\lambda = \sigma^2_\eta/\sigma^2_\varepsilon$ is the signal-to-noise ratio. Then, $\tilde{\mu}_t$ is a random walk and $\hat{\mu}_t$ is an ARIMA$(1,1,0)$ process with autoregressive coefficient $\phi = 1-\gamma$.

4 Simulation experiments

To verify the empirical effects of the frequency-reduction and UCM filters on the ADF and Johansen tests, we performed a set of Monte Carlo simulations. Each experiment evaluates the performances of ADF and Johansen tests under the null hypothesis, in order to evaluate the size of the tests. The first set of experiments aims at assessing the performance of the ADF test under the random walk plus (leptokurtic) noise model. We simulate time series from a RW buried in leptokurtic noise and each simulation experiment is characterized by a different combination of noise-to-signal ratio and kurtosis value. The data generating process (DGP) for the observation y_t is

$$y_t = \mu_t + \sqrt{c}\,\varepsilon_t, \qquad \varepsilon_t \sim i.i.d.(0,1) \qquad \mu_t = \mu_{t-1} + \eta_t \qquad \eta_t \sim \text{NID}(0,1),$$

where ε_t is the leptokurtic noise generated by a standardized Student's t with ν degrees of freedom (DF) and $c = \lambda^{-1}$ is the fixed parameter identifying the noise-to-signal ratio. The number of DF governs the thickness of the tails of the noise component: the lower the DF, the larger the kurtosis.

For both experiments on ADF and Johansen's test, we simulate 10000 paths of length 1095, corresponding to 3 years of daily observations, for all of the possible pairs of noise-to-signal ratio c in $\{0,1,2,...,10\}$ and degrees of freedom ν in $\{3,6,9,12\}$.

On each of the simulated time series we apply the mean-filter (mean), the Kalman filter (ucm_flt) and the smoother (ucm_smo). The ADF statistic (with drift and number of lags selected by AIC) was computed on every simulated time series and the empirical rejection rates for a nominal size of 5% are represented in Figure 1.

Looking at the four graphs we can conclude that the ADF applied to the filtered time series has size close to the nominal one, the size of the ADF test applied to the smoother (ucm_smo) time series is equal to the nominal size for all the considered noise-to-signal ratios and that the thickness of the tails of the noise distribution has virtually no effect on the size of the ADF.

Similarly to the univariate case, we developed a simulation scheme for multivariate time series in order to evaluate the statistical properties of Johansen's cointegration test in presence of leptokurtik noise. Data are simulated according to a VECM with r cointegrating relations and $k = 4$ underlying times series augmented by a leptokurtic noise term. The noise is randomly generated by a standardized Student's t random variable with ν degrees of freedom and affect directly the VECM through the noise-to-signal ratio. We performed the simulation analysis on the number of cointegrating relations detected by the test considering the case of $r = 1$. For the simulation ex-

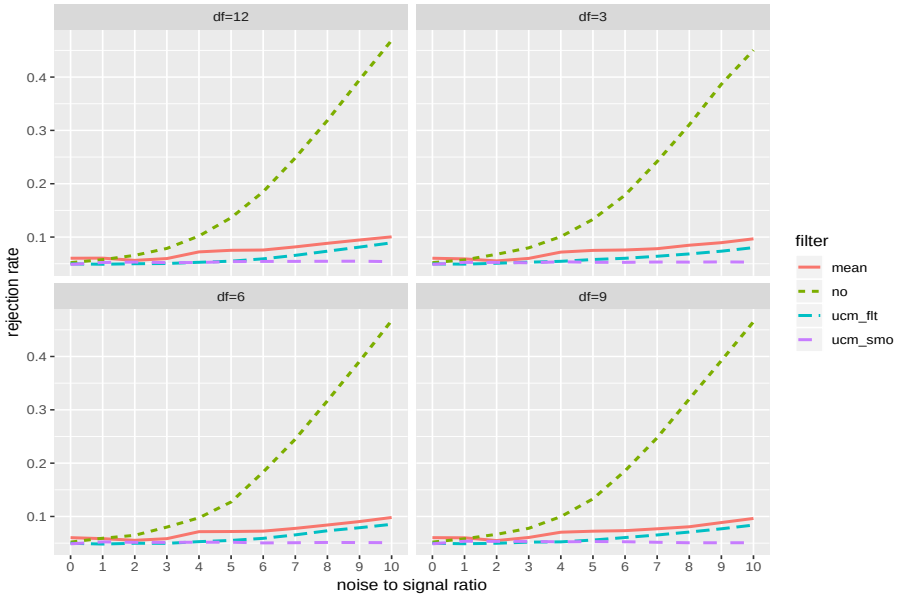

Fig. 1 Actual size of the ADF test for a nominal size of 5%.

periments involving the Johansen test we used the following two DGP: the cointegrating relations $\Delta\boldsymbol{\mu_t} = \boldsymbol{\alpha}\boldsymbol{\beta}'\boldsymbol{\mu}_{t-1} + \boldsymbol{\varepsilon_t}$ with $\boldsymbol{\alpha}' = [0\ 0.1\ -0.1\ 0.1]$ and $\boldsymbol{\beta}' = [1\ -1\ 1\ -1]$ and the noisy series $y_{it} = \mu_{it} + \gamma_i z_{it}$ with $\gamma_i^2 = c\frac{VAR(\Delta y_{it})}{VAR(x_i t)}$ and where z_{it} is a leptokurtic noise and c is a fixed parameter representing the noise-to-signal ratio. The three linear filters are then applied to the series, rising three further series sharing a common underlying process. The number of cointegrating vectors is finally tested on each simulated quartet using the Johansen's trace test. For each pair of degrees of freedom and noise-to-signal ratio and for each sequential value r^*, we computed the test's size (rejection rate) as the proportion of tests rejecting the null hypothesis over the total number of simulations. For values of r^* lower than the real one, the expected rejection rate should be the closest possible to 1; while it should tend towards zero approaching or overcoming the true value. We also estimate the selection rate as the unitary complement with respect to the rejection rate and use it to compare the test performance. High selection proportions should be associated to values of r^* close to the true one and low when r^* is enough lower from it.

Figure 2 shows the empirical selection rates when the real number of cointegrating vector is $r = 1$. Until the noise-to-signal ratio remains close to zero and independently by the degrees of freedom, both filtered and raw data perform similarly and no real advantages in pre-filtering are visible. But as soon as the signal-to-noise ratio gets unbalanced, the selection rates change considerably. Kalman filter and smoother are able to guarantee selection proportions in all situations, in particular the filter remains stable with values above 90%. The figure shows also that for highly unbalanced noise-to-signal ratios, just the filter is able to maintain acceptable performances, while the other filters, and obviously raw data, are not very effective.

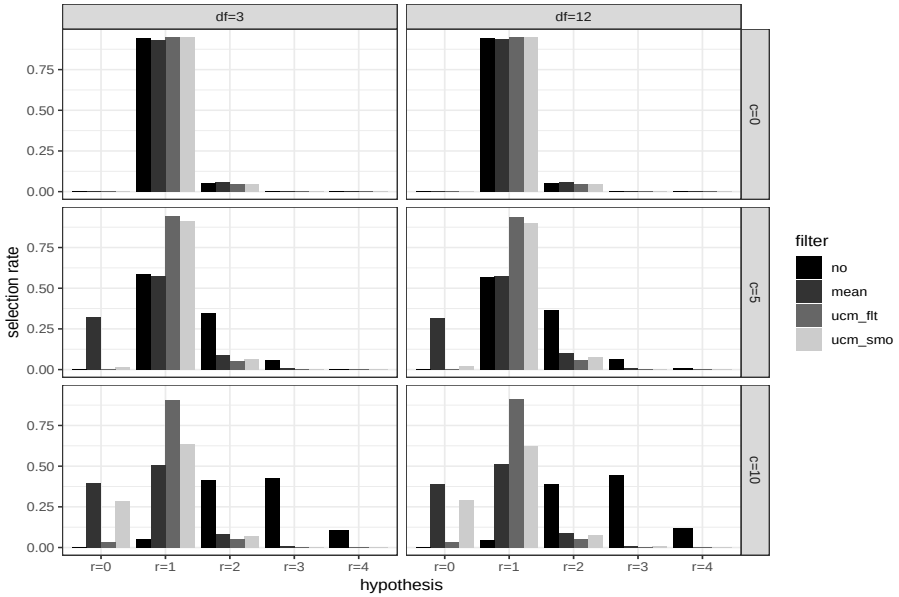

Fig. 2 Selection rate when $r = 1$.

5 Conclusions

The results assess that all the filtering methods improve the size of the ADF and Johansen tests, but the second one is the most effective for selecting the number of cointegrating relations. This kind of filtering should become routinary when testing for integration and cointegration dealing with series affected by high-frequency noise to avoid dominating spourious results.

Population and society

A dimensionality assessment of refugees' vulnerability through an Item Response Theory approach

Un approccio Item Response Theory per l'analisi di dimensionalità della vulnerabilità dei rifugiati

Simone Del Sarto[1] and Michela Gnaldi[2] and Yara Maasri[3] and Edouard Legoupil[3]

Abstract The present work deals with a key challenge for international agencies in charge of dealing with refugees' assistance, that of identifying clusters of refugees characterised by different vulnerability levels – so that the most vulnerable can benefit from support interventions (i.e., cash, livelihood activities etc.) – by at the same time accounting for the multidimensionality of the refugees' vulnerability condition. To this aim, we profile refugees on account of their vulnerability condition relying on a multidimensional and discrete Item Response Theory approach, whose main advantages consist in the possibility of clustering refugees into groups (latent classes) by concurrently taking into account the multidimensionality of the latent trait (i.e., vulnerability). First results of analyses carried out on extensive data provided the United Nation Higher Commission for Refugees highlight that vulnerability is a multidimensional condition, made of several sub-dimensions, some related to basic needs, and others to economic well-being and survival/social activities.

Abstract *Il presente lavoro tratta un topic rilevante per le agenzie internazionali che si occupano di assistenza ai rifugiati: identificare gruppi di rifugiati caratterizzati da diversi livelli di vulnerabilità – cosicché il gruppo più vulnerabile può beneficiare di interventi di sostegno (contanti, attività di sostentamento, ecc.) – e allo stesso tempo considerare la multidimensionalità della condizione di vulnerabilità. Il nostro obiettivo è quindi ottenere profili di rifugiati in base alla loro condizione di vulnerabilità, mediante un approccio IRT multidimensionale e discreto, il cui principale vantaggio consiste nella possibilità di raggruppare rifugiati in gruppi (classi latenti), tenendo conto della multidimensionalità del tratto latente (vulnerabilità). I primi risultati ottenuti su dati forniti dall'Alto Commissariato delle Nazioni Unite per i Rifugiati evidenziano che la vulnerabilità è una condizione composta da più dimensioni, alcune riguardanti il consumo di cibo e altre riferite al benessere economico e ad attività sociali e di sopravvivenza.*

1 Background

Due to the increase in humanitarian crises in the last several years, humanitarian agencies have to prioritise their interventions, by directing the most appropriate kind of assistance towards different groups, including the most socio-economically vulnerable. As one of those agencies, the primary purpose of the United Nations High Commissioner for Refugees (UNHCR) is to safeguard the rights and well-being of people who have been forced to flee, and strive to secure lasting solutions for them.

In this context, the present work deals with the multidimensional construct of refugees' vulnerability. Vulnerability as a concept is defined differently in the humanitarian context, depending on the mandates of the humanitarian agencies, the intended impact and the definition of the population to be assisted. For example, the World Food Programme measures food security though the Food Security Index [6], which brings together elements related to food consumption (quality and frequency), food expenditure share and specific coping mechanisms. As per UNHCR's mandate of providing international protection from persecution and refoulement[1], a vulnerability analysis and identification of refugees eligible for assistance will inevitably look at protection impact for any targeting strategies. UNHCR usually identifies risk profiles and protection vulnerabilities through the Specific Needs approach [5]: the agency has developed over 100 codes that assist frontline staff, who meet, interact with and assist refugees, to identify conditions and situations that can put a refugee at risk.

Item Response Theory (IRT) framework is particularly suitable for the context at issue, as it allows for the investigation of a latent phenomenon starting from a manifest observation of it (such as the response to a specific questionnaire). In this regard, by analysing data coming from a socio-economic assessment conducted by UNHCR in a refugee camp, we explore the dimensionality of this dataset in order to define refugees' vulnerability in terms of several dimensions contributing to its measurement. In doing this, we rely on a latent class multidimensional IRT model [2], in particular its version proposed for ordinal responses [1]. Given the latent class assumption, households may be partitioned into a certain number of groups, allowing us not only to identify the most vulnerable group(s), but, also, to characterise all the groups in terms of vulnerability multiple sub-dimensions. This latter point is crucial in order to identify a targeted assistance strategy.

This paper is organised as follows: in Section 2 we describe the data at issue and the statistical model employed for our purpose. Section 3 shows the results obtained from our analyses, while some concluding remarks are given in Section 4.

[1] Under Article 33(1) of the 1951 Refugee Convention relating to the Status of Refugees, refoulement is defined as the forcible return of refugees "to the frontiers of territories where his/her life or freedom would be threatened on account of his/her race, religion, nationality, membership of a particular social group or political opinion." (https://www.unhcr.org/3b66c2aa10)

2 Data and statistical model

We use data from a socio-economic assessment of refugees in Mauritania's Mberra camp, carried out by UNHCR during September-November, 2017. In fact, since 2012, the outbreak of armed unrest in northern Mali has led to major population movements to neighbouring countries, among which Mauritania hosts the largest number of refugees in Mberra camp.

The data at issue refer to 12,747 households and are collected through computer-assisted face-to-face interviewing by 124 enumerators and five supervisors. The dataset initially includes more than 200 variables (categorical and continuous) about the following contents: food consumption, item expenditure, sources of income, coping strategies, credit/debt, housing characteristics, asset and livestock ownership, social participation, household priority needs and preferences. After a careful inspection of the dataset record track and looking at the response rates, some variables have been discarded, while some others have been aggregated. The final dataset contains 23 categorical ordinal variables, summarised in Table 1.

As far as the statistical model is concerned, we use a latent class multidimensional IRT model for polytomous responses. Let Y_j be the response to item j, having l_j ordinal categories; the conditional probability of a generic response $y = 0, \ldots, l_j - 1$ is defined as $\phi_{j,y}(\boldsymbol{\theta}) = P(Y_j = y | \boldsymbol{\Theta} = \boldsymbol{\theta})$, where $\boldsymbol{\Theta}$ is the latent trait vector (D components) and $\boldsymbol{\theta}$ is its realisation. We assume a discrete distribution with k support points for it, which is equivalent to suppose that the population under study is divided into k latent classes, then units (i.e., households in our case) in the same class have the same latent trait level (i.e., a dimension of vulnerability).

We use the following model parametrisation:

$$g_y[\boldsymbol{\phi}_j(\boldsymbol{\theta})] = \gamma_j \Big(\sum_{d=1}^{D} I_{jd} \theta_d - \beta_{jy} \Big), \;\; j = 1, \ldots, J, \;\; y = 0, \ldots, l_j - 1$$

where $\boldsymbol{\phi}_j(\boldsymbol{\theta}) = [\phi_{j,0}(\boldsymbol{\theta}), \phi_{j,1}(\boldsymbol{\theta}), \ldots, \phi_{j,l_j-1}(\boldsymbol{\theta})]^\top$ and γ_j and β_{jy} are the discrimination parameter and difficulty levels of item j. Finally, I_{jd} is an indicator variable, equal to 1 if item j contribute to measure latent trait d, and 0 otherwise.

According to the definition of link function $g_y(\cdot)$ and to the constraints adopted for the item parameters, different model specifications may arise. In this work, we use a global logit link function with no constraints for the item parameters, allowing us to consider a latent class multidimensional graded response model [1].

In order to investigate the dimensionality of refugees' vulnerability, we need to find how many dimensions (or latent traits) this construct is made of and the items composing each of these dimensions. By looking at the model specification, this translates into determining the dimension of latent vector $\boldsymbol{\Theta}$ (i.e., D) and the specification of indicator variables I_{jd} for each item $j = 1, \ldots, J$ and each dimension $d = 1, \ldots, D$. To this aim, we adopt an exploratory hierarchical clustering algorithm [2, 3], which allows us to consider all the possible combinations of items (or groups of items), from the most restrictive model (one dimension for each item) to the most general (the undimensional model).

3 Results

In this section, we initially report the results of our analyses as regards the dimensionality assessment of refugees' vulnerability, using the dendrogram shown in Figure 1. We decide to use $k = 5$ latent classes in order to properly differentiate profiles of households, given the objective of a targeted assistance. According to the Bayesian Information Criterion [4], we can cut the dendrogram in correspondence of the dashed line, allowing us to select five groups of items (hence, $D = 5$).

Each of these groups consists in a different dimension characterising refugees' vulnerability. For example, dimensions from 3 to 5 clearly represent vulnerability

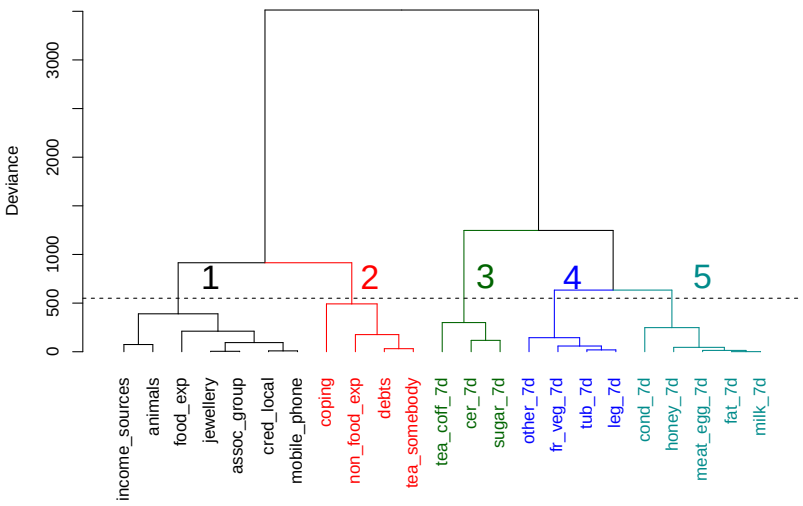

Fig. 1 Dendrogram resulting from the hierarchical clustering algorithm of the variables in the dataset.

sides connected with better food consumption. In particular, dimension 5 clusters animal-based foods while dimension 4 includes plant-based foods. They provide different nutritional components (fats and protein vs. carbs and fiber) and one group is harder to acquire (those in dimension 5) than the other. Moreover, dimension 3 includes foods that do not have high nutritional value but they are still highly consumed.

As regards the non-food dimensions, the first one (dimension 1 in Figure 1) appears as, say, the economic side of vulnerability, since it includes the possession of assets, the amount of income sources and food expenditure, as well as membership in an associative group, which in this context could be a cooperative of farmers, for example. Finally, we can say that dimension 2 mainly represents survival capacity, through specific coping strategies as well as by means of purchase of non-food goods, together with social integration opportunities within the community.

Taking into account these vulnerability facets, in Table 2 we report the latent trait estimates for each of the five latent classes (labelled from A to E), in order to describe refugees' household profiles. As we can see, the most vulnerable profile, identified by the lowest latent trait estimates (latent class A), includes almost 5% of the refugees' households and is characterised by low levels of food consumption (particularly far from the rest of the households), especially as regards dimensions 3 and 5. On the other hand, a quarter of the households belongs to the least vulnerable group (latent class E), having the highest estimates with respect to all the five vulnerability dimensions.

Table 2 Latent trait estimates for each latent class and each dimension, along with the prior probability estimates of each class ($\hat{\pi}$).

	Dimension					
Latent class	1	2	3	4	5	$\hat{\pi}$
A	-1.24	-0.95	-3.89	-0.95	-2.09	0.057
B	-1.60	-1.74	-0.33	-0.72	-0.86	0.161
C	0.04	0.35	0.24	-0.99	-0.63	0.329
D	-0.15	-0.40	0.18	1.01	0.75	0.212
E	1.44	1.26	0.65	1.17	1.27	0.241

4 Conclusions

This work stems from the need to target assistance to refugee households, which includes different types of assistance according to profiles. As such, refugees' vulnerability is a latent and multidimensional construct, since it may be considered as composed by several and related dimensions. In order to investigate such dimensionality, an Item Response Theory approach is carried out, by exploiting a survey administrated directly on a refugees' camp in Mauritania during the year 2017. A hierarchical clustering algorithm applied on the available variables is performed with the aim of exploring how items cluster together and how many dimensions contribute to define the vulnerability construct. Main findings reveal that in this case five dimensions characterise refugees' vulnerability, related to survival and basic needs, coping strategies, food consumption, as well as socio-economic well-being and social activities. Keeping in mind these dimensions and exploiting the latent class approach of the model at issue, we are able to highlight the different vulnerabilities that exist among the different profiles, including the most socio-economically vulnerable, in order to alert humanitarian agencies towards a focused intervention.

Acknowledgements This work is the result of a collaborative research agreement between the University of Perugia, Department of Political Science, and UNHCR. The authors would like to thank Dr Osama Abdelhay for his contribution to the research by having explored the problem, tested alternative statistical options and methodologies and recommended IRT as the methodology for in-depth research; Ms Irina Conovali to have coordinated the research efforts at UNHCR's side and many other UNHCR staff who have provided their time, knowledge and insights about the refugee situations in the Middle East and North Africa Region.

Accounting for Interdependent Risks in Vulnerability Assessment of Refugees

Rischi Interdipendenti per la Misura della Vulnerabilità dei Rifugiati

Daria Mendola, Anna Maria Parroco, Paolo Li Donni

Abstract The United Nations' Vulnerability Assessment Framework (VAF) of refugees encompasses a set of indicators of the living conditions in refugee camps in Lebanon and Jordan; it assumes the independence among its components. In this paper we maintain the importance to account for existing interdependencies, and provide a definition of vulnerability for high income countries. The proposed "vulnerability scale", based on the estimated joint risk of social isolation, economic deprivation and bad health, is a useful tool to address interventions toward selected groups of more vulnerable refugees. Analyses are based upon the survey of refugees carried on in Germany in 2016. Germany is the first country in Europe for the number of hosted refugees.

Abstract Per la misura della vulnerabilità dei rifugiati le Nazioni Unite hanno proposto il modello VAF, che adotta un insieme di indicatori delle condizioni di vita nei campi profughi in Libano e Giordania. Il VAF assume l'indipendenza delle sue componenti. In questo lavoro si propone invece di tener conto delle interrelazioni tra le componenti della vulnerabilità e si ragiona sul concetto di vulnerabilità nei paesi ad alto reddito. La scala di valutazione della vulnerabilità qui proposta- basata sulla stima del rischio congiunto di isolamento sociale, povertà e cattiva salute- costituisce un utile strumento per indirizzare le azioni di sostegno verso i gruppi maggiormente a rischio vulnerabilità. Le analisi sono basate sull'indagine sui rifugiati fatta in Germania nel 2016, il primo paese in Europa per numero di rifugiati accolti.

Key words: trivarite logit, poverty, health, social isolation, VAF, Germany, IAB-BAMF-SOEP.

1 Introduction and literature review

The UNHCR -United Nations High Commissioner for refugees- data [15] assessed in 2019 25.9 million of refugee worldwide in 2018. Most of them fled in neighbourhood countries. Refugees living in camps, such as those in Jordan, experience hard living conditions [5]. Worst conditions are experienced in Lebanon, where in 2015 the Government stopped the UNHCR's registration of refugees (but not the entrance) in order to make not visible the huge amount of hosted refugees (16.7% of its population according to the last UNHCR registration).

In recent years, a growing number of refugees arrived also to Europe and several countries are struggling in processing the high number of applications for international protection. The 2018 was a peak year in Europe, following the preceding 5 years of steep increase. Eurostat database counts for 1,127,690 new refugees in EU-28 at 31st December 2018 (up to 1,635,289 considering also holders of subsidiary protection), of these 662,954 were hosted in Germany (up to 888,016 including subsidiary protection). Recently emerging conflicts in West Asia and in several African countries make reasonable to think that these flows and stocks will increase rapidly in the next future.

While there are several academic and institutional studies on the quality of life and refugees' vulnerability in medium-low income countries, mostly on Lebanon and Jordan (e.g. [11, 5]), very few studies deal with the vulnerability of refugees and asylum seekers in Europe (see e.g., [2, 3, 8, 9, 10]).

In 2017 the UNHCR [13,14] developed the Vulnerability Assessment Framework (VAF). It is a scoreboard for targeting individuals for intervention. VAF encompasses 10 thematic areas, through 65 indicators, covering a wide spectrum of needs of refugees in camps (health, shelter, food security, documentation, education, economic deprivation, etc.). Noteworthy the UN's VAF hardly fits in high income countries where the dimensions of vulnerability go beyond that of basic needs.

Although this growing literature, still little has been done to study the vulnerability of refugees and asylum seekers in high-income countries. In qualitative study [2] on Iraqi and Iranian refugees in Greece, the authors discuss about adequacy of several indicators for measuring vulnerability at household and individual level; [3] measures vulnerability among refugees and asylum seekers living in informal settlements in Italy; [4] focuses on the assessment of the environmental health conditions and associated vulnerability of migrant residents in the Calais (France) refugee camp, analysing a set of indicators but not providing a synthetic measure of multidimensional vulnerability; [9] focuses on two health outcomes of forced migrants living in informal settlements in Italy and find that they are associated with both personal and settlement characteristics. None of these studies (except [3]) takes into account the correlations between items of vulnerability, which introduce a "double counting/weighting" effect in the measurement of vulnerability.

We propose a measure of vulnerability of refugee communities in high-income countries that deals with this correlation by modelling the joint probability of

experiencing interdependent risks. Our analysis focuses on Germany, since it is the 5-th hosting countries for refugees worldwide ([15]) and first in Europe.

In the following, we first briefly introduce our theoretical and then statistical model along with data on refugees living in Germany, then we discuss some results (primarily our vulnerability scale) and reflections on future research paths.

2 Models and Data

The Theoretical Model. Vulnerability is the "*state of high exposure to certain risks, combined with a reduced ability to protect or defend oneself against those risks and cope with their negative consequences*" ([12], p. 210). Our theoretical framework acknowledges that these risks are often highly interrelated, producing a cumulative disadvantage that goes beyond the sum of parts. In the context of high income countries, particularly Germany (the European country with the highest presence of refugees), where basic needs are usually provided to refugees under the mandate of the Genève Convention, we assume that main risks are those of social isolation, economic deprivation and bad health.

The Statistical Model. In order to accomplish for the interdependence of these risks, we estimate a trivariate logit model to evaluate how individual and household characteristics are associated with the probability of experiencing each risk, and make inference also on the residual association between pairs of risks, conditionally to a set of selected covariates. Hence, we jointly model: a) the univariate marginal distribution by assuming a linear model for each logit in equation (1), where Y_1 is the outcome variable "social isolation" (that is: feeling very/often socially isolated), Y_2 refers to "perceived economic difficulties" (i.e. being very/somewhat concerned about finances) and Y_3 to "bad health" (i.e. reporting poor or bad health); and b) the marginal association between each pair of responses, modelled by a set of odds ratios described in equation (2). We include a core set of variables explaining all the observed outcomes (household composition -size and marital status-, education -three levels-, employment -yes/no/seeking-, years since migration, having any form of international protection- and nationality groups- most likely to remain (Afghans, Syrians, Eritreans, Iraqis) vs. others-) and specific sets pertaining to each single risk Y_k (frequency of social relations, knowledge of German language, health problems limiting social relations for Y_1;allowances and benefits received, disability for Y_2; physical and mental health impairments-four variables- for Y_3) The whole matrix of covariates is here referred as *Z*.

The model for the risk of social isolation particularly includes language skills, social network and health measures; the risk of perceived financial difficulties is modelled including also benefits dependence, health and quality of housing measures, the one for the risk of bad health includes quality of housing and state benefit dependence.

Data are from the IAB-BAMF-SOEP Survey of Refugees in Germany that is a longitudinal survey of people who entered Germany between 2013 and 2016 and applied for asylum, whatever the result of the application. It includes information on individual socio-demographic characteristics and household level information.

The survey is provides yearly interviews of household members aged 18 and over. We exploit the first wave of the survey (2016). Our sample is made of 3,072 adults, with a prevalence of men (62%), a mean age of 33.6 years, with four nationalities (Afghan, Eritrean, Iraqi, and Syrian) accounting for about 82% of the sample. Among them, only 59% were granted any form of international protection - refugee status (73.66%), international protection, status of tolerance- while the remaining 41% is lacking of this status (among these 85.67% are asylum applicants with a pending request).

$$\log \frac{\Pr(Y_k = 1)}{\Pr(Y_k = 0)} = -\gamma_k + z_k^{'}\tau_k \qquad k=1, 2, 3 \qquad (1)$$

$$\lambda_{hk} = \log \frac{\Pr(Y_h = 1, Y_k = 1 \mid z)\Pr(Y_h = 0, Y_k = 0 \mid z)}{\Pr(Y_h = 0, Y_k = 1 \mid z)\Pr(Y_h = 1, Y_k = 0 \mid z)} \qquad \forall\, h, k \in \{1,2,3\} \qquad (2)$$

3 The Vulnerability Scale

Results from the trivariate logit reveals a significant conditional association between the three risks supporting the hypothesis of interdependent risks. Particularly, from equation (2): $\lambda_{y_1y_2}|z = 2.11$, $\lambda_{y_1y_3}|z = 1.31$, $\lambda_{y_2y_3}|z = 1.46$ are all statistically significant at 1%.

A useful by-product of the model in Section 2 are the predicted probabilities of experiencing one, two or three risks jointly (p_{ihk}). Hence, for each individual we can estimate 2^3 different probabilities, corresponding to the combination of presence/absence of three dichotomous risks. Table 1 provides a synthetic tools for grading risks, assumed as measures of different levels of vulnerability. It shows mean estimated probabilities over the selected sample and their standard deviations for each vulnerability profile, defined, in the second column, in terms of presence (1) or absence (0) of each of the three risks.

Mean probabilities in Table 1, column 3, can be assumed also as a measure of the (model) predicted incidence of each of eight vulnerability profiles, while categories introduced in column 1 can be used as a criterion for prioritizing interventions. The condition of severe vulnerability refers to a very small amount of individuals who may be the target for the very first intervention. On the opposite side of our scale, the level of low vulnerability may concern about 15% of individuals and, in this case, less (or no special) aid is presumably needed. Comparing the other different levels of our vulnerability assessment scale, the

highest probability is associated with economic deprivation that, controlling for the other two risks, has a mean value of 0.54. Other conditions have probabilities relatively low, not exceeding 10%.

Table 1: Vulnerability scale

Level of Vulnerability	***Isolated-deprived-bad health***	***Mean p_{ihk}***	***Standard Dev.***	***Min***	***Max***
Severe	111	0.019	0.035	0.000	0.470
High	101	0.018	0.030	0.001	0.336
	110	0.069	0.044	0.001	0.395
	011	0.074	0.111	0.002	0.633
Moderate	100	0.099	0.049	0.003	0.420
	010	0.536	0.172	0.010	0.925
	001	0.031	0.049	0.000	0.339
Low	000	0.154	0.060	0.004	0.434

The upper tail (last decile) of the distribution of p_{111} (the joint probability of experiencing all three risks, i.e. the condition of severe vulnerability) may be assumed as the target population for more urgent policy intervention. In this group about 64% have no international protection; 60.26% have no education and 28.66% have higher education; 78% live in household with 4 or less members; 57.65% has at least one child in the household.

4 Conclusion

Refugees can experience vulnerability in country of origin, while they are on route or in the destination country, which has a responsibility in the infringement of migrants' human rights and on migrant's welfare standards and social inclusion ([1]). In this paper, we propose a new approach for measuring vulnerability of refugees and asylum seekers, by means of the estimated joint effect of three risks they can experience in hosting high-income countries (social isolation, economic deprivation, bad health).

Although international laws recognize all refugees as vulnerable *per se*, an emerging strand of literature argues that once arrived in hosting countries, and assisted by welfare state, not all refugees are still vulnerable (see the Judge Sajo's dissenting opinion [6] against the European Court of Human Rights' qualification of asylum seekers as a particularly underprivileged and vulnerable population *per se*).

Our empirical appraisal to analyse vulnerability allows for partitioning refugees hosted in high income countries, and supported by welfare states, in some selected subgroups according to their vulnerability profiles. They should be the targeted for early interventions. Even if not considered here for the sake of brevity, it is possible to detect what risk/s is/are more likely to make them more exposed, hence more vulnerable, allowing addressing interventions toward specific hampering conditions.

Indeed, factors predicting vulnerability often change depending upon the way in which vulnerability is measured. Scoreboard approaches, ignoring the double counting effect implied by adding highly interdependent factors of risks (such as it is the case for the VAF exercise), may not provide a correct priority ranking of people needing aid.

Our approach can be extended in several directions. First of all, intensity of risk can be modelled by using a set of ordered rather than binary discrete risk indicators. Secondly, residual association can be allowed to depend also on a set of covariates, capturing in this way a sort of "propagation" effect between risk dimensions.

Active ageing in China: What are the domains that most affect life satisfaction in the elderly?

Invecchiamento attivo in Cina: Quali domini influenzano maggiormente la soddisfazione per la vita negli anziani?

Ilaria Rocco

Abstract Given the rapidly increasing life expectancy in China, more attention has recently been focused on the concept of active ageing as a more appropriate goal for policymakers and on the importance of monitoring its changes over time. The aim of the present work is to further explore the domains of the Active Ageing Index taking into consideration the perspectives of older persons.
The analysis was carried out utilizing the data produced by the fourth wave of the "China Health and Retirement Longitudinal Study". Generalized Structural Equation Model was applied to investigate the implications of the dimensions of active ageing on the perceived life satisfaction and to identify the domains more urgently requiring interventions.
Abstract *Dato il rapido incremento della speranza di vita in Cina, una attenzione crescente da parte della letteratura è stata dedicata al processo di invecchiamento attivo come obiettivo prioritario per i responsabili politici e al monitoraggio dei suoi cambiamenti nel tempo. Il presente lavoro è volto ad approfondire i domini dell'Active Ageing Index prendendo in considerazione la prospettiva delle persone anziane. L'analisi è stata condotta utilizzando i dati prodotti dalla quarta rilevazione dell'indagine "China Health and Retirement Longitudinal Study". È stato applicato un modello ad equazioni strutturali generalizzato per studiare l'implicazione delle dimensioni dell'invecchiamento attivo sulla soddisfazione percepita e per identificare i settori che richiedono interventi più urgenti.*

Key words: Active ageing, life satisfaction, elderly

Ilaria Rocco, Dipartimento di Scienze Statistiche, Sapienza Università di Roma; Istituto di Neuroscienze, CNR, Padova; email: ilaria.rocco.90@gmail.com

1 Introduction

Due to the dramatic decline in fertility rates and the rapid increase in life expectancy, the world's population is quickly growing older. This is particularly true in China, where those aged 65 and older make up 12% of the population and will probably make up 26% by 2050 [9].

A rapidly increasing life expectancy can be considered a positive step forward only if the additional years are characterized by good health and a satisfactory quality of life. If that is the case, human beings will be able to look forward to growing old if governments, international organizations, and the civil society promote "active ageing" policies and programmes that enhance the health, participation and security of older citizens [10].

The World Health Organization (WHO) adopted the term "active ageing" in the late 1990s to convey a more inclusive message with respect to "healthy ageing" and to recognize the factors in addition to health care that affect how individuals and populations age [5]. In 2002, the WHO defined it as "the process of optimizing opportunities for health, participation and security in order to enhance quality of life as people age" since it was sure that applying an active ageing framework onto a healthy ageing promotion program could more effectively solve the challenges of an ageing population [10].

Based on the WHO's definition of active ageing, in 2012 the United Nations Economic Commission for Europe experts developed the Active Ageing Index (AAI) as a tool to measure and monitor active ageing [11]. The AAI covers four domains of active ageing: employment, social participation, independent/health/secure living, and capacity and enabling environment. It includes 22 indicators collected from different questionnaires with scores ranging from 0 to 100, with the latter representing the best possible result. The index has been used in 28 European countries [11] and has recently been adopted by other countries, including China [12] where the overall AAI score in 2014 was 37.3, which was higher than the EU average (33.9).

According to its developers [11], the index has the following advantages: it is an appealing list of factors offering several analytical possibilities; it is useful for evaluating "the untapped potential of older people" in each country; it enables disaggregating the overall indices into domain-specific ones; it facilitates numerical interpretation for use by a wide audience.

Although the AAI is one of the main tools for monitoring active ageing policies particularly in the European context, several limitations in its construction and interpretation have been identified. A study argued that the AAI is an incomplete tool for policymaking purposes, since policymakers cannot be sure whether they should promote certain activities because the AAI does not clarify to what extent these activities are valued by older people or the degree of freedom they have in achieving valuable "doings and beings" [8].

The aim of the present work is to further explore the domains of the AAI in an "emic perspective", that is taking into consideration the perspectives and preferences

of older persons [4] so as to investigate which dimensions of active ageing influence more individual's overall life satisfaction.

2 Data and methods

The analysis of active ageing domains was carried out utilizing the data of the sample survey on "China Health and Retirement Longitudinal Study" (CHARLS), a biennial multistage longitudinal survey investigating the middle-aged and older population collected by the National School for Development (China Center for Economic Research) together with the Institute for Social Science Survey at Peking University. After a pilot study examining 2 provinces in 2008 [2], the baseline national wave of CHARLS was fielded in 2011; it included about 10,000 households and 17,500 individuals in 150 counties/districts and 450 villages/resident committees. We focused on the fourth wave which was carried out in 2015 and gathered data about 21,095 individuals. The present work was particularly interested in the respondents aged 65 years and above.

Life satisfaction was evaluated through the question: "How satisfied were you with life as a whole?" answered using a 5-point Likert scale. This single item to measure life satisfaction was proved to be a reliable and valid method and was widely used [1, 3].

The dimensions of the active aging considered were those from the original AAI [11]. However, not all the variables used to operationalize the dimensions in the original index were included in the measurement model: four variables were not available or computable in CHARLS dataset (i.e. physical exercise, relative median income, remaining and healthy life expectancy); the lifelong learning was available but not included due to the low percentage in the sample (<1.0%); the educational attainment, that referred to the past history of the elderly, was not suitable of variation, hence it was used as control variable with age and gender.

The "Employment" (EMP) domain of the AAI framework was represented by the employment status. We defined as employed people who were engaged in agricultural work or worked at least one hour the week before the interview.

The "Participation in society" (PIS) domain included the participation in voluntary activities; the provision of care to children/grandchildren; the provision of care to older adults or disabled relatives; the participation in political activities.

The "Independent, healthy and secure living" (IHSE) domain was measured considering: access to health care, independent living arrangements, poverty risk, material deprivation and physical safety.

Finally, the "Capacity and enabling environment for active ageing" (CEE) domain included: mental wellbeing, use of ICT, and social connectedness. The description and the percentage distribution of the variables used to measure each domain are reported in Table 1.

In order to test the viability of the AAI framework, a confirmatory factor analysis was conducted on each of the four above-described domains. To estimate

the effect that the AAI domains have on the individual quality of life, the Structural Equation Modelling (SEM) approach was adopted.

SEM is a very general statistical modelling technique, widely used in the behavioural sciences, which combine the strengths of factor analysis and multiple regression in a single model that can be tested statistically.

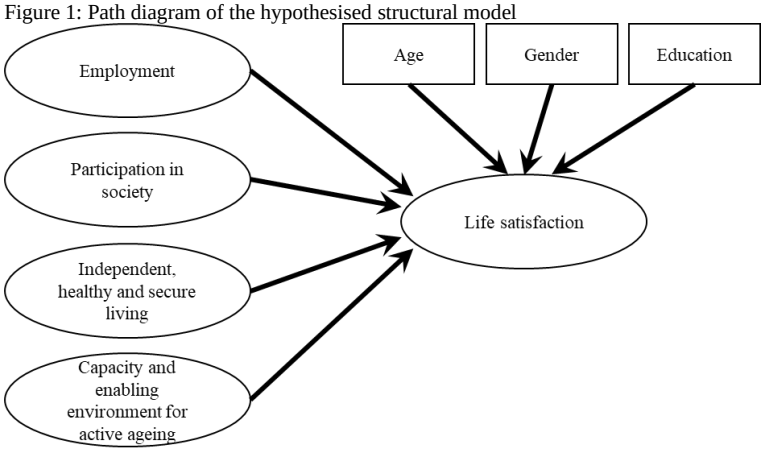
SEM has been further extended to the generalized form (GSEM) for the evaluation of categorical and time-to-event outcomes [7]. In this work, the model was analysed using the ordinal distribution and logit link.

The model consisted of two parts: the measurement model, where the four AAI domains were reflected by their respective variables [6]; and the structural model (in Figure 1) representing the relationships between the AAI domains and the life satisfaction. Age, gender and education were included as control variables. Weighted data have been used to account for sampling design.

The statistical analyses were performed using the SAS 9.4 software (SAS Institute, Cary, NC, USA) and Stata version 13 (StataCorp, USA).

Although 21,095 individuals were surveyed in the 2015 CHARLS study, 5,508 respondents were 65 or older, had complete data on satisfaction variables and valid individual sample weight: 49.4% were men, the mean age was 72.0 years (SD = 5.8) and 10.6% completed at least high school. Only 7.7% of the respondents were not very satisfied or not satisfied at all, while 43.0% were completely or very satisfied.

Figure 1: Path diagram of the hypothesised structural model



3 Results and preliminary conclusion

The results of the GSEMs estimation are reported in Table 1. It emerged that two AAI domains (EMP and PIS) do not have a significant effect on the perceived life satisfaction (p-value>0.05).

Table 1: Description and percentage distribution of the variables used to measure each AAI domain. Estimate (coefficient and p-value) of the measurement and structural model

Measurement model				
Domain	Variables (Description)	%	Coef.	p-value
EMP	Employment status (% Engaged in agricultural work; or Worked at least one hour last week)	38.5	-	-
PIS	Participation in voluntary activities (% Provided help to family/friends/neighbours; or Did voluntary or charity work)	10.5	0.2088	<0.001
	Provide care to children/ grandchildren (% Provided care to children/ grandchildren)	33.4	0.0355	<0.001
	Care to older adults or disabled relatives (% Provided care to older adults or disabled relatives)	2.1	0.0390	<0.001
	Participation in political activities (% Went to a sport, social, or other kind of club; or Took part in a community-related organization)	10.0	0.0719	<0.001
IHSL	Access to health care (% have access health care when ill last month, or who had not accessed health care but this is not due to poor delivery or provision of care)	96.3	0.0432	<0.001
	Independent living arrangements (% who live alone or in a couple)	78.8	0.0993	<0.001
	No poverty risk (% had a household income above the median income (=9000 yuan))	49.9	0.1099	<0.001
	No severe material deprivation (% had at least one of the following equipment: refrigerator, washing machine, TV, air conditioner.)	89.3	0.0889	<0.001
	Physical safety (% did not feel fearful most of the time (5-7 days))	95.1	0.0646	<0.001
CEE	Mental wellbeing (% had good mental wellbeing)	77.3	0.2844	<0.001
	Use of ICT (% Used the Internet)	3.6	0.0146	<0.001
	Social connectedness (% Interacted with friends or Played Ma-jong/chess/cards, or went to community club)	42.3	0.0353	0.002

Structural model			
Path	.	Coef.	p-value
Age → Life Satisfaction		0.0247	<0.001
Gender (ref: Male) → Life Satisfaction		0.1333	0.018
Education (ref: Up to lower secondary) → Life Satisfaction		-0.4532	<0.001
EMP → Life Satisfaction		-0.0285	0.627
PIS → Life Satisfaction		0.0690	0.091
IHSL → Life Satisfaction		0.3458	<0.001
CEE → Life Satisfaction		0.6296	<0.001
Cutpoints	c1	-2.3316	<0.001
	c2	-0.7822	0.049
	c3	2.2135	<0.001
	c4	4.7619	<0.001

The IHSL and CEE domains positively affect how older people perceive their life satisfaction. Therefore, the most important aspects for active ageing are: the mental wellbeing, the independence, both in term of financial resources and living arrangement, the safety, and the accessibility of the health care needed.

The application of SEM was able, taking into account several latent dimensions, to simultaneously estimate the implication of the active ageing dimensions on the perception of the individual life satisfaction. This exploration of the domains in an "emic perspective" has revealed that not all the dimensions included in the AAI affect the individual's perception of life. Therefore, this allowed the identification of the two domains in which there is a real need felt by older people for an urgent intervention that mobilizes them to make their "contributions" to the respective societies.

Analyzing the waiting time of academic publications: a survival model

Un modello di sopravvivenza per i tempi di accettazione delle pubblicazioni accademiche

Francesca De Battisti, Giuseppe Gerardi, Giancarlo Manzi, Francesco Porro

Abstract In this paper a survival model is used to perform an analysis of the waiting time to publication for academic articles. The model is a multilevel excess hazard model and it allows to include non-linear and non-proportional effects of the covariates. The analysis is performed by considering covariates at two levels: the first one is the article level, the second one is the journal level.

Abstract *In questo articolo viene utilizzato un modello di sopravvivenza per effettuare un'analisi del tempo di attesa per la pubblicazione di articoli accademici. Il modello utilizzato é un modello multilivello con excess hazard che permette di includere effetti non lineari e non proporzionali delle covariate. L'analisi é condotta considerando covariate a due differenti livelli: articolo e rivista.*

Key words: Peer review, Waiting times, Net survival, Excess hazard model

1 Introduction

The topic of waiting time in academic publication decisions is very relevant and interesting. The overall process of submission, especially for top-level journals, and any required revisions is such that many months, if not years, must pass between the submission and the acceptation of an article, if ever there will be one. De Battisti and Manzi [4] put forward some considerations on such issue, and suggested to apply multilevel models to find determinants affecting the waiting time until acceptance. The aim of this paper is to extend these considerations by carrying out a multilevel excess hazard model to analyze the waiting time to publication, working on the hierarchical data. We propose to consider the waiting time for academic publication as survival time, with article as units of interest, and model the effects of potential explanatory factors.

2 The methodology

Survival analysis typically considers the time until an event occurs. We usually refer to the time variable as *survival time*, because it measures the time that an individual has survived over a certain follow up period. We also usually refer to the event as a failure, because the event of interest usually is death, disease incidence, or any other negative individual experience. However, survival time may be for example the time to return to work after an elective surgical procedure, in which case failure is a positive event. As argued in [2], in the context of survival analysis, "the main survival indicator when comparing populations is net survival, that is, the hypothetical survival that patients would experience could they die only from their cancer ([3], [6])". In the general case, beyond the medical framework, the net survival refers to the occurrence of the event under study only because of specific causes. Moreover, the net survival is estimated comparing the all-cause hazard of death experienced by the patients to the general population from which the individuals come. One of the approaches proposed in literature to estimate net survival is modelling the excess hazard (see [2], [5], [7]). Starting from these proposals, in [2] a methodology to estimate an excess hazard regression model with non-linear and non-proportional effects due to the covariates and including a random effect is developed. The excess hazard approach is based on the assumption that the total hazard of the event occurrence, denoted by $\lambda(t,\mathbf{x},\mathbf{z})$, can be decomposed into the sum of a cause-specific hazard, denoted by $\lambda_+(t,\mathbf{x})$, and a hazard due to all the other causes, denoted by $\lambda_P(a+t,\mathbf{z})$ (the latter being usually estimated from general population life tables in the case of death). This means that:

$$\lambda(t,\mathbf{x},\mathbf{z}) = \lambda_+(t,\mathbf{x}) + \lambda_P(a+t,\mathbf{z}),$$

where $\mathbf{x}$ is a vector of prognostic variables, $\mathbf{z}$ is a vector of demographic characteristics, and a is the age at the diagnosis, so that $a+t$ denotes the age at death or at

censoring. The excess hazard is associated with the net survival through the classical relationship between hazard and survival function:

$$S(t) = \exp\left(-\int_0^t \lambda(v)dv\right).$$

Moreover, in [2] a multilevel excess hazard model is proposed. For each individual (or unit) j (with $j = 1,...,n_i$) from cluster (or group) i (with $i=1,...,D$), let t_{ij} denote the observed time-to-event and δ_{ij} be an indicator variable taking the value 1 in case of the event occurrence and 0 in case of censoring. Then the total hazard is:

$$\lambda(t, \mathbf{x}_{ij}, \mathbf{z}_{ij}, w_i) = \lambda_+(t, \mathbf{x}_{ij}) \exp(w_i) + \lambda_P(a+t, \mathbf{z}_{ij}), \quad (1)$$

where w_i denotes a random effect at the cluster level. This model allows to introduce multiple covariate effects. For example, by expressing $\mathbf{x}_{ij}$ by its components, i.e. $\mathbf{x}_{ij} = (x_{1,ij}\ x_{2,ij}\ x_{3,ij})$, the following formula:

$$\log(\lambda_+(t, \mathbf{x}_{ij})) = \log(\lambda_0(t)) + \beta \cdot x_{1,ij} + f(x_{2,ij}) + g(t) \cdot x_{3,ij}$$

represents the logarithm excess hazard, with a linear and proportional effect related to $x_{1,ij}$, a non-linear and proportional effect due to a continuous function f of $x_{2,ij}$, and a non-proportional (time-depending) effect due to $x_{3,ij}$.

3 The dataset

The dataset used in this application is formed by 3489 published papers between 2011 and 2016 in the following top-level statistical journals: *Journal of Statistical Software* (J Stat Softw), *Fuzzy Sets and Systems* (Fussy Set Syst), the *Journal of the Royal Statistical Society - Series A - Statistics in Society* (JRSSA), the *Journal of the American Statistical Association* (JASA), the *Annals of Probability* (Ann Prob), the *Journal of Business Economic Statistics* (JBES), *Advanced in Data Analysis and Classification* (ADAC), and *Biostatistics*. The distribution of the articles is described in Table 1. We apply survival analysis on the waiting time of academic

Table 1 Distribution of articles across journals

J Stat Softw	UCLA Dept.Stats	USA	AUT, SWI, GER	386 (11.06%)

publications, namely the time that elapses between the submission and the publication of an article in a journal. More in details, for each article (uniquely identified by the Document Object Identifier - DOI) the waiting time (variable *Age*, in days) is calculated as the difference between the date of the acceptance when this was available (otherwise the date of the online publication or the date of the final revision) and the date of the submission (always available). The covariates considered in this application and their meanings are:

- *Bayes*: dichotomous variable (1=Bayesian article, 0=otherwise);
- *Month Scopus cit*: the average monthly number of Scopus citations per article;
- *Avg h Index*: the average *h* index of the authors;
- *Junior less 5*: dichotomous variable (1=if the Scopus *h* index of one of the authors is lower than 5, 0=otherwise);
- *Senior more 20*: dichotomous variable (1=if the Scopus *h* index of one of the authors is greater than 20, 0=otherwise);
- *Number author*: number of the authors;
- *USA all*: dichotomous variable (1=if all the authors are affiliated to US institutes, 0=otherwise);
- *USA*: dichotomous variable (1=if at least one author is affiliated to an US institute, 0=otherwise);
- *Same country*: dichotomous variable (1=if all the authors are affiliated to institutes in the same country, 0=otherwise);
- *Same nationality eds*: dichotomous variable (1=if the institutions of the most important author and of the journal editor have the same nationality, 0=otherwise);
- *Age journal*: age of the journal since its first issue;
- *IF*: the 2017 Thomson Reuters impact factor;
- *AI*: the AI index (Article Influence index) that measures the average influence of an article over the first five years after publication.

It is worth remarking that the last three variables refer to the journal level, that is they are second-level variables, meaning that they assume the same value for all the articles published in the same journal. The application of the survival analysis to this particular context requires some adjustments. First, our data refer only to published paper, not to all the submitted papers. For this reason, the event of interest (publication) occurs after a reasonable period of time for all our observed units. This is different from the usual case, in which individuals can be dead or alive at the end of the study period. In order to have a situation similar to the classical one in survival analysis models, we have to censor the data: we have to choose a time interval (which corresponds to the follow up period) to evaluate whether the article is published or not. In this way, it is possible to model the article waiting time. All the articles with a waiting time to publication (variable *Age*) greater than 3 years are censored. For these articles the variable δ (the indicator variable mentioned in Section 2) is set equal to 0. We selected the value of 1095 days (3 years) in order to have a restrained percentage (less than 5%) of censored articles. In this way, the censored articles represent the 4.39% of the total number of articles. The average of the waiting time (with censored data) is 451.49 days, the median is equal to 397.

4 Results and discussion

We applied the mixed effect excess hazard model described in (2) to the aforementioned dataset. We consider the 3489 articles as units, clustering them by the corresponding journal. In this work, following [2], we focus on the excess hazard function $\lambda_+(t,\mathbf{x}_{ij})\exp(w_i)$ of formula (2), and we assume a normal distribution of the random effect w, with zero mean and standard deviation σ.
The aim of this analysis is to identify which variables have a relevant impact on the waiting time to publication. We ran more than one hundred models, by setting different kinds of effect for each covariate. The calculations have been performed by using the R package *mexhaz* (Mixed Effect Excess Hazard Models). Such package provides estimates by MLE method, throught the implementation of numerical methods. We considered the following types of effects: linear and proportional, linear and non-proportional (that is, time-depending), non-linear and proportional, and non-linear and non-proportional. As suggested in [2], the logarithm of the baseline excess hazard and the functions (of time) for the time-dependent effects are modelled by cubic B-splines with two knots at 365 and 1094 days, respectively. For explicative purposes, in the following we report three models with a hierarchical level of complexity:

- Model 1: the effects of all the covariates are linear and proportional;
- Model 2: the effects of the covariates *Avg h Index*, *Number authors*, *IF*, *Age journal* and *AI* are linear and non-proportional. The effect of all the other covariates are linear and proportional;
- Model 3: the effects of the covariates *Avg h Index*, *Number authors*, *IF Age journal* and *AI* are non-linear and non-proportional.The effect of all the other covariates are linear and proportional.

The fittings of the three models are compared by using the Akaike Information Criterion (AIC), (see [1] for details). Table 2 reports the parameter estimates (and their standard errors) for the covariates with linear and proportional effects. For each model also the AIC index is reported. The model with the best fitting is Model 2, and, for this model, the highest Hazard Ratio (HR) is the one related to the covariate *Same nationality eds* and it is given by

$$HR_{Same\ nationality\ eds} = e^{0.064} = 1.066.$$

This value shows that if the nationality of the main author of an article is the same of the journal editor, the hazard rate is, *ceteris paribus*, higher than otherwise: this implies that in this case the waiting time to publication is smaller. Similarly, all other conditions being equal, articles with all US authors present a smaller waiting time than the others, since the corresponding HR is equal to

$$HR_{USA\ all} = e^{0.03} = 1.03.$$

Conversely, the model shows that articles with at least one author affiliated to an US institution, experience a higher waiting time than those with no author affilied to an

Table 2 Parameter estimates and the corresponding AIC for the three models

Variable	Model 1 AIC=45237.52	Model 2 AIC=45002.07	Model 3 AIC=45266.02

AI	-0.277 (0.051)	LIN-NPH	NLIN-NPH
Standard deviation σ	1.698	1.723	2.758

US institution, everything else being equal, as the HR for the variable *USA* is

$$HR_{USA} = e^{-0.064} = 0.938,$$

therefore teams with all US members seem to be more successful than mixed ones.

Clustering of food choices in a large sample of students using university canteen

Profili di scelta rispetto alla composizione del pasto in un campione di studenti che utilizzano le mense universitarie

Valentina Lorenzoni, Isotta Triulzi, Irene Martinucci, Letizia Toncelli, Michela Natilli, Roberto Barale, Giuseppe Turchetti[1]

Abstract In view of the crucial role eating habits represent in academic life and in the development of obesity and chronic condition, both forthwith and in the future, the present study aim at detecting eating choices in a large sample of students accessing canteens serving the University of Pisa, Italy. Based on the frequency of food groups' choice evaluated from cashier transaction and a model-based clustering relying on the beta distribution, 5 different mixture components were identified and each assimilated to a specific behaviour towards food choice. The mixing proportion estimated suggested that the mixture resembling "healthy choice" comprises about 11.2% of the study population while component resembling students with limited choice of vegetables and fruits were the most represented.

Abstract *Dato il ruolo delle abitudini alimentari nella vita accademica e nello sviluppo dell'obesità e delle malattie croniche, il presente studio mira a raggruppare le scelte alimentari in un ampio campione di studenti che utilizzano le mense dell'Università di Pisa. Utilizzando la frequenza di scelta dei cibi rilevata automaticamente dalle transazioni e un metodo di clustering basato sulla distribuzione Beta, sono stati identificate cinque misture assimilabili a diversi "profili" di scelta. Tra queste quella che identifica scelte salutari rappresenta appena rappresenta appena l'11,2% della popolazione in studio, mentre maggiormente rappresentati sono i sottogruppi caratterizzati da una scelta poco frequente di verdure e frutta.*

Key words: eating habits, food choices, university students, mixture models

Introduction

During the university period students are exposed to radical changes and to high risk of adverse health behaviours, being less influenced by parents while tending to comply with the behaviour of their peers (Kandiah et al., 2006; Vella-Zarb and Elgar, 2010).

In particular, a branch of literature suggested unhealthy eating and lifestyle habits among university students also associated with increasing prevalence of overweight and obesity(Kapinos et al., 2014; Nelson et al., 2008). Unhealthy eating behaviours that developed during this period may persist into adulthood thus carrying out potential health consequences in the short and long-term; forthwith habits acquired may also interfere with academic achievement and student' retention.

In this context, universities (and their facilities) while playing a pivotal role in improving student engagement also represent a suitable context for the promotion of students' health, appropriate lifestyle with the opportunity to prevent disease and future consequence (Guagliardo et al., 2011; Lupi et al., 2015; Nelson et al., 2008).

Accordingly, this study aims at providing empirical evidence about food choices in a large sample of students using university canteens serving the University of Pisa (Italy) on the basis of data automatically collected from cashier transactions.

Study population and data

This work is part of part of the RASUPEA project: "Le mense Universitarie: ricerca sulle abitudini alimentari dei giovani e d'educazione e prevenzione alimentare". The project was supported by a grant of the PRAF 2012-2015 REGIONE TOSCANA program of the Tuscany Region and aimed at evaluating eating habits and their correlates with gastrointestinal disorders among students enrolled at the University of Pisa, Central Italy.

The population under study is composed of students enrolled in courses at Pisa University who access canteens serving the university of interest in the academic years from October 2015 to September 2016.

Analyses were performed using the database of the Azienda Regionale per il Diritto allo Studio Universitario (DSU) that contained records about all of consumed meals.

Analysis of eating choices was allowed by the fact that canteens serving the University are equipped with an automatic system that records detailed data about

each meal transaction: date and hours, number and type of dishes, student ID and price applied. All these data are collected into a dedicated Oracle database owned by the DSU that whose used in the present analysis to extract records about meal consumption.

On the basis of dish details, foods were classified according the main dish components mainly according to the coding system established by the Eurocode (Ireland and Møller, 2000) and adding fried foods, pies and omelettes as representing "fatty foods" and also pizza and sandwich because identifying a habit related to a quick meal. Accordingly, eleven different food groups were identified and used in the analyses: (1) grains, (2) miscellaneous and soups, (3) meat, (4) fish, mollusks, crustaceans and their products, (5) vegetables, (6) potatoes, (7) fruits, (8) pulses, (9) sugar products, chocolate products and confectionery, (10) fried foods, pies and omelettes, (12) sandwiches and pizza.

Statistical analyses

The frequency of different food-groups consumption was described in terms of the number of times the specific food group is selected over the total number of access.
Given the nature of those variables, constrained in the [0,1] interval and highly skewed, a model-based clustering relying on multivariate beta distribution (Dean and Nugent, 2013) was used to detect different food choices.

Model-based clustering (MC) is a particular approach of cluster analysis, MC is based on finite mixture models and allows for the automatic selection of the number of clusters (Fraley and Raftery, 2002; McLachlan and Peel, 2000).
According to the general notation used in the MC approach, a set of observations on j variables $X = \{x_1, x_2, \ldots, x_j\}$ is assumed to be made of independent and identically distributed samples from some unknown population density $f(x)$ where each group g in the population is represented by a mixture component $f_g(x)$. The population density could thus be assumed as a weighted mixture of these components

$$f(x) = \sum_{g=1}^{G} \pi_g \, f_g(x; \theta_g)$$

where π_g represents the probability of belonging to group g, so that $0 \leq \pi_g \leq 1$ and $\sum_{g=1}^{G} \pi_g = 1$.
Parameter of the mixture model were estimated using the expectation-maximization (EM) algorithm (Dean and Nugent, 2013). The number of G mixtures (i.e., clusters) better fitting data could then be chosen on the basis of the Bayesian Information Criterion (BIC) and modified Integrated Completed Likelihood alternative, BIC-ICL (Bertoletti et al., 2015; Dean and Nugent, 2013).
Each observation was assigned to the component (representing a different eating profile) on the basis of the highest posterior probability of membership.
All analyses were performed using R version 3.3.3.

Main results

The study population consisted of 4,643 students for whom more than 200 thousand meals consumed in between October 2015 and September 2016 were analysed.

In the study group mean age was 23.6±3.6 years and more than half of the students were male (n=2,786).

Overall, frequencies of food-group choices suggested that grains were the most frequently selected to compose the meal, meat and fried food were included in 1/3 of meals each, similarly vegetable and fruit that were chosen in less than 40% of accesses (Table 1).

Table 1: Frequency (as percentage) of food-group choice in the study group

	Median [25-75perc]
Grains	67.9 [43.8-87.5]
Miscellaneous and soups	0.8 [0-8.4]
Meat	40.7 [20.8-58.3]
Fish	3.1 [0-8.3]
Vegetables	35.7 [20.2-53.3]
Pulses	3.9 [0-9.1]
Potatoes	17.6 [10-25.4]
Fried foods, pies and omelette	36.4 [22.1-50]
Sandwich and pizza	11.5 [2.6-25]
Fruits	39.8 [16.5-66.7]
Sugar/chocolate products and confectionery	4.7 [0-12.5]

According to BIC and ICL-BIC values five mixture components better fit the data.
The first component (G1) grouped students with healthy eating habits characterized by a varied choice of all the food groups with a frequent selection of vegetables and fruits; the second (G2) and third component (G3) represented students limiting the selection vegetables and fruits in fewer than half of the meals while exceeding in the choice of proteins, fried foods/pies/omelets, sugars/chocolate products and confectionery (G2) or grains (G3); the fourth component (G4) resembles the quick eaters who frequently had meals of sandwiches or pizza. Finally, the fifth component (G5) identified students who usually had a light meal with grains or a main dish (Figure 1).

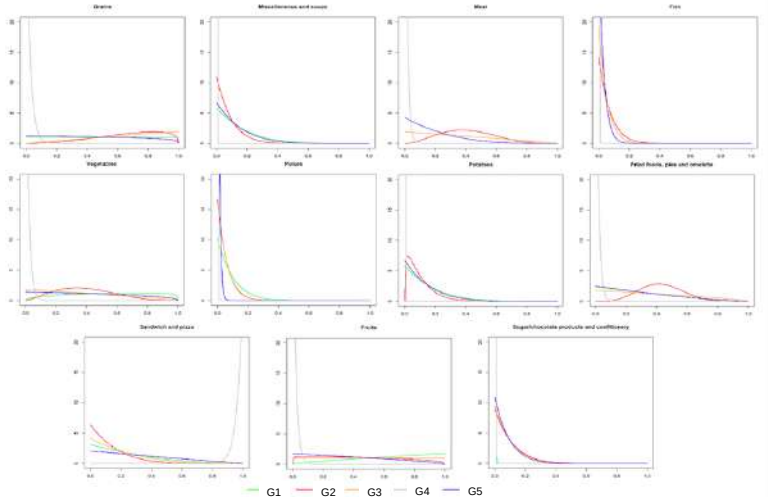

Figure 1: Normalized densities for the five components estimated

The mixing proportion estimated describing the distribution of the diverse eating profile in the study group suggested that G3and G2 were the most represented the study population (42.9% and 32.7% respectively). Healthy eaters were about 11.2% of the study group while he other components, G4 and G5, represented a small proportion of the study population (3.3% and 9.8% respectively).

Conclusions

Findings from the present study outline the relatively low widespread of healthy food choice among university students accessing canteen, while attitudes towards the composition of meal with fatty food is the prevalent behaviour.

Although findings from the present study are limited to students using canteens and could not be immediately extrapolated to the overall group of university students, results are in line with international available evidence on the general population of university students.

Indeed, results corroborate existing evidence and stress the need to implement policies on this “vulnerable” group. Moreover, given the peculiarity of university canteens in Italy that allow students access to meal at relatively limited price, thus guaranteeing access also to healthy food for all category also preventing food insecurity, for the specific context results suggest that allowing students to access healthy foods at affordable price is not sufficient to enable healthy choice rather, inducing changes in individual-making choice require more effort for the design an effective environment enabling consciousness of choices and healthiness.

Cruise passengers' expenditure at destinations: Review of survey techniques and data collection

La spesa dei crocieristi nelle destinazioni: Revisione delle tecniche di indagine e raccolta dati

[1]Caterina Sciortino, [2]Stefano De Cantis, [3]Mauro Ferrante, [4]Szilvia Gyimóthy

Abstract Spending by cruise passengers constitutes an important contribution to the economy of destinations. The issues related to the analysis of the expenditure have been widely debated for many years both in the scientific literature and in the common political debate. Despite 20 years of empirical research on this topic, not consolidated quantification methods exist to inform the debate. This work offers a brief review of the principal research on cruise tourist spending. It analyses the main characteristics of the surveys, reviews the different methods and techniques employed as well as assesses the main results. The article concludes with a discussion of the studies conducted and identifies future research directions.
Abstract *La spesa dei crocieristi costituisce un importante contributo all'economia delle destinazioni. Le questioni relative all'analisi della spesa sono state ampiamente dibattute per molti anni sia nella letteratura scientifica che nel dibattito politico comune. Nonostante 20 anni di ricerca empirica su questo argomento, non esistono metodi di quantificazione consolidati per informare il dibattito. Questo lavoro offre una breve rassegna delle principali ricerche sulla spesa dei crocieristi. Analizzerà le principali caratteristiche delle indagini, esaminerà i diversi metodi e tecniche impiegati e valuterà i principali risultati. L'articolo si conclude con una discussione degli studi condotti e identifica le direzioni di ricerca future.*

1 Introduction

The cruise industry experienced important development in recent years, both in terms of expansion and diversification of the sector and of market volume. Over the last twenty-years, cruise tourism represents one of the fastest growing sectors in tourist field [12].

This work contributes to understanding how cruise passengers' expenses were analysed, from a methodological point of view. This is done by mean of a revision of the survey techniques for collecting information on cruise passengers' expenditure at their destination, implemented in various studies that emerged from the literature on this topic. In particular, this paper aims at critically assessing and improving the tools of data collection on cruise passengers spending and addresses one of the most relevant research questions in this area of study: *How is cruise passengers´ expenditure defined, operationalised and measured in tourism research literature?* In order to consider the most relevant articles dealing with an analysis of the spending behaviour of cruise passengers, the following selection criteria have been applied: studies that deal exclusively with cruise tourism and its economic impact; studies which primary aim was to analyse spending behaviour through interviews with cruise passengers; studies that used questionnaire as empirical data collection method. A better knowledge of the way in which cruise passengers' expenditure can be surveyed in practice represents a crucial step in order to determine the economic impact of the cruise sector in terms of costs and benefits [1].

2 Sampling scheme and Questionnaires

A review of relevant literature from the past two decades (1998-2018) were performed, mainly based on the assessment of three macro-themes (Table 1). The first theme addresses questions related with the definition and operationalization of tourist expenditure; the second one analyses issues in data collection procedures. The third theme focuses on the analysis of questionnaires and related survey techniques.

Table 1: Articles included in the review, by authors, year of publication and journal.

12	Pino J.F.B. & Tovar B.	2019	Tourism Economics

2.1 Defining cruise tourist expenditure

Cruise passengers differ from tourists. Due to the time spent at the destination (from 2-4 to 8-10 hours) they could be considered as same-day travellers. During the stay period, their expenditure is characterized by a high degree of variability which depends, among other things, from the differences between two main categories of cruise passengers: Guided visitors, i.e. those who buy (almost always on board) a tour package (which usually includes entrance to museums and attractions, tour guide services, transportation costs, etc.) and the independent visitors: i.e. those who decide to visit the destination without buying any package, generally with no pre-defined itinerary. According to the UNWTO “visitor expenditure” is defined “as the total consumption expenditure made by a visitor or on behalf of a visitor for and during his/her trip and stay at destination” [13, p.85]. Similarly, we can define the expenditure of an independent cruise tourist at the destination as the total consumption expenditure made by the visitor or on behalf of the visitor during his/her visit at the destination, during the time spent for the visit. We can identify category-specific expenditure as "the total amount spent for one specific category of consumption good": food and beverage, transportation, shopping and souvenirs, etc. It is clear that the concept of cruise tourist consumption expenditure includes a wide variety of items, from the purchase of consumption goods and services related with their visit at the destination to the purchase of small durable goods for personal use and of souvenirs and gifts for family and friends. However, it is not easy to operationalize this definition, due to several issues. One of these issues is related to the size of the group size to which the total expenditure is referred to. Type and amount of expenditure greatly varies according to group composition, also by considering that some types of expenditure may not comprise all the people of the group, and due to the presence of scale economies in the degree of expenditure, which makes an estimate of “per-capita” expenditure difficult to determine.

2.2 Data collection procedure

Data collection is a crucial stage in empirical research. In the context under analysis temporal and spatial dimension must be clearly defined, especially in the implementation of sampling procedure, as a fundamental stage of the research design. The selection of units to be included in the sample is one of the most delicate procedures under the methodological perspective. In the considered research, the sampling procedures used are manifold, for instance, some have endeavored to use rotation samplings [7], others general random sampling [9], while some others opted for a stratified procedure (Table 2). Another aspect to consider is the interview time: it is possible to divide the research into two macro areas: "Cross-sectional analysis" and "Time series analysis". The first can be considered as a "snapshot" of a certain phenomenon in which the time dimension is not considered. Studies of this type have a clear advantage of greater simplicity and prompt availability of results compared to longitudinal analysis. Other problems in data collection includes: the time span, the choice of the unit under analysis, which represents critical elements.

A second relevant issue is related to the spatial dimension. In the majority of studies considered, the places considered are the ports, the cruise ships and the cities of destination. In the majority of cases the units are interviewed at the end of the visit to the city and just before they return on board in the ship [2,9,12].

Table 2: Sampling scheme, sample size, and target population.

#	*N*	Sampling scheme	Crew Members	Tourists
1	1500	Random pattern	No	No
2	1592	Stratified random	Yes	No
3	1121	Not specified	No	No
4	1361	Convenience random	No	No
5	8371	Not specified	No	Yes
6	127	Accidental sampling	No	No
7	3348	Stratified sampling	Yes	No
8	357	Random sampling	Yes	No
9	5500	Stratified sampling	Yes	No
10	278	Stratified random with selection criteria	No	No
11	161	Random sampling	No	No
12	12578	Two-step stratified	No	No

In table 3, information on study location and on survey period for the papers considered in the review are reported. The most significant problems in data collection are caused by the fact that some cruise passengers remain on board the ship, and this may causes problems in terms of sampling, since the size of the population became unknown. Moreover, some others may decide to come back to the ship for a break, and performing a second visit afterwards, causing issues in the implementation of probabilistic sampling scheme.

Table 3: Study location and survey period.

#	**Study Location**	**Survey period**
1	Ocho Rios, Jamaica	Five years (1993-1997)
2	Croatia	Four months (Jun-Sept 2006)
3	Costa Rica	One-Year (2008)
4	Cartagena de Indias, Colombia	Two Months (Oct-Nov 2009)
5	Bergen, Norway	Summers (2010-2012)
6	West Mediterrean	Spring season (2013)
7	Uruguay	2009-2010 season
8	Port of Koper, Slovenia	One month (Sept 2013)
9	Port of Messina, Italy	Eight-months (March-Oct 2014)
10	Port of Palermo, Italy	April (2014)
11	Tarragona, Catalonia	Three months (Aug-Oct 2017)
12	Canary Islands	Six cruise seasons (2001-2015)

2.3 The questionnaire

The most common survey tool for collecting data on cruise passengers' spending is via questionnaire. The use of questionnaires to evaluate the spending behaviour of

cruise passengers has been a step forward compared to the self-compiled diary and over time, survey techniques and questionnaire building have improved. In the literature examined, the questionnaires are generally divided into sections and each section is dedicated to the collection of information on factors that are likely to affect the spending level at destination, such as psychological, socio-demographic or contextual factors. For example, some surveys include activities carried out and post-consumption items, such as satisfaction [11], others include motivation items at the beginning of the visit [1], while some scholars consider the number of visits to other destination during the same trip, or the number of cruise trips made in the past [2]. Spending is typically measured across standard expenditure categories (food and drinks, tours, souvenirs, transport and others). Only few and more recent publications consider the spatiotemporal characteristics of the visit, such as average time spent in port, the distance travelled or list of places visited [4,5]

As regard the spatio-temporal choice, most of the early studies collected data at one point of time, while others [4,5] divides the data collection into an opening and a closing stage, allowing the interview to take place at separate moments in time (disembarkation vs. embarkation).

3 Main results and conclusion

The empirical results of the various studies conducted offer a certain degree of homogeneity for some factors, uneven for others. Research has shown that as time elapses, money spent in port is increased [7] and there is also a high probability of returning to the destination [1]. Propensity to return is also positively correlated with high satisfaction levels [1], and higher average age of visitors. Repeat visitation affected the overall spending of cruise passengers positively: it was observed that those who had already visited the place, spent significantly more than the so-called “first-time visitors” [6]. An important component that has been deepened by various researchers is the word-of-mouth [10]. The empirical evidence has shown that the opinion of others, the opinion that people have and perceive from the destination, is an important factor. As far as gender is concerned, there is no empirical evidence on significant differences between the two sexes, although some studies have shown that female cruise passengers spend more on average than men [9]. Age differences does not have a great impact in the categories of expenditure [9], instead it presents evidence in terms of total expenditure [5]. Spending by cruise passengers is also associated with the number of visitors: if they are part of a large group, they are likely to spend more money [3]. The size of the group is in fact an important factor, which many consider when it comes to cruise spending, because it has a significant impact on total expenditure. Another socio-demographic aspect considered is nationality, although the results seems to be conflicting. Many authors have shown that the nationality of the cruise passengers does not make significant differences in expenditure [1], others have shown that there are significant differences between expenditure levels among different nationalities [6,9]. Another highly influential factor in cruise passengers' spending is the duration of the visit as well as the distance travelled onshore: those who stay for short periods and/or near the port area

spend less at the destination and spend more money on board [8]. This issue has been deeply investigated, especially through comparison with tourists in general [3], by showing that cruise passengers tend to spend less than tourists.

Research related to the spending of cruise passengers has undergone an extraordinary evolution, accompanied by the development of the cruise sector. Each research, having different populations and samplings, different places and methods, offered a broad investigation of the topic. This work aimed at collating various studies conducted on this topic, placing particular attention to the implementation of survey techniques and of the underlining research hypotheses. The evaluation of the extent to which cruise passengers' spending can be measured and analysed can contribute to the development of policies for cruise tourism management.

Educational integration of foreign citizen children in Italy: a synthetic indicator

Un indicatore sintetico dell'integrazione scolastica degli studenti con cittadinanza straniera

Alessio Buonomo, Stefania Capecchi and Rosaria Simone

Abstract Social inclusion and integration are prominent topics in social sciences, and specifically in the educational field, in order to contrast the experience of inequality conditions at school. Using data from the 2015 national survey on "Integration of the second generation", the paper proposes a synthetic indicator of educational integration of second-generation children in Italy. The chosen methodology is suitable to model subjective assessments on rating scales while accounting for both agreement and heterogeneity in response patterns.

Abstract *L'inclusione sociale e l'integrazione rappresentano temi cruciali nelle scienze sociali ed assumono rilievo specifico nell'ambito dell'istruzione. Utilizzando i dati dell'Indagine Istat sull'integrazione delle seconde generazioni (ISG 2015), lo studio propone un indicatore sintetico di integrazione scolastica che considera sia la percezione del tratto in esame che l'eterogeneitá delle risposte.*

Key words: Model-based indicators, Educational integration, Second-generation, Foreign children, Rating data

1 Introduction

The issue of migrants' integration is a key topic in social sciences, and it is particularly relevant in the educational field to counteract the experience of inequality conditions by children with a migratory background, especially of those born abroad. Focusing on Italy, the number of foreigners has rapidly increased in the last two

decades from about 350,000 residents in the early nineties to over 5 million, according to the Population Registers. The consequent growing number of their children have attracted the interest of scholars [10].

Due to the fact that the increase of the second generations in Italy is a relatively recent phenomenon, the school environment is a particularly important field of study [3]. Educational and social integration can boost placement into community and labour market [1], especially in the case of immigrants, and thus be beneficial to the whole society. Indeed, studies that focus on immigrant-specific educational inequalities have proven that social and scholastic integration are fundamental in determining educational success [8, 4].

Considering the CI-CUB procedure proposed by Capecchi and Simone [2], the paper aims at introducing an indicator of integration at school for both Italian and second-generation foreign children, distinguishing by nationality. The study provides a synthetic measure able to summarize subjective evaluations expressed by a large number of respondents, relying on CUB models framework [9].

After a brief introduction to the available data, the implemented methodology is illustrated, some results are discussed and further developments of the research are outlined.

2 Data and methods

The "Integration of the second generation" survey (ISG) has been conducted in Italy by the Italian National Statistical Institute [5] in 2015 and offers information on students of secondary schools in Italy. The overall unweighted sample amounted to $68,127$ individuals, of which 52% were students in upper secondary school. In order to deal with a more homogeneous subset, our analyses focus on opinions of students attending higher secondary state schools. Thus, the final target sample consists of $35,427$ unweighted individuals.

We investigate students' assessment - in terms of agreement - to 20 items referred to their perceived conditions/habits gathered in four different batteries: (A) relationships with classmates; (B) homework and study habits; (C) relationships with teachers; (D) family attitudes towards school importance. Variables of interest are comprised in question 14, in section *C* of the questionnaire. Each battery is composed by 5 items, whose responses are expressed on a 5 point Likert scale (1="strongly agree", 5="strongly disagree"). For interpretative purposes, the variables were reversed (with the exception of items A_3, B_3, B_5 and D_4) and organized in order to have the same direction, from the lowest to the highest agreement.

In the target sample, male students are about 50%; 15% of respondents are under the age of 15, and 58% are aged 15-17, whereas 27% are over 17. Italian interviewees represent 53% of the sample. Among foreigners, the three more frequent nationalities are Romanian, Albanian and Moroccan (10%, 7% and 4%, respectively). Foreign children born in Italy (second generation) are 9% of the sample, whereas those born abroad are 38%. Since foreign students represent a heterogeneous group

due to different origins and characteristics, a synthetic measure of their perception of integration may be useful both for research and policy purposes.

In order to illustrate multifaceted and sometimes elusive constructs, as in the case of subjective evaluations and perceptions, the number of composite indicators is growing. In fact, to general readership it may be easier to comprehend a single synthetic measure rather than inspect results from different separate indicators [7].

When dealing with ordinal data, CUB models allow to consider the uncertainty component in response behaviour, usually neglected in standard approaches. In this respect, Capecchi and Simone [2] recently proposed the novel CI-CUB - Composite Indicator CUB - to compute a model-based indicator within the CUB framework [9].

In its simplest version, a CUB model (acronym of Combination of Uniform and shifted Binomial) is implemented on ratings R to single questions to provide a global measure of individual assessment. CUB models are specified via a two component mixture of discrete distributions, one designated to measure the *feeling* towards the item (Binomial), and the other accounting for the inherent *uncertainty* (Uniform).

Then, a CUB model assumes that, for a given number of categories m, the random variable R is specified by the probability mass distribution:

$$Pr(R = r \mid \boldsymbol{\theta}) = \pi \binom{m-1}{r-1} \xi^{m-r} (1-\xi)^{r-1} + (1-\pi)\frac{1}{m},\ r = 1,2,\ldots,m.$$

The parameter $(1-\xi)$ of the Binomial and the weight of the uncertainty in the mixture $(1-\pi)$ provide a description of both perception towards the item (which can be indicated as "agreement" with given statements on perceived integration in the present case study), and heterogeneity of the response distribution. Since the two featuring parameters are normalized measures ranging in (0;1], different items and groups can be displayed and compared at a glance in the unit square. Therefore, CUB models establish a different paradigm, providing a unifying tool to interpret and compare the responses given to a number of items, even if measured on scales with different lengths, in a parsimonious way. The possibility of assessing the veracity of the rating evaluations with respect to the analyzed items/dimensions by means of easy-to-interpret graphical outputs is indeed one of the strengths of CUB framework. A comprehensive R library is devoted to CUB model fitting on the official CRAN repository.

In this setting, CI-CUB indicators provide a synthesis of CUB models applied to K items by n respondents: the random variable R_k associated to the *k-th* item follows $R_k \sim \text{CUB}\ (\hat{\pi}_k, \hat{\xi}_k)$, for $k = 1,\ldots,K$. Then, the CI-CUB indicator is a weighted CUB model $\tilde{R} \sim \text{CUB}\ (\tilde{\pi}, \tilde{\xi})$ where

$$\tilde{\pi} = \sum_{k=1}^{K} w_k \hat{\pi}_k, \qquad \tilde{\xi} = \sum_{k=1}^{K} w_k \hat{\xi}_k, \tag{1}$$

with $(\hat{\pi}_k, \hat{\xi}_k)$, for $k = 1,\ldots,K$ being the estimated parameters for the K variables of interest.

A CI-CUB can be seen as a two-dimensional composite indicator for the latent trait under investigation such as, in this case study, the perceived educational integration as measured through the 4 batteries of items (A, B, C, D).

The choice of the weights' system w_k is usually driven by specific circumstances and available information. In the present study, due to the underlying structure of the data along the 4 dimensions, we select the weights expressed by the (normalized) squared factor loadings of the 4 categorical principal components computed on the selected variables.

3 Results

While additive data-driven approaches may lead to neglect an inherent uncertainty component when present, CUB models separately estimated for each of the 20 items of question 14 (here not reported for space constraints) show a medium-high level of agreement, with the uncertainty being substantially not negligible for most of the items. More specifically, item C_1, referred to the perception of an equal treatment received by teachers, shows the highest level of uncertainty with a substantive agreement; on the other hand, item D_4 gets the highest level of agreement with a low uncertainty, meaning that family members do consider studying to be a prominent aspect of life success.

Analysing the whole dataset, the advantages of the implemented CI-CUB indicators are highlighted. In order to provide synthetic probabilistic measures of students' perceived integration, CI-CUB procedure has been implemented according to a twofold trajectory: results are presented graphically in Figure 1 where responses are aggregated by item subgroup and nationality. Notice that the parameter space is narrowed to improve readability, since a large part of the indicators lays in the uncertainty range $0.2 - 0.45$, and the agreement is always higher than 0.5. To save space, details about fitting procedure are not reported.

Left panel of Figure 1 shows the synthetic indicators for each item subgroup, corresponding to the above mentioned batteries (A, B, C, D), as compared with the overall CI-CUB indicator (ALL). For the items altogether (ALL), the level of agreement is quite high with a moderate level of uncertainty.

It seems evident that items referred to family attitudes (D) are those for which the overall level of agreement is the highest, immediately followed by those related to schoolmates (A), both manifesting a low level of uncertainty; estimates for the two subgroups pertaining to study habits (B) and assessments of relationships with teachers (C) get a lower agreement, with a larger uncertainty. Moreover, this representation allows to consider the impact on the overall indicator (ALL) of deleting one subgroup of items at a time. Specifically, removing B and C subgroups, the resulting synthetic indicators ($-$B and $-$C) show higher agreement and lower uncertainty, therefore highlighting the contribution of these two subsets in terms of *feeling*. These results are expected given the mutual positions of the subsets in the parameter space.

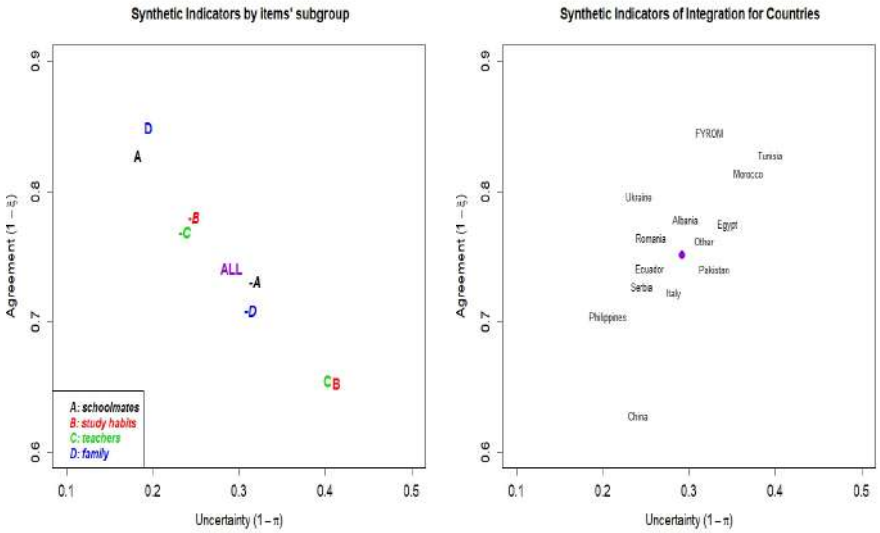

Fig. 1 Synthetic Indicators by item subgroups (left) and nationalities (right)

Right panel of Figure 1 collects CI-CUB indicators by respondents' nationality. In general, the agreement level is higher than 0.6 and the uncertainty spans between 0.10 and 0.43. Specifically, respondents from FYROM and Tunisia manifest the highest levels of agreement. Chinese respondents are quite far from the others in terms of *feeling*. Interestingly, Italian students express one of the lowest level of agreement, followed by respondents from China and Philippines. This finding is consistent with the so-called "Immigrant optimism approach" that assumes that immigrants are a positively selected group: individuals that leave the country of origin are supposed to be more motivated, ambitious, stronger and optimistic as compared to the national counterpart [6].

Table 1 CI-CUB estimated probabilities of the highest agreement

Nationalities	$Pr(\tilde{R}=5)$	Nationalities	$Pr(\tilde{R}=5)$
China	0.165	Egypt	0.308
Philippines	0.237	Romania	0.318
Italy	0.252	Albania	0.320
Serbia	0.260	Morocco	0.356
Pakistan	0.269	Ukraine	0.356
Ecuador	0.272	Tunisia	0.368
Other	0.295	FYROM	0.415

Table 1 presents the estimated probabilities to express the highest rating ($\tilde{R} = 5$), conditional to the nationality, which can be considered as an overall measure of educational integration, as derived by the CI-CUB models. In line with evidence in Figure 1 (right panel), Chinese students have the lowest estimated probability, whereas Macedonians (FYROM) have the highest. It turns out that there is not a clear geographical pattern of the estimated probabilities in terms of agreement, since different and distant countries present very similar estimated probabilities, see: Morocco, Ukraine and Tunisia, or Serbia, Pakistan and Ecuador.

Further developments of the study will follow two directions. From a methodological point of view, the main effort will be devoted to derive the confidence ellipses. For the empirical analyses, more investigation is needed on a geographical basis, as well as on the effects of individual characteristics, such as gender and migratory generation.

Estimating the Change in Housework Time of the Italian Woman after the Retirement of the Male Partner: An Approach Based on a Two-Regime Model Estimated by ML

Come Stimare la Variazione del Tempo Dedicato al Lavoro Domestico dalla Donna in Italia, dopo il Pensionamento del Partner. Un Approccio Basato sulla Stima di Massima Verosimiglianza di un Modello a Due Regimi.

Giorgio Calzolari, Maria Gabriella Campolo, Antonino Di Pino and Laura Magazzini

Abstract Using Italian data from the Time Use Survey (Istat), in this study we analyse the influence of the retirement of the male partner on the housework time of the woman in Italy. As a novelty, our ML estimation of the across-regime correlation parameter, obtained applying a Two-Regime Switching model, allows us to better interpret the relationship between retirement of man and the woman's commitment in housework.

Abstract *Utilizzando i dati italiani sull'Uso del Tempo (Istat), abbiamo analizzato l'influenza del pensionamento del partner maschile sul tempo dedicato alle faccende domestiche dalla donna in Italia. Come novità, la nostra stima ML di un parametro di correlazione tra regimi, ottenuta specificando un modello a switching endogeno, consente di interpretare meglio la relazione tra pensionamento dell'uomo e l'impegno della donna nel lavoro domestico.*

1 Introduction

The aim of this study is to provide a convincing specification and estimation of the relationship between a man's retirement and the female partner's commitment in housework time.

As several previous studies found, commitment of the woman in housework generally decreases if the male partner is retired [1,3,5,6, for Italy; 9, for France). However, if a woman with higher bargaining power wants a more equitable distribution of housework time with her partner, this can induce the male partner to retire earlier to have more time to devote to work in the home and family. The opposite occurs if the woman has lower bargaining power.

Neglecting these endogenous aspects of the decision to retire may lead to an overstatement of the effect of a man's retirement on the time devoted to housework by a woman with a higher bargaining power and, conversely, an understatement of the effect of a man's retirement on the housework time of a woman with lower bargaining power.

Battistin et al. (2009) and Ciani (2016) faced the problem of influence of the endogenous choice of the agents between one of the two "regimes" (retirement or not) by adopting a "regression-discontinuity" approach. Campolo and Di Pino (2020) provided an identification strategy of the endogenous bargaining performing a Generalized Structural Equation Model (GSEM) as predictor of woman's bargaining power. In this study, we identify the endogenous latent effects on retirement in the across-regime correlation parameter, obtained by applying the Maximum Likelihood estimation procedure to an endogenous switching model, recently introduced by Calzolari and Di Pino (2017). Following this method, we specify two regression equations, each one referred to one of the two regimes. In the regime 1 we estimate the domestic work of the women whose male partner is retired, in the regime 2 we estimate the domestic work of the women whose partner is not retired. The across-regime covariance (or correlation) between the errors of the two outcome equations is here estimated simultaneously with the coefficients and variances of both regression equations. We use this parameter to identify a possible endogenous latent effect of housework on the retirement of the male partner. In particular, we assume that the unexplained components of the outcomes in both regimes may include latent factors related to the choice of the man to retire. A positive sign of the across-regime correlation indicates if the agent (the woman, in our case) gains an "absolute" (dis)advantage in both regimes [7]. Conversely, a negative sign of this parameter means that endogenous self-selection leads the agents to prefer the regime in which they have a comparative advantage in terms of their skills (in our case, we assume that the woman has more bargaining power if the male partner is retired).

However, the across-regime correlation parameter is generally not empirically identifiable as a consequence of the selection rule adopted specifying a Two-Regime switching model; namely the dependent variable referred to an observation cannot be jointly observed in both regimes. Calzolari and Di Pino (2017) solved the identification difficulty by modeling a selection rule based on the difference between

the outcome gained by the agent in the chosen regime (outcome is observed) and the outcome potentially expected in the alternative regime (outcome is latent). More details on the methodology are reported below in Sect. 2.

Following the ML procedure of Calzolari and Di Pino (2017), we use Italian data from the Time Use Survey (Istat) to estimate domestic work of Italian women in both regimes (partner is or is not retired). The estimated across-regime correlation will provide a convincing explanation of the influence of latent factors on male retirement. As post-estimation results, we obtain the probabilities to retire of the male partners by the log-Likelihood function, and we use these probabilities as propensity scores to estimate, by matching, the "treatment parameters" measuring the impact of retirement of man on the housework time of the woman. Estimation results are discussed in Sect. 3.

2 Data and Methods

The sample is drawn from the Italian Time Use Survey 2008-2009 provided by Istat (Italian National Institute of Statistics). In our analysis, the sample was composed of 3126 married or cohabiting women with a male partner whose age is ranged between 50 and 65 years (age compatible with eligibility for retirement). The men were either employed (2096 observations) or retired (1030 observations).

The dependent variable adopted in both equations of the Two-Regime model is the time (minutes) devoted by the woman to domestic work on a weekday. Explanatory variables used in the model provide demographic and socioeconomic information on the subjects: the woman's age (Woman's age), the woman's education expressed in years of school (Woman's edu), the health status of man (Man's health: 1= if man suffers from long-term health problems or chronic disease, 0=otherwise) and of woman (Woman's Health), the woman's working status (Woman retired: 1=yes; 0=otherwise), a dummy variable that assume the value 1 if the family received paid help in domestic work (Help received: 1=yes; 0=otherwise) and the daily time (in minutes) devoted to leisure activities by woman (Woman's leisure). Following Stancanelli and Van Soest (2012), and Ciani (2016), we introduced in the regressors set a second order polynomial indicating the man's eligibility for retirement (in the years 2008-2009, the man achieved the eligibility for retirement if he was aged 58 or more). Moreover, as in the study of Campolo and Di Pino (2020), we use as predictor of woman's bargaining power a latent construct of economic and behavioural factors (Bargaining-MIMIC), previously obtained applying a procedure known as Multiple Indicators and Multiple Causes Model (MIMIC) of a Generalized Structural Equations Model (GSEM) [8].

For the empirical analysis we adopt the ML estimator of Calzolari and Di Pino (2017) of an endogenous switching model with two regression equations whose dependent variables (outcomes) are mutually exclusive in a cross-sectional framework, and where selection is simply based on the choice of the larger outcome.

$$y_{1i} = \mathbf{x'}_{1i}\boldsymbol{\beta}_1 + u_{1i} \quad \text{if observed in regime 1; otherwise latent} \qquad (1)$$

$$y_{2i} = \mathbf{x'}_{2i}\boldsymbol{\beta}_2 + u_{2i} \quad \text{if observed in regime 2; otherwise latent} \qquad (2)$$

A relevant characteristic of this model is that the two dependent variables, y_{1i} and y_{2i}, are explicitly factors in the choice of the regime. For each individual, y_{1i} - y_{2i} represents the net gain (or net loss) from the choice between two options.

The error terms u_{1i} and u_{2i}, given by: $u_{1i} = y_{1i} - \mathbf{x'}_{1i}\boldsymbol{\beta}_1$ and $u_{2i} = y_{2i} - \mathbf{x'}_{2i}\boldsymbol{\beta}_2$ are assumed to be normally distributed with zero mean and variances σ_1^2 and σ_2^2. The identification of the across-regime covariance, σ_{12}, is based on the probability of a subject to gain the outcome of the two regimes, given by the probability density of the observed outcome, multiplied by the conditional probability that the other outcome (latent) is smaller than the observed. The two set of explanatory variables**,** $\mathbf{x'}_{1i}$ and $\mathbf{x'}_{2i}$, can be partially different in each regime. A partially different specification of the regressors in each equation may be helpful to identify the choice of the regime. In many cases, the regressors appear significant only in one among the regimes. Therefore, to improve the performance of the estimation procedure, may be convenient to include these variables only in the equation in which their contribution is significant.

We obtain the following contribution of the i-th observation to the log-likelihood:

$$\ln L_i = -\frac{(y_{1i} - \mathbf{x'}_{1i}\boldsymbol{\beta}_1)^2}{2\sigma_1^2} - \frac{1}{2}\ln\sigma_1^2 + \ln\Phi\left(\frac{(y_{1i} - \mathbf{x'}_{2i}\boldsymbol{\beta}_2) - \frac{\sigma_{12}}{\sigma_1^2}(y_{1i} - \mathbf{x'}_{1i}\boldsymbol{\beta}_1)}{\sqrt{\sigma_2^2 - \sigma_{12}^2/\sigma_1^2}}\right)$$

$$-\frac{(y_{2i} - \mathbf{x'}_{2i}\boldsymbol{\beta}_2)^2}{2\sigma_2^2} - \frac{1}{2}ln\sigma_2^2 + ln\Phi\left(\frac{(y_{2i} - \mathbf{x'}_{1i}\boldsymbol{\beta}_1) - \frac{\sigma_{12}}{\sigma_2^2}(y_{2i} - \mathbf{x'}_{2i}\boldsymbol{\beta}_2)}{\sqrt{\sigma_1^2 - \sigma_{12}^2/\sigma_2^2}}\right) \qquad (3)$$

where σ_{12} is the covariance between the error terms of both regimes, known as the across-regime covariance. Φ() is a normal cumulative distribution function (cdf) used to specify the contribution to the likelihood of censoring y_{1i} or y_{2i}.

Applying this *Two-Equation ML* procedure, the across-regime correlation parameter ρ_{12} (and the across regime covariance σ_{12}) can be directly estimated under the assumption of endogenous selection. After estimating the model's parameters, the following probabilities could be calculated:

-probability of being in regime 1 (male partner is retired):

$$\Phi\left(\hat{u}_{1i}\right)=\Phi\left(\frac{y_{1i}-\mathbf{x'}_{1i}\hat{\boldsymbol{\beta}}_1}{\hat{\sigma}_1}\right) \tag{4}$$

-probability of being in regime 1 (male partner is retired) for observations in regime 2 (male partner is not retired):

$$1-\Phi\left[\frac{\left(y_{1i}-\mathbf{x'}_{2i}\hat{\boldsymbol{\beta}}_2\right)-\frac{\hat{\sigma}_{12}}{\hat{\sigma}_1^2}\left(y_{1i}-\mathbf{x'}_{1i}\hat{\boldsymbol{\beta}}_1\right)}{\sqrt{\hat{\sigma}_2^2-\hat{\sigma}_{12}^2/\hat{\sigma}_1^2}}\right] \tag{5}$$

3 Results

In Table 1 we report the estimation results of the *Two-Equation ML* procedure. In order to better explain the choice of the regime, we adopt a different specification of each regime. In particular, we excluded the variables *Woman's health* (dummy) and *Bargaining-MIMIC* from the explanatory variables of the Regime 1, being these regressors significant only in the equation of Regime 2. Analogously, we dropped out the variable *Woman's leisure time* from the regressors of Regime 2.

Table 1: Woman's domestic work: ML estimation results

	Regime 1 = Man retired			Regime 2 = Man not retired		
	coef.	Std.Err	P value	coef.	Std. Err.	P value
Woman retired: 1= yes	39.70	10.37	***	-32.63	11.90	**
Education of woman	-8.08	0.95	***	-6.84	0.90	***
Woman's age	1.23	0.91		-2.06	0.81	*
Man's health: 1 = Sick	17.55	8.71	*	-8.83	8.52	
Retirement Eligibility of man (*Eligibility*) = 1 if he is 58 years old, at least)	23.27	22.75		-26.28	18.47	
1-Eligibility *(Age-58)	51.43	14.37	***	-14.57	8.68	
1-Eligibility *$(\text{Age-58})^2$	3.24	1.60	*	-1.67	0.93	
Woman's leisure time	-0.19	0.03	***			
Paid help received: 1 = yes	-88.62	17.57	***	-31.78	13.33	*
Woman's Health: 1 = Sick				-13.54	4.70	**
Bargaining-*MIMIC*				-165.0	24.72	***
Constant	336.69	55.41	***	576.91	49.85	***
r_{12} (Across-regime correlation)	**0.612**					

The table shows the estimated coefficients of the equation under the regime 1 (man retired) and the estimated coefficients of the equation under the regime 2 (man not retired). The estimated value of the across-regime correlation ρ_{12} is equal to 0.612. As post-estimation results we calculate: the probability of being in regime 1

(male partner retired) for observations in regime 1 (Eq. 4), and the probability of being in regime 1 for observations in regime 2 (Eq. 5). We use these estimated probabilities to perform a (Propensity Score based) matching procedure in order to calculate the Average Treatment Effects for treated (ATT). The estimated ATT parameter measuring the effect on the woman's domestic work is equal to -26.04 minutes in a day. Namely, housework time of the woman is expected to decrease in mean of 26.04 minutes in a day as a consequence of the retirement of the male partner. This result essentially confirms what previous studies found in terms of reduction of the woman's commitment in domestic work [3,5,6].

However, the novelty of our analysis is given by the interpretation of the effect of retirement in terms of "absolute" or "comparative" advantage for the woman. In particular, the positive sign of the across-regime correlation coefficient indicates that the women gain an "absolute" advantage in both regimes. This means that women, especially those who live in families with higher socioeconomic status, are not constrained by the need to devote a large part of their time to domestic work, regardless of the partner's working condition. However, if they aim to increase their weight in terms of the responsibility of managing the home and family affairs [2], they could encourage the male partner to retire in order of improving his commitment in household affairs.

First and Second Year Careers of STEM Students in Italy: A Geographical Perspective

Primo e Secondo Anno di Carriera degli Studenti Italiani di Area STEM: Una Prospettiva Geografica

Antonella D'Agostino, Giulio Ghellini, and Gabriele Lombardi[1]

Abstract The mobility behaviour of Italian university has feed an increasing interest on the public debate. The very particular geographical characteristics of the country, jointly with the recognized persistence of the economic gap between the Southern and Northern regions, push more and more students in moving from the first macro-region toward the latter. This article will focus on the differences in the performance of those students who decide to move for their studies, against those who remain close to their hometowns. In order to analyse this issue, we conduct multilevel modelling techniques, using administrative microdata from the Italian Ministry of Education, University and Research (MIUR) referring to the first two years of the career of students from the cohort 2014/2015, enrolled in STEM fields.

Abstract *La mobilità degli studenti universitari italiani sta permeando sempre di più il dibattito pubblico. Le peculiari caratteristiche geografiche della nazione, unitamente al persistente gap tra il Nord e il Sud della penisola, spingono una frazione sempre più grande di studenti meridionali a spostarsi verso le regioni settentrionali. Questo lavoro si focalizza sulle differenze di performance tra gli studenti che decidono di emigrare per i loro studi e quelli che decidono di restare a studiare vicino casa. A livello metodologico verrà impiegata una tecnica di modellizzazione multilivello, utilizzando microdati amministrativi provenienti dal Ministero dell'Istruzione, Università e Ricerca (MIUR) riferiti ai primi due anni di carriera degli studenti appartenenti alla coorte di immatricolati 2014/2015 a dei corsi di studio STEM.*

Key words: student mobility, STEM, performance, multilevel model, transfer shock

1 Introduction

The issue of internal mobility within countries is acquiring a growing interest among scholars, as one of the main events suitable for the analysis of transition through adulthood (see among the others, D'Agostino et al. 2019a; Contini et al. 2015; Dotti et al 2013). In particular, this paper explores the differences in the first academic year's performance among those Italian freshmen newly-graduated at the high school, who have decided to move away for their hometowns for their higher education studies in STEM (science, technology, engineering, and math), or remain in the nearby of their residences. This investigation is particularly important in light of the strong gap between the Northern and Southern regions of the country and it is related to the crucial role played by STEM fields for the local development (D'Agostino et al., 2019b). Indeed, few students who migrate return home to take advantage of their investment and many students stay in the host region to escape low returns on education in their region of origin (Attanasio and Enea, 2019).

In the international literature, several contributions are available concerning about earning a STEM degree and the migration of students pursuing STEM degrees. As an example, Crisp et al. (2009) evidence how, despite to the fact that these fields are acquiring constantly a greater importance in those public programs stimulating higher education attendance, it seems still to be present a difficulty in pursuing successfully a STEM degree by some categories of people, such as women or ethnic minorities. Public support seems to not play any role in mitigating this evidence, while the presence of a strong cultural capital seems to be much more effective. There is an evident stratification in the kind of people who decide to enrol a STEM course, and the growing interest in these fields is globally causing an increasing adoption of strategies in order to stimulate enrolments. This has to come with a bigger attention to the speed of students in adapting themselves to the new context (Lopez and Jones, 2017), with the awareness that the presence of better economic opportunities is the strongest pull factor for STEM students (Gesing and Glass,2019).

Although the importance of studying STEM field in educational analysis from different perspective, the number of empirical analysis on this topic are still poor in Italy. Some exceptions are, for instance, Chise et al. (2019) and Granato (2018), who both highlight the importance of environmental and cultural factors in explaining the main differences in STEM attendance.

Our goal is to contribute towards filling this gap. Precisely, focusing on the specific issue of the so-called *transfer shock* (Hills, 1965). Indeed, movers could suffer a decrease in their own performance after the transition to higher education, namely during their first year of enrolment, then gradually recovering the original achievement. Indeed, all transfer students generally present some degree of transfer shock in the transition from an educational context to another, and a low performance in the first year of studies can be just a sign of the emergence of this phenomenon. The youngest freshmen are usually the most affected by transfer shock, as the lowest performers in previous institutions. More specifically, Glass and Harrington (2002) find that movers in the long run seem to perform better than stayers, but they

experience a drop in their performance during the first semester. Regarding specifically to STEM students, Cejda (1997) finds that freshmen in this area experience a stronger transfer shock with respect to their colleagues in other fields.

2 Data Structure

The analysis is based on micro-data provided by the Italian Ministry of Education, University and Research (MIUR) and collected into the Italian University Student Register (ANS)[1], referring to the Italian university system as a whole. In particular, the database is restricted to 38,773 freshmen enrolled in STEM fields in the academic year 2014/2015 and that have information on their academic credits earned for the first and second year of their university career[2].
The working sample that resulted from this procedure is composed of 77,546 repeated measures clustered in 658 university courses.
The response variable that we use in this paper is the students' academic performance measured using the academic credits earned in each a.y. Indeed, as regulated by the Ministerial Decree 509/1999 by the MIUR, academic credits are a measure used by Italian Universities to estimate the workload required in order to graduate. In particular, we normalized it, as suggested by Leckie (2013)[3]. Firstly, the N observations are ranked basing on their original scores. Then, the standard normal score for the j^{th} ranked observation in the data is calculated as:

$$\boldsymbol{\Phi^{-1}\left[\frac{j-0.5}{N}\right]},$$

where Φ^{-1} denotes the inverse of the standard normal cumulative distribution function. The advantage behind this simple transformation is that it is order preserving and students with the same number of credits will also receive the same standard normal score. As independent variables in the econometric model we used the set of variable available in dataset. The main object of this study concerns the effect of the mobility indicator from South to North. Thus, in order to exploit this effect, we fix stayers and movers from North/Centre as the baseline, comparing them with both movers and stayers from South, separately. Additionally, in our control strategy, the following variables are included: gender (male – baseline), grade earned at high school coded as a dummy variable (grade lower than the 75th percentile – baseline), type of high school classified into three categories: scientific lyceum (baseline), classic lyceum,

[1] Database MOBYSU.IT [Mobilità degli Studi Universitari in Italia], research protocol MIUR – Universities of Cagliari, Palermo, Siena, Torino, Sassari, Firenze and Napoli Federico II, scientific reference Prof. Massimo Attanasio (UNIPA), Data Source ANS-MIUR/CINECA.
[2] All students enrolled in Italian universities' STEM fields in a.y. 2014/2015 are 51,821. About 13% of these freshmen drops-out the system and about the 3% of them changes course during the first a.y. Another 11% of them has missing information about their performance.
[3] It is worth note that we use this data transformation for using a simple econometric model in the empirical analysis. Nevertheless, more complex approach for such kind of data exist in literature (see for instance, Grilli et. 2016)

technical and or other diploma in secondary education. Then, another binary indicator informs if student, enrolled university later than one year after the end of the high school (less than one year – baseline). Finally, a dummy variable for time effect (a. y. 2014/2015 – baseline) has been considered, aiming at investigating the pattern of student's performance over time and to test the hypothesis of a transfer shock effect through its interaction effect with the mobility indicator.

3 Methodology

In a nutshell, Multilevel Analysis is a typology of hierarchical linear model, which allows to compute regression analysis for data with several nested levels. The underlying idea is that each level should be a potential source of unexplained variability (see among the others, Hox et al. , 2017).
The importance of relying in such a technique in educational studies is widely addressed by Grilli and Rampichini (2009). Consequently, this kind of methodology allows to characterized our three-level longitudinal design that includes repeated measures on students nested in STEM courses (Hair and Fàvero, 2019).
Our preferred specification considers the following three-level variance-components model:

$$\boldsymbol{CFU_{tjk} = \beta_0 + v_k + u_{jk} + \beta_{Time} year_{jk} + \beta_{SS} x_{jkSS} + \beta_{MS} x_{jkMS}}$$
$$\boldsymbol{+\beta_{tSS} year_{jk} \cdot x_{jkSS} + \beta_{tMS} year_{jk} \cdot x_{jkMS} + \sum_{h=1}^{H} \beta_h x_{hjk} + \varepsilon_{tjk}.} \qquad (\mathbf{1})$$

Equation (1) states that CFU_{tjk} (the normalized credit earned) in year t for the student j ($j=1,\dots,J$) in STEM course k ($k=1,\dots,K$) is a linear function of student level explanatory variables **x** and a time indicator variable (year). Whereas, $\beta_{Time}, \beta_{SS}, \beta_{MS}, \beta_{tSS}, \beta_{tMS}$ and β_h $(h = 1, \dots, H)$ are the unknown parameters to be estimated. The errors components $\boldsymbol{\varepsilon_{tjk}}$., v_k and u_{jk} are assumed to be mutually uncorrelated and i.i.d. normally with mean 0 and variance σ_ε^2 , σ_v^2 and σ_u^2, respectively. The main parameter of interest is $\boldsymbol{\beta_{tMS}}$ that indicates whether movers from South actually experiment a transfer shock in the transition toward the new environment. A positive sign of such parameter suggests in which measure they are able to overcome the transfer shock effect in the second year of their STEM studies.

4 Results and Discussion

Table 1 present the results of the model specified in equation 1 (see Model 4). The four models presented differ for the number of variables included in the estimation

process. Findings show that credits earned in the second year tend to decrease. In STEM studies women seems to have lower performances than men. The top-performing students, who come from a Scientific Lyceums, who apply on time for a STEM degree course are more likely to outperform during their university career. Finally, both stayers and movers from South appear to perform worse than their northern colleagues. Nevertheless, the positive estimate of the coefficient of the interaction effect ($\boldsymbol{\beta_{tMS}}$) clearly shows that movers from the South recover part of the performance lost during the transition experimented as freshmen. These results, to be confirmed by some in-depth analysis on previous cohorts of STEM freshmen, might suggest that South of Italy is experimenting a strong loss in its best human capital, emigrating far away for attending higher education studies in STEM.

Future Scenarios and Support Interventions for the Family: Involving Experts' Participation through a Mixed-Method Research Study

Scenari Futuri e Interventi a Supporto della Famiglia: un Approccio basato sugli esperti

Mario Bolzan, Simone Di Zio, Manuela Scioni and Morena Tartari

Abstract A recent Delphi survey on possible scenarios that will involve the family in the next ten years saw the emergence of some situations judged by experts as particularly relevant. Specifically, these emerging situations are the growing conditioning of women when organizing their family life because of professional commitments, the increasing tendency of young adults to live with their parents and the intensity of solidarity networks between generations. On the basis of some focus groups, eight possible intervention proposals have been identified to deal with any difficulties related to the emerging scenario and, in particular, to support families. In order to rank the proposals according to their efficacy and feasibility, the multi-criteria decision-making technique Analytic Hierarchy Process has been applied.

Abstract *Una recente indagine Delphi sui possibili scenari che interesseranno la famiglia nei prossimi dieci anni ha permesso di evidenziare alcune situazioni, che secondo gli esperti, acquisiranno particolare rilevanza che riguardano il crescente condizionamento per la donna nell'organizzazione della vita familiare a causa degli impegni professionali, la crescente tendenza dei giovani a permanere in famiglia anche quando trovano lavoro e l'intensità delle reti di solidarietà tra generazioni. Sulla base di alcuni focus group, sono state individuate otto proposte di intervento con l'obiettivo di fronteggiare eventuali difficoltà correlate allo scenario ipotizzato e in particolare per sostenere la donna e la famiglia. Infine, con l'obiettivo di creare una classifica di queste proposte è stata applicata la tecnica decisionale multi-criterio detta Analytic Hierarchy Process.*

1 Introduction

The political, social, economic and cultural events affecting our present situation, both nationally and internationally at a macro level will affect, at a micro level, family dynamics and the day-to-day relationships between family members, but how these and other events will influence the intra-family evolution has still to be deciphered. Through the construction of plausible future scenarios, one of the aims of this work is to provide answers to the question: "What will happen to the family in the next 10 years?" The participative process for the definition of the scenarios does not involve predictions for the future, because this is practically impossible with this type of time horizon. Rather, on the one hand, the reasoning concerning the future helps us to understand how we live/think today and, on the other hand, it offers the opportunity to discuss possible policy actions that would be necessary if negative situations are to be prevented and/or to facilitate widely desirable outcomes (FAMILYPLATFORM, 2011; OECD, 2011). Therefore, we are speaking of explorative scenarios that contrast with normative scenarios (Kosow and Gaßner, 2008). In the first case, the goal is to explore the future consequences of possible decisions and actions that could be taken today. We must ask ourselves: “What will happen in the future if today we do or do not do something? What could tomorrow's family be like if we take certain actions today?” Contrastingly, in the case of normative scenarios, a desirable future is depicted as if it were a goal to be achieved, and questions such as “How do we want our future to be? How can we get there?" arise (Gordon and Glenn, 2018). The usefulness of the scenarios lies in the possibility of understanding how the future depends on our actions today and in forcing the debate on the key factors and dynamics of a system. In this way, decision-makers can abandon an action already initiated, correct it, or take new actions.

2 Methods

Over the past three years, a study called "Tomorrow in the Family" has been conducted in the Veneto region—one of the richest and best organized regions in Europe. Several focus groups were conducted with the aim of identifying some areas of interest for the present and the future of the family. A Delphi survey was conducted with a panel of 32 experts, asked to answer a questionnaire containing 41 items divided into seven sections: Parents; Spouses; Extended Family; Children; Housing; Family Models; Policy and Services; Communication; and Solidarity. Each item is a brief statement aimed at describing a specific phenomenon, relating to one of the seven themes under consideration (Di Giulio, Fent, Philipov, Vobecká and Winkler-Dworak, 2013; Bolzan, 2018).
In order to investigate the future development of each item, the experts were asked to provide two assessments using an ordinal scale of 0-100, the first concerning Evolution, that is the spread of the phenomenon indicated in the item, the second regarding Relevance, or its importance. Both evaluations were provided considering the situation hypothesised in 10 years compared to the current time. Scores lower than, close to, or above 50 indicate reduction, substantial immutability, and expansion respectively. The two dimensions, if considered jointly, are intended to represent the future visibility of the phenomenon itself. The survey was carried out in four successive stages, the first through a face-to-face interview and the subsequent ones with a CAWI (Computer Assisted Web Interview) survey method based on the self-administered computerized questionnaire. The 32 experts selected to participate in the Delphi survey are stakeholders, professionals in the sectors of services or production of

family goods, officials, public managers, and scholars who, by culture and professional position, are knowledgeable about family dynamics[1].

The Delphi method serves to differentiate the proposed items and, in some way, to classify them according to their different degree of consensus achieved. On the one hand, there will be items with a full convergence of opinion, on which the experts agree on their future relevance and/or evolution. On the other hand, there will be items with little consensus, which will therefore require further study and analysis, given that the experts do not agree when estimating their relevance and future evolution.

Furthermore, the Delphi survey has made it possible to identify those phenomena that, according to the experts, will be characterized in the future by an important increase in relevance and a medium-high increase in terms of evolution. In practice, by selecting those items on which the experts have had a convergence of opinion regarding their high future evolution, we have the basis of an explorative scenario, because using a future perspective, the key factors and the main dynamics of the "family of tomorrow" emerge. To complete the exploratory scenario, it is necessary to define the possible policy actions to be taken today. Indeed, a mere description of plausible futures does not in itself constitute a scenario, because it must also contain the key decisions that may or may not lead to a possible change in the future (Gordon and Glenn, 2018). For this purpose, a further panel of experts (15) was asked to discuss a scenario characterized by different levels of relevance and evolution that emerged identifying, through concrete examples from their experience, the factors supporting the well-being of family members, in particular as will be indicated below, of the woman, the factors that put her at risk and the factors adverse to her well-being.

The scenario-based research methodology is frequently used in the context of interdisciplinary studies, also known as future studies. A definition shared by some scholars, and applied here, considers the use of scenarios as a 'research tool' that is able to support stakeholders in discussing the relationships between variables, the data that emerges and any indicators and that connects the present to the future, keeping in mind current policies and those that would be necessary for the future (Morgan, 1983; Ramirez et al., 2015). This method has the advantage of reducing any bias inherent in stakeholders from different disciplines, placing the emphasis on social problems and the need to suggest solutions in the public interest (Öborn et al., 2013).

Finally, with the aim of creating a ranking of the factors supporting the family members' well-being and building a priority list of interventions, the identified proposals were subjected to expert evaluation using the Analytic Hierarchy Process (AHP) method.

The Analytic Hierarchy Process is an effective tool for dealing with complex decision-making, and it has been applied in a wide variety of settings. Usually, decision-makers involved in this process are characterized by a personal background and experience pertinent to the problem to be solved. In the AHP, a set of evaluation criteria and a set of alternative options, among which is the best decision to be made, are arranged in a hierarchical structure. First of all, the AHP generates a weight for each evaluation criteria, according to the experts' pairwise comparisons of the criteria. Next, for a fixed criterion, each pair of alternatives is compared and a score is assigned to each of them. Finally, the AHP combines the criteria

[1] More in detail: 10 representatives of the institutions (a Major, some municipality leaders, an alderman, a manager of the Social Department of the Veneto Region, two ULSS managers, a Judge of the Family, a President of the Family Section of a Court, a President of the Juvenile Court); 3 exponents of the school: an headmaster, an education superintendent, a teacher; 9 Representatives of associations/unions: CGIL, CISL, Confcommercio, Confesercenti, National Consumer Union, Coldiretti, Adiconsum; 3 representatives of the volunteering; 7 Professors (sociologists, statisticians, educators, political scientists, demographers).

weights and the alternatives' scores, thus determining a global score for each alternative. Criteria and alternatives are compared in a pairwise way using a scale of absolute numbers known as the Saaty scale, which has been shown to capture individual preferences with respect to quantitative and qualitative attributes (Saaty, 1980). Overall, more than 60 experts will be involved, a relatively large number for this kind of decision tool.

3 Results

The Delphi survey has made it possible to identify items that have the experts' consensus on high values of evolution and relevance and that merit, also with respect to their content, to be the subject of analysis for a reflection regarding possible family support solutions. The three items selected are: (A.4.) "For the mother, the organization of family life will be conditioned by professional commitments"; (G.2.) "The networks of solidarity between generations (elderly, adults, young people) will be intense"; and (B.5.) "Young people will stay with their parents even after they have found a job." The Delphi survey, with respect to the three items considered, provided stability, convergence speed, and consensus level parameters, which all show satisfactory performance. This premise appears important to support the following applications and hypotheses. The conditioning in the organization of family life as a result of a mother's professional life resulted in a significant increase in relevance (Median = 85, Interquartile Range [IR] = 10) and evolution, albeit minor (Median = 70, IR = 15). The phenomenon of the permanence of young people in the family home is also characterized by an important increase in terms of relevance (Median = 80, IR = 20) and a slight increase in terms of evolution (Median = 60, IR = 20). It must be considered that in Italy, the dimension that the phenomenon already assumes today is peculiar: the proportion of "young adults" between 18 and 34 years old, who still live at home with their parents in 2018 (66.1%), is more than 15 percentage points above the average for all 28 EU countries (48.2%) (Eurostat, 2018). Finally, the phenomenon of solidarity networks between generations is characterized by an increase in relevance (Median = 70, IR = 10) and a slight increase in evolution (Median = 60, IR = 5). In summary, the permanence of young people in the family home and the existence of solidarity networks are phenomena that, according to the panel of experts interviewed, will assume greater importance even if their diffusion could remain of the same order of magnitude as today.

Starting from these three key factors, a scenario was hypothesised that factored in the substantial increase in the mother's conditioning when organizing family life because of her professional commitments, a presence similar to today of the solidarity networks between generations, and the permanence of young people in the family home more conspicuous than today. The panel of experts, therefore, identified the following eight intervention proposals to support family members, particularly women, in the context of the hypothesised scenario:

1) Facilitate greater autonomy for young children;
2) Improve public welfare (e.g. availability of services to the individuals, such as the elderly or children);
3) Provide direct financial subsidies to families with children, the elderly, etc.;
4) Strengthen the support networks within the family (e.g. grandparents, relatives, etc.);
5) Strengthen the support networks outside the family (e.g. peers, friends, etc.);
6) Promote a cultural change in family members (father, mother, children) through training to promote awareness of shared responsibilities;
7) Improve corporate welfare to support workers with dependent children and elderly family members;

8) Increase the accessibility and availability of family counselling services for family difficulties of different types (not only psycho-emotional, but also social, economic, etc.).
The application of the AHP to experts at the level of the North East of the country is currently being undertaken, and it is believed to involve at least sixty experts in the three regions. To date, nine experts have participated in the survey. The alternatives were compared according to two different criteria: "Feasibility" and "Efficacy." Regarding the evaluation criteria, experts recognized efficacy as more important (0.626) than feasibility (0.347). Provisional global weights of the intervention proposals to support the considered scenario are shown in Table 1.

Table 1: *Provisional global weights from AHP (n=9)*

Rank	***Intervention Proposals***	w_{global}
1	Promote a cultural change in family members (father, mother, children) through training to promote awareness of shared responsibilities	0.226
2	Strengthen the support networks outside the family (e.g. peers, friends, etc.)	0.158
3	Improve corporate welfare to support workers with dependent children and elderly family members	0.138
4	Increase the accessibility and availability of family counselling services for family difficulties of different types (not only psycho-emotional, but also social, economic, etc.)	0.117
5	Strengthen the support networks within the family (e.g. grandparents, relatives, etc.)	0.106
6	Provide direct financial subsidies to families with children, the elderly, etc.	0.100
7	Improve public welfare (e.g. availability of services to the individuals, such as the elderly or children)	0.084
8	Facilitate greater autonomy for young children	0.071

4 Discussion

The scenario that emerged from expert evaluations through the first Delphi survey is confirmed by the data. In Italy, female employment (15-64 years) has increased steadily over the past 15 years from 45.5% in 2004 to 49.5% in 2018 (ISTAT, 2018). In Italy, unlike in Northern Europe, the increase in female employment did not lead to a corresponding redistribution of personal responsibilities within couples (ISTAT, 2012), so that much of the family and care work remained in the hands of women. The experts' picture hypothesised for the future corresponds consistently with the trend recorded in recent years in terms of a significant increase in the work commitment of women, including those who have families. Family relationships are already the first source of informal support on which working mothers with young children, the elderly, disabled people and, more generally, those who need support rely. To give a figure, the proportion of children usually entrusted to grandparents is approximately 65% (ISTAT, 2011); grandparents are fundamental within the family support network. Husbands/partners do not seem ready to share household chores. As concerns older children, staying with the family of origin represents an increasingly important

and visible phenomenon. By the AHP's first application, we note some interesting results: the first factor with a weight of 0.226—quite distinct from the others—is the promotion of a cultural change in family members. In contrast, in final position with a weight of 0.071 is the autonomy of young children.

Gender and Monetary Policy Preferences: a Diff-in-Diff Approach

Genere e preferenze di politica monetaria: un'analisi differenze nelle differenze

Donata Favaro, Anna Giraldo and Ina Golikja

Abstract The aim of this article is to assess whether monetary policy preferences of central banks' female chairs differ from male chairs' monetary policy preferences. We study the relationship between the gender of central banks chairs and central banks' attitudes to pursue a more (or less) conservative monetary policy. The analysis is based on a database of 179 central banks observed over the period 1980-2018. We specify a Phillips-curve equation where the inflation rate is regressed on the output gap, trade openness, a dummy that detects central bankers' gender and time. Using a diff-in-diff approach, where the treated countries are the ones who experienced a period of female presidency, we found that women pursue a less conservative monetary policy.

Abstract *In questo lavoro studiamo il rapporto tra il genere dei presidenti delle banche centrali e le "preferenze" delle banche centrali nel perseguire una politica monetaria più (o meno) conservatrice. L'analisi si basa su un database di 179 banche centrali osservate nel periodo 1980-2018 per le quali stimiamo un'equazione della curva di Phillips in cui il tasso di inflazione è spiegato dal gap di produzione, dall'apertura commerciale, da una variabile dicotomica che rileva il genere dei banchieri centrali e dal tempo. Utilizzando un approccio diff-in-diff, in cui i paesi "trattati" sono quelli che hanno vissuto un periodo in cui il presidente della banca centrale era una donna, il nostro studio mostra che le donne a capo delle banche centrali tendono ad implementare politiche monetarie meno conservatrici.*

Keywords: monetary policy, gender, diff-in-diff.

Introduction

The aim of this article is to assess whether monetary policy preferences of central banks' female chairs differ from male chairs' monetary policy preferences. The literature divides monetary policy makers into two categories: doves and hawks. A "monetary hawk" is a central banker who advocates keeping inflation low as the top priority in monetary policy. In contrast, a "monetary dove" is a central banker who emphasizes other issues, especially low unemployment, over low inflation. According to the existing literature, central banks' chairwomen appear to be more conservative (hawks) than chairmen. Women seem to be more "hawkish" than man in their willingness to use monetary policy tools to fight inflation volatility and to keep inflation at the target level.

There is an increasing interest in the study of how female composition of central banks' committees influences monetary policy. Farvaque et al. (2011) use a sample of nine OECD central banks – the ECB, the Reserve Bank of Australia, the Bank of Canada , the Bank of Japan, the Reserve Bank of New Zealand, the Swedish Riksbank, the Swiss National Bank – to analyse how the composition of central bank committees affect central banks' final outcomes. They estimate a kind of Phillips curve equation of the inflation level (where the regressors are some macroeconomic indicators such as the lag of inflation variation and the output gap, plus country-specific fixed effects) by including additional explanatory variables related to different characteristics of the committee. The gender factor enters the estimation as the share of women in monetary policy committee. The results show a negative coefficient associated with a hawkish attitude: a higher share of females in the boards of central banks contributes in making the committee more prone in lowering inflation levels. Farvaque et al. (2014) use a Data Envelopment Analysis (DEA) to evaluate the performance of central banks in terms of reduction of volatility of both inflation and output. They show that a higher share of women in central banks' boards increases inflation aversion.

More recently, Masciandaro et al. (2016) studied a sample of 112 countries and constructed an index of Gender diversity in Monetary Policy (GMP index) to evaluate the "dovish" and "hawkish" attitude of central banks' committees in relation to the proportion of females in their boards. They ran a regression for the 5-year average inflation rate in function of the GMP index (during 2010 and 2015), the lagged 5-year average inflation rate, the average output gap in the previous 5 years and a vector of country specific factors (level of central bank independence, trade openness, OECD membership). Their results show that a higher presence of females in central banks' committees implies a significant and negative effect on the inflation rate. Thus, they confirm the results of previous research that associates women with a higher degree of risk aversion towards inflation. Masciandaro et al. (2018), by using an augmented forward-looking Taylor rule to include the share of women in monetary policy committees among the regressors, confirm more conservatism in monetary policy as the share of women in central banks' boards increases. Last but not less important, Diouf et al. (2017) confirm that central banks' chairwomen put more emphasis on price stability then output stability, compared to

male chairs, by using a forward-looking Phillips curve equation where the output gap affects the inflation rate with one-year lag. More specifically, women are 73% less attached to the stabilization of output than men.

Taking inspiration from the discussed literature, in this article we propose a study of the relationship between the gender of central banks chairs and central banks' attitudes to pursue a more (or less) conservative monetary policy. The analysis is based on a database of 179 central banks observed over the period 1980-2018. Similarly to other previous studies, we specify a Phillips-curve equation where the inflation rate is regressed on the output gap, trade openness, a dummy that detects central bankers' gender and continental dummies. In addition to these variables, a time trend is included.

The innovative contribution of the study is twofold. First, differently from previous studies we focus on the gender of the president of central banks and not on the female composition of central banks' committees. Second, we employ a Differences-in-Differences methodology (DD). The DD estimation method is a quasi-experimental design (Meyer, 1995), that allows to evaluate the effects of a specific intervention. The method compares the differences or changes in outcome over time between two groups: the group enrolled in a program and a reference group that is "not treated". In our specific case, the "treated" group is represented by countries that had a central bank's chairwoman at some point in the considered period. The nontreated group is given by the rest of the countries. The advantage of DD over other quasi-experimental methods is that it controls for observed and unobserved fixed effects, making possible to compare countries with very different economic situations.

Data and model

Central banks (and relative countries) were selected using the list of central banks provided by the Central Bank Hub on the website of the Bank of Institutional Settlements (BIS). The database includes 179 central banks and related countries. A first delicate decision was how to treat European countries that are part of the European Monetary Union (EMU) nowadays. A possible choice was to exclude these countries from the database. A second choice was to include in the dataset all EMU countries up to the year of the adoption of the Euro and to drop them from the database from that year onwards, when information on the whole EMU area was added to the database. To avoid losing important observations from the database (and to bias the analysis), we chose the second alternative and we kept EMU countries in the database.

Original data on inflation rates and all explicative variables were recovered from the World Bank. Regarding the inflation rate, we also used a second measure recovered by the International Monetary Fund, which describes the inflation rate as the average of consumer prices. The output gap was built using the World Bank GDP expressed in nominal US dollars. After computing the real GDP by means of the GDP deflator (base year 2010), we applied the Hodrick-Prescott (HP) filter to

estimate each country potential GDP and took the difference between real GDP and its potential. Each country's output gap was finally relativized by its real GDP. Regarding trade openness, the index measures the ratio of each country's imports plus exports on GDP.

A critical point was to decide the minimum number of years of a female appointment as central bank president for a country to be considered treated. We decided for a period of at least three years, since the transmission mechanism of monetary policy can lasts for some years

To estimate the effect of the treatment – a central bank having a female president, on the outcome variable – the inflation rate - we use a DD approach that allows comparing differences in the inflation rates of treated and nontreated countries. The assumption that allows the identification of the effect of the treatment is the so-called common trend assumption; this means that, in the absence of the treatment, the inflation rate of treated and nontreated countries would behave similarly.

The DD method can be specified as a regression model (Meyer, 1995) where the observations are countries, treated and not treated, observed in two time points: before the treatment (t=0) and after the treatment (t=1). This implies making some choices. We assume t=0 the year before the appointment of a female chair and t=1 three years after the start of the appointment. Then, treated countries enter the estimation procedure only once in the covered period (1980-2018) whereas nontreated countries enter the estimation more than once. Their "repeated" participation in the estimation procedure is for single time spams of 4 years (as for the treated countries) that do not overlap.

The regression formulation of the DD estimates allows easily obtaining the estimates – the coefficients of interest are estimated by OLS – and the Standard Errors (Angrist and Pischke, 2009).

The general specification is then:

$$Inflation_{ict} = cons + \beta_1 D_t + \beta_2 I_c + \beta_3 D_t * I_c + X'_{ict}\,\boldsymbol{\beta_4} + \varepsilon_{ict}$$

Where i refers to the single country, t refers to time (with $t=0$ and $t=1$) and c indicates whether the country has been treated. D_t is a dummy variable that takes value 1 when $t=1$ whereas I_c takes value 1 when the country is treated. The parameter of interest is the coefficient of the interaction between these two dummies (D_t.*I_c). This parameter captures the situation in which a country i) has a central bank chairwoman and ii) it is observed at $t=1$, that is the time period in which we assume to be able to observe some effect of her monetary policy on the inflation rate. The explicative variables introduced in the model (output gap, trade openness, continental dummies all measured at time $t=0$, together with a trend variable) are summarised in X. The inclusion of the explicative variables is a simple way to adjust for observable differences between treated and nontreated countries (Meyer, 1995).

To take into account the fact that a nontreated country can appear more times in the estimation procedure, Standard Errors are adjusted for clustering at the country level.

Results and discussion

First results are reported in Table 1. As previously explained, control variables (output gap, trade openness, control dummies) are assessed in the year preceding the appointment of a female central banker (t=0). Then, the estimated coefficients are not to be interpreted as in a static model. To be clear, the coefficient of the output gap, for example, is almost significant with a negative sign. This means that when the output gap is positive – and the economy produces more than its potential – the inflation rate is lower than when the output gap is negative. This appears to contradict the predictions of the Phillips curve. Yet, the coefficient represents the relationship between the output gap at t=0 and the inflation rate three years later. Then, the negative coefficient need not worry. Indeed, in these types of model the only variable whose coefficient is relevant is the variable that captures the effect of the treatment, in our case variable D_t*I_c.
Regarding this variable, first estimates detect an upward effect on the inflation rate when a female is appointed as a central banker. Thus, our analysis suggests that women are more "dovish" than men in using monetary policy tools; female central bankers appear to emphasize issues other than low inflation, such as low unemployment and higher growth. This is an interesting and original result compared to the existing literature.

Table 1: Regression model results

Variables	***Coefficients***	***Robust SE***	***pvalues***
constant	1186.361	214.877	0.000
D_t	- 2.372	1.004	0.019
I_c	- 4.547	2.585	0.080
D_t*I_c	4.171	1.912	0.031
Output gap	- 13.820	7.354	0.062
Trade Openness	- 0.218	0.029	0.448
Year	- 0.590	0.107	0.000
Africa	8.131	2.044	0.000
Asia	6.592	2.410	0.007
Europe	5.021	2.503	0.047
Oceania	1.503	1.384	0.279
Center and South America	18.732	4.412	0.000

These first results are robust to different model specifications (with single year dummies instead of a continuous variable "year") and to the choice of different time periods, but still need some sensitivity analysis with respect to different treatment/time specifications. Some sensitivity analysis for the common trend assumption is also necessary. Moreover, to better control for observed heterogeneity, we are planning to apply a matching procedure for pairing treated

countries to similar nontreated countries. Even if a control for time is already in the specification, we also plan to deal with a possible structural change by dividing the 18 year time spam in smaller periods and estimate separate models. More sophisticated models such as a growth model or a latent variable model, including heterogeneity and time dependency, could be interesting future improvements of this work.

Headcount based indicators and functions to evaluate the effectiveness of Italian university education

Valutazione dell'efficacia della formazione universitaria italiana attraverso indicatori e funzioni basate sul conteggio del numero di presenze/assenze

Silvia Terzi[1], Francesca Petrarca[2]

Abstract In the present paper we suggest the use of Alkire-Foster (2007, 2011) dual cut-off method to compute a multidimensional performance indicator and of a simple headcount based function (an original suggestion) to detect association among the different dimensions of a performance indicator. In our illustrative application we apply the suggested dual cut-off method and the local concordance curve to synthesize relevant features of student opinions on their study programmes.
Abstract *Nel presente lavoro suggeriamo l'uso del metodo del doppio taglio di Alkire-Foster (2007, 2011) per calcolare un indicatore di performance multidimensionale e di semplice funzione basata sul conteggio delle unità presenti (proposta originale) per misurare l'associazione tra le diverse dimensioni di un indicatore di performance. Nel nostro esempio applicativo utilizziamo l'indicatore suggerito e la curva di concordanza locale per sintetizzare le caratteristiche rilevanti delle opinioni degli studenti sui loro programmi di studio.*

Keywords: Multidimensional Poverty Index, local concordance.

1. Introduction

Alkire-Foster (AF), [1],[2], [3], dual cut-off method was first introduced to measure the Multidimensional Poverty Index (MPI), but it is equally well suited to measure performance and/or quality or customer satisfaction both in business environment and in public organizations [5]. In particular, we suggest its use to evaluate the effectiveness of the Italian university education. Theoretical concepts like satisfaction or performance are generally recognized as multidimensional latent

[1] *Economics Department Roma Tre University, silvia.terzi@uniroma3.it*
[2] *MEMOTEF Department, La Sapienza University Rome, francesca.petrarca@uniroma1.it*

constructs exactly as non-income poverty. To define a synthetic indicator of performance (or satisfaction) we need to aggregate the sub-indicators related to the different dimensions the multivariate indicator is based on. Aggregating different dimensions, it would be extremely useful to embed in the performance indicator some information concerning the association between the single dimensions. This is the main reason why we suggest AF methodology. The second reason is due to the fact that sub-indicators concerning performance are often measured on ordinal scale, when not binary (success/failure).

To complement such information we introduce the notion of local concordance and suggest a *local concordance coefficient* and a *local concordance curve* [6]. Our intent is not to have an overall measure of concordance, i.e. a global indicator, but local concordance coefficients instead, in order to detect different degrees of concordance in the head, tail, or centre of the multivariate distribution of the components of a multidimensional indicator.

In our case study we have a set of several indicators measuring different types of good performance for undergraduate and graduate courses of a certain university, say U. Let us assume that we can set a reference value for each indicator, a benchmark indicating a good-quality standard. Of course, we could count for how many indicators each under-graduate or graduate degree programme reaches the reference value and then define as effective a degree programme that reaches reference values for at least k% of the indicators. This is the basic idea. The overall performance indicator is obtained counting how many degree programmes are well-performing (for each Department or each University). We then proceed with the plot of a local concordance function to see whether the local concordance is high and whether it varies within different windows of the distribution.

The outline of the paper is the following: in section 2 we discuss AF methodology and the head-count based multivariate performance indicator, in section 3 we introduce local concordance and the local concordance curve, in section 4 we illustrate our illustrative application.

2. Alkire-Foster counting approach

Let us assume we have d different performance dimensions (or poverty as in the original context) and no natural definition of an aggregate variable. The different dimensions could be - and indeed will often be - measured on an ordinal scale, such as customer satisfaction/appreciation in the evaluation of the quality of services. For each dimension, one could define a specific threshold/reference value or *cut-off* (as defined by Alkire and Foster, [1]) and identify who is either above or below each of such one-dimensional thresholds.

The second step consists in establishing a second reference value (or second level cut-off) usually indicated with k, to define as multidimensionally effective (poor in the original context) the unit that exceeds the first threshold in at least k dimensions or key-indicators. In other words, the second cut-off value defines how many

successes a unit must record in order to be defined as effective *tout court.* If we set $k=d$ this would lead us to the intersection-based approach, i.e. to consider multidimensionally effective the units that reach or exceed the reference thresholds in all key indicators. Vice versa, if we set the second cut-off value equal to 1 (i.e. $k=1$) this would lead us to the union based setting: an effective unit is successful in any of the key indicators. For $1<k<d$ we have intermediate solutions; and this is one of the advantages of the method.

Let w_j ($j=1, ..., d$) be the weight applied to the j-th dimension, and let $\Sigma w_j = d$, so that the weights w_j of the different dimensions add to the total number of areas d. Let c_i ($i=1, ..., n$) be the weighted number of achievements reached by the i-th unit; choose a performance cut-off k such that $0 < k \leq d$, and define multidimensionally effective the unit whose achievement count c_i is $\geq k$. Let q be the number of effective units and let $c_i(k)$ be the count of the (weighted) achievements only for the effective units. P_0, the performance indicator can be defined as: $P_0 = \Sigma\, c_i(k)/nd$, i.e. the weighted average of the number of achievements in the population. P_0 can also be expressed as a product between two measures: the incidence of effective units (H) and the intensity of achievements (A); more precisely: $P_0 = HxA$, where $H=q/n$ and $A=\Sigma c_i(k)/dq$.

It is logical to expect that, as the cut-off k varies, both the degree of incidence and the intensity will change. More specifically, as the second cut-off k increases, H is reduced because fewer and fewer units will be able to obtain a sufficient number of achievements; but at the same time, the positive variation of k increases A, producing an opposite effect on the final indicator P_0. On the contrary, by choosing a lower value for k, the increase in incidence contrasts with the reduction in intensity, with an uncertain effect on P_0, an effect that depends on the individual univariate distributions.

It is important to underline two other important properties of the methodology proposed by Alkire and Foster: multidimensional monotonicity and decomposability by subgroups. The first property implies that if an additional achievement is recorded for a statistical unit, the overall index increases. The decomposability, on the other hand, is based on the fact that if there were two distinct populations x and y (for example two different Universities, or two different departments or degree programmes of the same University), of n_x and n_y units, the index P_0 referred to the union of the two populations will be the average of $P_0(x)$ and $P_0(y)$ weighted with their respective numerosity.

3. Local concordance

Loosely speaking d variables are concordant if for a unit i, (i =1, … , n) large values on some variables are associated with large values on all the others and conversely for another unit i' small values on some variables are associated with small values on all the others. Perhaps the most widely used coefficient of concordance between 3 or more distributions is Kendall's W [4], designed to assess the agreement

between d raters[1]. This is where we take moves from to introduce the notion of *local concordance* and suggest a *local concordance coefficient* and a *local concordance curve.* Let $\boldsymbol{X}$ be the data matrix of n units and d variables: $\mathbf{X} = (x_{ih})$, $i=1, ..., n$, $h=1, ..., d$. We rank all the observations within each of the d dimensions. Then we partition our ranked observations in contiguous subsets (*slices*) of fixed size s[2]. For each ranking we have a first, a second, …, a last slice. We call *window* the union of the d corresponding slices. To assess local concordance we count how many units are ranked in each window. We have maximum agreement within the r-th window when the s units belonging to the r-th slice of the first distribution also belong to the r-th slices of all the other distributions. So, the smallest the number of units, the greatest the local agreement.

Vice-versa maximum disagreement is when the units belonging to the r-th slice of the h-th distribution do not belong to the r-th slice of any of the other d-1 distributions, so that the total number of units ranked in the window is maximum. Thus if we count the number of units belonging to the r-th window we reach a minimum (s) in case of maximum concordance and a maximum (sd) in case of maximum disagreement. This is the simple and intuitive idea our multivariate association coefficient K_r stems from. It is in fact a concordance coefficient since it assumes co-monotonicity for all variables.

Let C_r be the number of units ranked in the r-th window on at least one of the d rankings. To measure local concordance we can define a *relative indicator:* $K_r = \frac{sd - C_r}{sd - s}$. By computing the local concordance coefficient K_r for all the distinct slices of size s of the multivariate distribution, we can derive and plot a *local concordance curve*.

As for the choice of s, we suggest choosing a significant quantile, for example, some kind of benchmark. Unfortunately, however, the choice of s affects not only the maximum and minimum values of our head count criterion but also what we are defining as agreement. For example setting $s = 3$ means that the first 3 ranks are equivalent: if one unit i is assigned - respectively - ranks 1, 2, 3 on $d = 3$ distributions, we are stating that these rankings agree, coincide; when $s = 10$ we are stating equivalence among the first 10 ranks. In fact, what we call *agreement in rankings* means *agreement among classes of ranks of size s*.

4. An illustrative application

Assume that we want to evaluate student's appreciation of the study programmes held by a certain Department D, based on the results of the questionnaires on student opinions. Suppose that this particular Department offers one undergraduate study course and three masters. The students that attend lectures are asked 13 questions, concerning three distinct macro-environments, relating to the organisation of the course, teaching skills and openness of the lecturer, overall satisfaction.

For each question the student is asked to indicate a degree of satisfaction: totally unsatisfied, rather unsatisfied, rather satisfied, totally satisfied.

---

[1] W = S/maxS, where S is the sum of the squared deviations among the sum of the ranks achieved by each unit, and max S is the value S in case of maximum concordance.

[2] For the sake of simplicity we assume $s \leq n/d$.

We choose to give the same weight to each question; and to set as first level threshold a % of "totally satisfied" at least equal to 50%, i.e. a level of excellence. As far as the second level threshold *k* is concerned, we set *k*=8.

Recalling that $P_0=\Sigma c_i(k)/nd$, is the weighted average of the number of achievements in the population; $H = q/n$ is the incidence of effective units; $A=\Sigma c_i(k)/dq$ is the intensity of achievements; and furthermore P_0= HxA, we computed P_0, H and A for all study courses but also, separately, for the undergraduate course and for the master courses. Then we computed the performance indicator separately for the four different disciplinary areas (that we have called W, X, Y, Z). The results are collected in table 1:

Table 1- Performance indicators for different course levels (Overall, Undergraduate and Master), for four different disciplinary areas (W, X, Y, Z), k=8,

	Undergraduate	*0*	*0*	*not a number*
	Master	*0,06*	*0,09*	*0,62*

We next tried to see whether the not-so-good performance of disciplinary area Z is critical (i.e. a severely poor performance) or not. So, we defined a different first-order threshold below which each performance can be considered poor: a first order cut-off corresponding to a % of rather satisfied **and** totally satisfied of at least 50% and computed the frequency distribution of the number of thresholds achieved. Most lecturers (81%) reach and exceed all first order cut-off values, all of them achieve at least 8 thresholds. This means that if we maintain the second order cut-off at *k=8* and set this new and more attainable first order cut-off value, all courses in disciplinary area Z are above the standard of adequacy we have defined.

Table 2-Frequency distribution of the number of "new" thresholds for area Z

N. thresholds	8	9	10	11	12	13	Total
Frequency	1	2	1	5	12	91	112

To compute the concordance curve let us set $s = n/d = 8$. It is interesting to note that the local concordance is fairly low in the first and last window and much higher and fairly stable in the central part of the multivariate distribution. In particular, this means that the worst (best) performing units are worst (best) performing only on some dimensions but not on all (as can be seen for disciplinary area *Z* in table 2), whereas for non-extreme evaluations there is fairly high degree of agreement. The overall Kendall's concordance coefficient W = 0,54.

Figure 1- Local concordance curve

Identify the speech code through statistics: a data-driven approach

Identificare il codice linguistico attraverso la statistica: un approccio empirico

Andrea Briglia, Massimo Mucciardi, Jérémi Sauvage

Abstract Language is what makes humans a unique species of «symbolic animals» by providing them a way to convey meaning through sounds, and it is undoubtedly one of the pillars of our lives, yet we learn it so spontaneously and effortlessly that it is impossible to remember how we came up in its mastery or to give any account on any stage of its acquisition. Thanks to recent advances in data storage, information visualization and automated processing (*e.g.* data mining), there is a growing interest in cutting-edges researches between statistics and linguistics aimed at unfolding the "linguistic genius" of babies by testing hypotheses mining large spoken longitudinal datasets in order to understand - by means of an inductive procedure - the way each of us learnt his/her language without being aware of it.

Abstract *Il linguaggio è ciò che rende gli esseri umani una specie unica nel suo essere degli "animali simbolici" perché ci fornisce un modo di trasmettere significati attraverso suoni. Esso è indubbiamente di fondamentale importanza nella vita di ognuno, ma lo impariamo in un modo così spontaneo che è impossibile ricordare come ne abbiamo acquisito la padronanza così come è impossibile spiegare una qualsiasi delle tappe del suo apprendimento. Grazie ai recenti sviluppi tecnologici nella memorizzazione, visualizzazione e trattamento automatico di grandi quantità di dati è nato un crescente interesse verso studi che combinano statistica e linguistica per spiegare il c.d "genio linguistico" dei bambini verificando tale ipotesi su corpus longitudinali tramite una procedura induttiva.*

Key words: Phonetic Variation Rate; CHAID Model; First Language Acquisition

1. Identify the speech code through statistics

The so-called “linguistic genius” of babies (Kuhl, 2010) is a matter of long-standing debate in the scientific community: being adults, we realise how much easier is for a toddler to spontaneously learn every kind of language compared to adults’ struggle to maintain a sufficient mastery of a foreign language required – for instance - to attend international conferences. A number of evidences (Saffran, 2003) show that infants are geniuses because it is hypothetically plausible that they can rely on “statistically biased learning mechanisms” (Saffran, 1996) and on an “automatic” pattern recognition neuronal “device”. So, a fundamental question arises: “What is it about the human mind that allows a young child, merely one year old, to understand the words that induce meaning in our collective minds, and to begin to use those words to convey their innermost thoughts and desires?” (Kuhl, 2010). Every infant is facing a huge challenge: learning a sound system made up of many units that - combined together in an almost infinite set of combinations – gives rise to an arbitrary relationship between sounds’ sequences and meaning. According to Saffran’s metaphor, the task is the following: « You must discover the underlying structure of an immense system that contains tens of thousands of pieces, all generated by combining a small set of elements in various ways. These pieces, in turn, can be combined in an infinite number of ways, although only a subset of those combinations is actually correct. However, the subset that is correct is itself infinite. Somehow you must rapidly figure out the structure of this system so that you can use it appropriately early in your childhood» (Saffran, 2003). In fact, the balance between speed and accuracy in learning a language should be of primary importance in the survival of an individual: for this reason we supposed that human brains have been evolutionarily selected to their specific way of detecting regularities and patterns from the external world in order to retroactively syntonize their cognitive potentialities to the environment (Friston, 2010). The literature on « perceptual attunement» (Fort et al., 2017) demonstrates how early children become familiar with their mother language by focalising their speed and accuracy of the recognition task on what they have been experienced to and – symmetrically – by losing the capacity to readily detect and decode unfamiliar cues. So - as language is acquired through cognitive mechanisms that we could consider to be analogous to statistical engines that store probability distributions and formulate predictions based on means and expectancies on what has been previously stored - our attempt is to try to uncover what we have called “statistical learning” by mining a set of longitudinal *corpora* in french language.

2. Data structure and model

Colaje-Ortolang (2020) is an open access french database, part of the broader CHILDES project (2020): seven children have been recorded in a natural setting one hour every month, from their first months of life approximatively until six years old.

Data are available in three different formats: IPA, orthographic norm and CHAT (acronym for Code for the Human Analysis of Transcription), each of them is aligned to the correspondent video recording, allowing researchers to see the original source and to eventually reinterpret every utterance on their own. The main coding structure of the database consists in the fundamental division between "*pho*" (what the infant really says) and "*mod*" (what the infant should have said according to the adult's standard phonetic/phonological norm): we define "variation" every occurrence in which "*pho*" differs from "*mod*". How much the density of the sampling can influence the range of deductions and generalizations that we could draw from data is a debated question: is there a threshold beyond which the sampling is sufficiently representative and, *a fortiori*, any logical implication from it will be empirically valid? The answer depends on the level of analysis, in other words: the scale at which we want to focus on (Tomasello, 2004). In linguistics there are many scales: from the most basic units such as vowels and consonants to complex syntactical constructions. In a *corpus* such as the MIT Media Lab's pioneering "Human Speech Home project" (Roy, 2006) that consists in 400'000 hours of audio and video recordings, every level of analysis will be granted by a strong empirical support, as nearly everything the infant said has been recorded. The sampling of the "Paris Corpus" (Morgenstern et al., 2012) is obviously many times less statistically representative (one hour every month, that is roughly 0.5 – 1% of what the infant listen and say during the sample period, assuming he is awake about ten hours per day) so it probably could not provide sufficient empirical support to highly specific research on particular lexical phenomena or the emergence of specific syntactic structures, but on the other hand we think it suffices to provide a fair statistical support in order to account to the more general phonetic units' level, as well as the emergence of word categories such as pronouns, articles and determinants, being the probability of finding at least one target from any given sample higher for more basical units (Tomasello, 2006). Further, the age span is wider and – having been recorded 7 infants by using the same research protocol – it gives to researchers an easy way to compare development's intercourses between infants. Goal is to verify whether and how "any variation does not randomly vary into any other, but it rather should follow an underlying pattern, as every variation has an order in itself" (Sauvage, 2015). We first import 4 *corpora* of a single child named "Adrien" at 3 years and 1 month of age (time 22), 3 years and three months (time 24) and then time 27 and time 34. To turn raw data in a computationally and statistically tractable format we unbundle them into a data structure in which every sentence appears on the row side and every word on the column side. In table 1 are summarized the main statistics for 4 *corpora*: we can see how a quantitative increase in the number of words and length of sentences in which these words are combined causes an increase in S.D. that is due to a parallel increase in the lexical variability (type/token ratio) that – in turn - expands the range of possible variations a child can utter.

Table 1: Corpus statistics

Time	Mean	Length	S.D.
22	2.64	343	1.80
24	2.80	324	1.76
27	3.34	580	2.39
34	5.89	641	4.28
Total	3.98	1888	3.32

Mean = average number of words within a corpus; Length = length of the corpus; S.D.= standard deviation of the number of words within a corpus

Consequently, considering a single phrase of a *corpus*, we define "phonetic variation rate" (PVR) the ratio between the number of phonetic variations (NPV), that is the number of differences detected between "pho" and "mod", on the total numbers of words (TNW). In formula, for the phrase "i" and the total numbers of words "j": $PVR_{ij}=NPV_{ij}/TNW_{ij}$. In this way, by appropriately setting the subscript "j", we obtain for each corpus the PVR_j which represents the phonetic variation rate considering a definite number of words "j". Table 2 summarizes the results of the PVR considering j = 1, 2, 3,4,5 and 20 (max number of words in a single sentence.) From table 2 we can see how nonlinearity affects language acquisition: globally, PVR decreases over time but counterintuitive phenomena such as regressions (Morgenstern et. al, 2012) are frequent: it could happen that a child mispronounces something that he had previously correctly pronounced. The same holds for PVR over sentence's lenght: we expect (and observe) that rate increase as the lenght increases, but there are some exceptions to the norm that could require a specific account.

Table 2: Main statistics for PVR by time and number of words

Time	Statistics	PVR_1	PVR_2	PVR_3	PVR_4	PVR_5	PVR_20
22	Mean	0.477	0.556	0.655	0.513	0.667	0.577
	Length	*132*	*62*	*56*	*40*	*18*	*343*
	S.D.	*0.501*	*0.416*	*0.311*	*0.299*	*0.322*	*0.415*
24	Mean	0.494	0.528	0.525	0.538	0.608	0.553
	Length	*79*	*90*	*68*	*39*	*26*	*324*
	S.D.	*0.503*	*0.362*	*0.322*	*0.247*	*0.268*	*0.371*
27	Mean	0.558	0.532	0.563	0.471	0.440	0.483
	Length	*154*	*108*	*87*	*86*	*50*	*580*
	S.D.	*0.498*	*0.388*	*0.284*	*0.247*	*0.239*	*0.359*
34	Mean	0.305	0.281	0.244	0.278	0.260	0.246
	Length	*82*	*57*	*71*	*89*	*63*	*641*
	S.D.	*0.463*	*0.341*	*0.270*	*0.208*	*0.232*	*0.266*

In a second step, we used CHAID (Kass G., 1980) to get a general insight on how PVR changes over time and which kind of phonetic units are correctly articulated and which are not. From the results obtained[2], we can clearly see how time is the main regressor because it splits most part of the *corpus*, then the lenght of sentences

[2] All statistical analyses were performed using R, Excel and SPSS. In the CHAID model, cases are weighted by TNW.

plays a role as well, as we can observe in the *corpus* "time 34", where the fourth word causes the formation of an additional branch to the tree. The main pattern CHAID has detected in a "blind" way is the morphological difference between phonemes: as we can see from the tree table of the CHAID model (table 3), in the node 15 (PVR_20 mean 0.971, variation rate very high) words are longer and contains many "r" and couples of consonants, sounds typically learnt later in development.

Table 3: Tree table for CHAID model (main results - first and last three PVR_20 values)

Node	PVR_20 (Mean)	N	Primary Independent Variable	p-value	Split values
15	**0.971**	68	w_mod_1r	0.000	ɑ̃kɔʁ; sɛlsi; spidœʁma; isi; vjɛ̃; pʁefɛʁ; boku; bɔ̃ʒuʁ; vwatyʁ; vɛʁt; kaʁgo; osito; ɛskaʁgo; pjɛʁo; by; tʁwa; katʁ; sɛ̃k; sis; sɛt; ɔ̃z; duz; tʁɛz; katɔʁz; kɛ̃z; sɛz; dissɛt; dizɥit; diznœf; vɛ̃; vɛ̃teœ; vɛ̃tdø; vɛt; vɛ̃tkat; tɛ; tetɛ; kwɛ̃kwɛ; kwɛ̃; ʁjɛ̃; kɔʁnəmy; flœʁ; vɛʁ
20	**0.918**	255	time	0.000	22
4	**0.880**	490	w_mod_1r	0.000	etɛ̃; ty; sɔʁ; muje; lə; ɑ̃kɔʁ; lwi; sɛlsi; spidœʁma; akʁoʃe; otuʁ; sali; tɔ̃be; uvʁ; dɛʁjɛʁ; pɔʁt; isi; sɥisi; alɔʁ; ɑ̃; adʁijɛ̃; aj; tɛ̃kjɛt; naomi; puʁ; lotʁ; metɛ; zafiʁa; sypɛʁ; desine; mɔ̃tʁ; nunuʁs; dɔʁmevu; ʒak,
30	**0.079**	165	w_mod_1r	0.000	wi; la; ø; œ̃; bɛ̃; komɑ̃; dø; ba; duz; tʁɛz; katɔʁz; dɑ̃; noemi; tɛl; twa; kwa; ə; tjɛ̃; konɛ; ɛm; ka; pe; y; ve; igʁɛk; zɛd; ɛn; potiʁɔ̃; kɑ̃guʁ; s; sɥila; paʁl; tʁo; tabul; taʁɛt
24	**0.033**	152	w_mod_2r	0.000	la; vø; papa; apɛl; bum; dudu; mamɑ̃; sa; lə; akemi; dɔn,
27	**0.025**	119	w_mod_2r	0.000	nɔ̃; le; papa; lə; isi; bys; ʒoli,

while in the node 11 (PVR_20 mean 0.267 – not shown) words are shorter and contain more vowels and bilabials (e.g. "ma","ba") and - more generally - sounds pronounced by using the external part of mouth (easier to learn because infants can spot them by seeing them and thus providing cues for imitation, unlike sounds such as "r" or "l" who are articulated at the bottom of the throat and thus they have to be deducted by the child). We wrote "blind" because CHAID cannot distinguish morphological differences between phonemes, yet it performs a remarkable result simply by calculating interactions between occurrences. In conclusion, in this paper we have shown how the use of the CHAID model could provide us a way to analyse and evaluate child language development in a quantitative manner. Our results are sufficiently coherent to the state of the art of phonetic units acquisition (McLeod et

al. 2018). The main limit is that this technique doesn't take into account morphological differences, as the PVR is calculated on the difference between "pho" and "mod", regardless of what they represent linguistically: in order to overcome this limit we start to use Python to analyse *corpora* according to a predetermined list of phonetic units to track and quantify every variation, then we turn them into a "Multistream graph" (Cuenca et.al, 2018). These are the future directions of our research, once again we are trying to combine statistics and linguistics to try to test whether and how "any variation does not randomly vary into any other, but it rather should follow an underlying pattern, as every variation has an order in itself" (Sauvage, 2015).

Inspecting cause-specific mortality curves by simplicial functional data analysis

Ispezione di curve di mortalità specifiche per causa attraverso l'analisi di dati funzionali simpliciale

Marco Stefanucci and Stefano Mazzuco

Abstract Cause-specific mortality rates describe the structure of mortality for a particular country and year. In this work we propose to analyze the dynamics of the rates through years and among countries using Functional Data Analysis (FDA). The particular nature of the data – compositions of a whole – requires nontrivial modifications of standard FDA procedures. Specifically, we applied a simplicial FPCA to data in order to show the main modes of variation. Preliminary results about a clustering are also discussed.

Abstract *I tassi di mortalità specifici per causa descrivono la struttura della mortalità per un dato paese e anno. In questo lavoro proponiamo di analizzare la dinamica dei tassi attrverso gli anni e tra paesi usando l'Analisi di Dati Funzionali (ADF). La particolare natura dei dati – composizioni di un totale – richiede modifiche non banali delle procedure standard dell'ADF. Nello specifico, abbiamo applicato la FPCA simpliciale ai dati per rivelare le principali forme di variabilità. Vengono inoltre discussi anche risultati preliminari riguardo al raggruppamento.*

Key words: Compositional Data; Functional Data Analysis; Cause-specific Mortality Curves.

1 Introduction

The study of the mortality is one of the main branch of demography. A recently published work [6] tries to furnish some insights regarding the decreasing trend of US life expectancy by inspecting mortality by cause. The authors show that midlife mortality caused by drug overdoses, alcohol abuses, suicides, and a list of organ system diseases have particularly increased in the last years. However, the study of cause–specific mortality rates is not straightforward. The key aspect of such quantities is the fact that they represent *compositions*, being part of a whole – the total mortality rate. Recent articles [2, 3] consider this feature of the data and apply models from Compositional Data Analysis (CoDA) [1] literature. However, in this work we are also interested in the evolution over time of cause–specific mortality rates and our approach is to think of these quantities as realizations of smooth *functions*, and apply tools from Functional Data Analysis [5]. The direct application of standard FDA methodology in this context would lead to imprecise analyses and the models have to be modified to take into account the compositional nature of the data. In section 3 we will briefly present a simplicial version of Functional PCA. To be more technical, a simplicial functional datum is a function $\mathscr{C}(t) : I \in \mathbb{R} \to \Delta^n$, from a compact subset of the real numbers to the n-dimensional simplex. Cause–specific mortality rates fall into this category. As an illustrative example, a sample of simplicial functional data taking values in the 2-dimensional simplex is presented in fig 1. This figure could be a simplicial representation of cause–specific mortality rates with only three causes, however a sensible grouping of causes of death would lead to a larger number of categories.

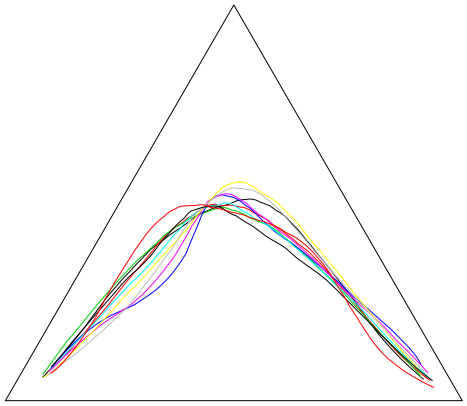

Fig. 1 Synthetic simplicial functional data.

2 Data

The data come from WHO mortality database, a public repository where mortality rates for several European countries and some non-European countries are collected. However, most of these countries does not have a time series long enough to be part of our analysis and we remove them. The final number of countries that entered the study is 22. For these countries we consider age–adjusted rates and age class–specific (i.e. 25–44, 45–64, 65+) rates, distinguishing by sex. The first and last years where data are available are 1959 and 2015, thus the functions are observed on a grid of 57 points. For the sake of simplicity we only consider 8 classes for the mortality: infectious and parasitic diseases, neoplasms (all cancers with the exception of lung cancer), lung cancer, endocrines diseases, circulatory diseases, respiratory diseases, digestive diseases and external causes. A plot of data for some selected countries is produced in fig 2.

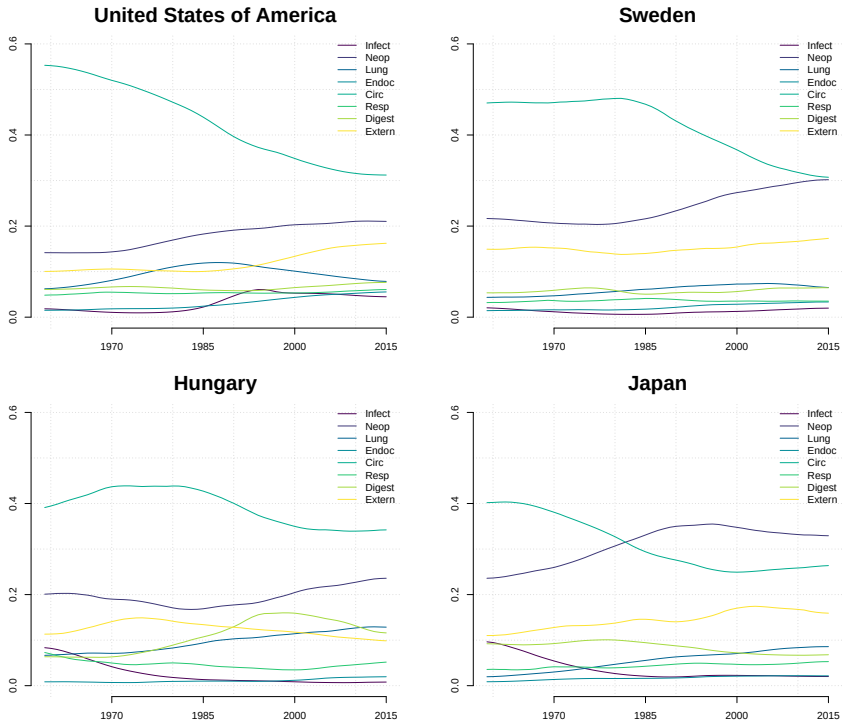

Fig. 2 Cause–specific mortality rates divided by the overall mortality rate for some selected countries in the analysis. Men, age 40–64.

3 Methodology

We first transformed the data by dividing the j-th cause–specific rate of the t-th year $\mu_x^{j,t}$ by the total mortality rate of that year, μ_x^t, obtaining $\tilde{\mu}_x^{j,t}$ (see [4]). These values are proportions that necessary sum to one:

$$\sum_{j=1}^{8} \tilde{\mu}_x^{j,t} = 1$$

This operation is called *closure* and can be further formalized as

$$\mathscr{C}(t) = \mathscr{C}\left\{\mu_x^{1,t}, \mu_x^{2,t}, \ldots, \mu_x^{8,t}\right\} = \left\{\frac{\mu_x^{1,t}}{\mu_x^t}, \frac{\mu_x^{2,t}}{\mu_x^t}, \ldots, \frac{\mu_x^{8,t}}{\mu_x^t}\right\}$$

The object $\mathscr{C}(t)$ is a multivariate functional object that takes values in the 7-dimensional simplex. Thus, as introduced in section 1, we need to take into account this aspect when building a model (i.e. principal components) for this objects. Specifically, thanks to the logratio transform [1] we are able to reduce the analysis to a multivariate functional PCA as illustrated in [5].

4 Results

Here we present preliminary results for males. The overall trends can be spotted in figure 2: neoplasms and circulatory diseases are the main causes of death, but while the former exhibit an increase in the last 50 years, the latter show a constant decrease. Infectious and parasitic diseases had a non-negligible level until the 80s. Lung cancer and endocrines diseases are slowly increasing in the male population. About the variability, the principal components that we computed reveal further interesting aspects of the mortality: most of the variability is due to neoplasms and circulatory diseases with a little contribution of infectious diseases, mainly in the first part of the considered period. This component accounts for about 1/3 of the total variability. Neoplasms and circulatory diseases are dominant also in the second component – that accounts for about 1/5 of the total variability , the only difference being the time period they are linked to: in this case is from mid 80s to now. The third and last component we considered explains about 15% of the total variability and it is mainly related to the overall level of lung cancer and external deaths, with a little contribution of respiratory diseases in the first years.
The projections of the data on the first three components are depicted in fig 3 and reveal a meaningful portrait of the mortality by cause over the years. Preliminary results regarding clustering show coherence with our geographic and demographic knowledge of the countries we considered. Further aspects are still under investigation such, for example, the main modes of variation of the mortality in the female populations.

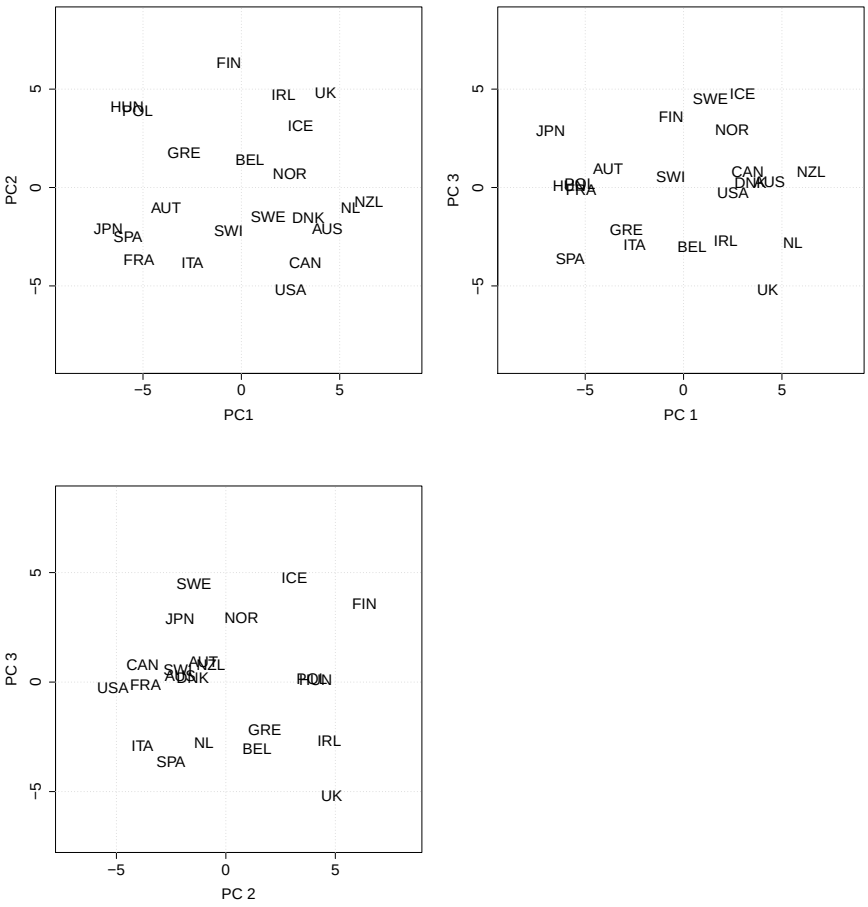

Fig. 3 Scores of the 22 countries in the first three principal components.

Intertemporal decision making and childless couples.

Decisioni intertemporali e coppie senza figli.

Daniela Bellani, Bruno Arpino and Daniele Vignoli

Abstract Economic research has addressed the role of intertemporal decision making in occupational, financial and educational decisions. Very few studies have empirically analysed the association between this preference and the reproductive behaviour. In this study, we use data from the Survey of Household Income and Wealth (SHIW) carried out by the Bank of Italy. In particular, we make use of a question included in the 2004, 2008, 2010 and 2012 waves to examine whether patience has an impact in influencing childlessness in Italy. Results of logistic regressions indicate a non-linear relationship. Individuals with high or low levels of patience are more likely to remaining childless.

Abstract *Studi economici hanno evidenziato l'importanza delle scelte intertemporali nelle decisioni riguardanti la sfera occupazionale, finanziaria ed educativa. Pochi lavori hanno analizzato, da un punto di vista empirico, l'associazione tra le preferenze intertemporali e il comportamento riproduttivo. In questo studio utilizziamo i dati dell'Indagine sui Redditi e la Ricchezza delle Famiglie Italiane della Banca d'Italia per gli anni 2004, 2008, 2010 e 2012 che forniscono informazioni sulle preferenze temporali degli intervistati. I risultati ottenuti dalle regressioni logistiche mostrano che la relazione tra pazienza e non avere figli risulta essere non-lineare. Coloro che mostrano alti o bassi livelli di pazienza hanno una maggiore propensione a non avere figli.*

Keywords: childlessness, time preferences, SHIW.

1 Introduction

In the last decades, the literature on fertility has extensively analysed several micro-, meso- and macro-level determinants influencing the decision-making process underlying the fertility timing and quantum choices (see Balbo et al., 2013 for a review).
Values and preferences, socio-economic conditions, demographic characteristics, health, social networks are among the micro-level factors that have been found to impact fertility behaviours. Although to a more limited extent, personality traits have also been analysed as determinants of fertility behaviours (Jokela, 2012).
In this paper we consider the specific trait represented by time preferences. They are strictly related to the trade-off between costs and benefits occurring in different time periods. Sociological and demographic studies of fertility have largely overlooked the role of impatience. One exception is De Paola and Gioia (2017) that studied the association between impatience and marital dissolution. In their study they found that impatient individuals are more likely to experience divorce. This is because they invest less time to find the best match that, in turn, increases the likelihood of separation. They add also that another mechanism that links impatience and marital dissolution is associated with the ability to manage for unanticipated shocks. While patient individuals are more prone to wait for the resolution of marital conflicts, this is not the case for those that prefer immediate (but lower) gains today.
This article gives us important insights for the study of the relationship between time preferences and other demographic behaviours, such as fertility decisions.
Italy represents an ideal context for this analysis given that couples carefully plan fertility behavior (Dalla Zuanna, De Rose, and Racioppi, 2005).

1.1 Hypotheses

One could expect that impatient individuals prefer to avoid or limit the material and immaterial costs of having a child thus reducing their fertility. Since they prefer short-term benefits and they tend to avoid sacrifices for long-term benefits, in a certain sense, they are more aware to immediate costs of fertility (in economic and non-economic terms) than to future gains (children as a security in old age). This implies that the relationship between impatience and the likelihood of remaining childless should take a positive sign (Hyp 1a).
However, it is likely that extremely patient individuals wait for a too long period of time to have a child because they want to achieve the best conditions for the new born. For example, they search for a high level of marital quality and job stability which might affect the likelihood of planning a child. This could increase the likelihood of remaining childless (Hyp 1b).

2 Data and empirical strategy

We use data from the Survey of Household Income and Wealth (SHIW) carried out by the Bank of Italy every two years since mid-sixties. SHIW collects information on consumption, income and wealth in addition to several household characteristics for a representative sample of Italian households drawn in two stages from population registers. The sample used in the most recent waves comprises about 8,000 households (20,000 individuals). From the 1989 wave a rotating panel component has been introduced. The share of panel households on the total has been around 45-50% of the total since 1993. The SHIW provides very detailed information on the demographic and socio-economic characteristics of individuals that belong to the same household unit. Moreover, the questionnaire of the survey includes questions that allow us to precisely capture time preferences of the head of the household. In this sense, SHIW is one of the very few surveys (together with GSOEP, NLSY and PSID) that provide this type of information. The question on time discounting preferences provided by SHIW data has been previously used, for example, to study trust (Albanese et al 2017) or divorce (De Paola and Gioia 2017) and is widely used to elicit impatience from a survey (Frederick et al 2002). It was included in the 2004, 2008, 2010 and 2012 questionnaires. It examines the choice a head of the household would take in a hypothetical situation. He/she has to decide how much money he/she renounces in order to receive a certain amount of money in the present instead after one year. After the description of the hypothetical situation, the respondent has to answer a series of questions about the amount s/he prefers to renounce. More precisely, heads of the households are asked the following question:
Q. Imaging receiving an unexpected inheritance (or lottery) equal to the amount of income that your family earns in a year. Now, imagine that the inheritance is only available after one year.
Would you be willing to sacrifice 10 % of that amount to have immediate access to the remaining 90 %? *yes: go to question (Qa) *no : go to question (Qb)";
Qa. "Would you sacrifice 20%? *yes *no
Qb. "Would you sacrifice 5%? *yes *no

The corresponding indicator operationalizes time discounting preferences as the rate of which the head of the household discounts future utility. We transform these values in rates, thus subtracting to 1 the percentage chosen in order to obtain the money immediately. We then compute the discount rate, thus generating our explanatory variable (as in De Paola and Gioia 2017). It is a continuous variable that can assume values between 0 to 0.25. In the case the respondent prefers a bigger economic reward in the future but smaller in the present, the variable will take low values. In the case he/she prefers higher rewards in the present but lower in the future the variable will take higher values.

We restrict our sample to the panel component of households where the respondent answers at least one time to the question of interest. In case more than one answer is given, we compute the measure of impatience taking the average value of the answers given across the waves. The study of the association between

time discounting preferences and reproductive behaviour covers the period 1995-2016. We consider married and cohabiting couples in a heterosexual partnership. We restrict our sample to female partner aged between 16 and 45 and male partner aged between 16 and 55 (N=760).

2.1 Method

Our dependent variable is the likelihood of remaining childless, i.e. not progressing from zero parity to one parity. Facing the classical trade-off between tractability and flexibility of specification, we model the probability of remaining childless versus progressing to first parity using logistic regression models.
Our main explanatory variable is the time discounting preferences. The majority of individuals who answered the time preferences question declared a value higher than zero of their hypothetical winnings they are prepared to give up as to gain immediate access to the money– only 21.72% declared the value of zero. Among those that declared a value higher than zero, 8,5% declared that they would sacrifice a 20% of the hypothetical winning to receive the sum immediately. We observe a considerable heterogeneity in those that declared a renounce higher than 0% and lower than 20%.

3 Empirical results

We model the probability to remain childless versus having the first child during the observation period. We include in our model time preference and its squared value – since it produces a better fit of the model. We control for the woman's age (and its squared), man's age, year, region of birth, gender of the respondent, female and male partner's educational level (low, medium and high education corresponding to ISCED 1-2, 3-4 and 5-6), credit rejection, liquidity constraints and equivalized income.

In Table 1 we present our main findings. For all specifications (M1, M2 and M3) the coefficient of the squared term of the TDP remains positive and statistically significant, and the size of the estimates does not vary substantially. All in all, our findings show a u-shaped association between impatience and not progressing to the first child. Results show that for both very low (patience) and very high (impatience) respondents, the probability to progressing to first parity is lower.

4 Conclusions

In order to examine whether time discounting preferences influence childlessness we use a nationally representative survey from Italy, the Survey of Household Income and Wealth (SHIW). By estimating logistic regression models, we find that there is a u-shape relationship between the degree of time discounting preferences and remaining childless. In particular, very impatient and very patient individuals have a higher likelihood of not having any child, while the opposite is valid for those with an average value of patience.

Italian Households' Material Deprivation: Multi-Objective Genetic Algorithm approach for categorical variables

La deprivazione materiale delle famiglie italiane: un algoritmo genetico multi-obiettivo per dati categoriali

Laura Bocci[1] and Isabella Mingo[2]

Abstract Material deprivation is a complex concept referring to the inability of families to meet certain needs. Some indicators of material deprivation, included in the EU portfolio, are collected by EU-SILC survey on households and individuals through categorical variables. In this study, the large dataset provided by EU-SILC survey collected in Italy in 2017, on a sample of 22,226 households is analysed. The main goal is to identify clusters of Italian households to take into account the multiple aspects of material deprivation conditions, including environmental ones. To that end, a multi-objective genetic algorithm as a clustering technique for categorical data is proposed. The results are compared with those obtained by applying a *K*-means algorithm to latent variables scores.

Abstract *La deprivazione materiale è un concetto complesso che si riferisce all'incapacità delle famiglie di soddisfare determinati bisogni. Alcuni indicatori di deprivazione materiale, inclusi nel portfolio UE, vengono rilevati con l'indagine EU-SILC su famiglie e individui, attraverso variabili categoriali. In questo studio, viene analizzato l'ampio set di dati fornito dall'indagine EU-SILC rilevato in Italia nel 2017, su un campione di 22,226 famiglie. L'obiettivo principale è quello di identificare clusters di famiglie italiane per tenere conto dei molteplici aspetti delle condizioni di deprivazione materiale, inclusi quelli ambientali. A tal fine, viene proposta un'applicazione di algoritmi genetici multi-obiettivo come tecnica di raggruppamento per dati categoriali. I risultati ottenuti vengono confrontati con quelli di un algoritmo K-means applicato a punteggi di variabili latenti.*

Key words: material deprivation, multi-objective genetic clustering algorithm, categorical data.

1 On Material Deprivation in the EU: Indicators and Data

Material deprivation (MD) is the second criterion of the social exclusion target group, included in the EU portfolio of commonly agreed indicators in 2009, to better reflect the different living standards in the EU [3]. It is a complex concept which involves several variables based on the enforced lack of some items and referring to the inability of families to meet certain needs. The selected indicators are: 1. arrears in mortgage or rent or utility bills; 2. ability to keep home adequately warm; 3. to face unexpected expenses; 4. to afford a meal with meat, chicken, fish (or vegetarian equivalent) every second day; 5. to afford paying a one week annual holiday; 6. to have a colour television set; 7. to have a washing machine; 8. to have a car; 9. to have a telephone. These indicators are provided by European Union Statistics on Income and Living Conditions survey (EU-SILC) through categorical variables: some of them (variables 2, 3, 4, 5) are binary (response modes: Yes / No), while those referred to durable goods (variables 6, 7, 8, 9) have three response modes (Yes / No, cannot afford / No, other reasons) in order to differentiate between individuals who cannot afford a certain good and those who do not have it for other reasons; variable 1 have also three response modes (Yes / Yes, once / Yes, twice or more).

The standard material deprivation indicator adopted in 2009 uses a threshold of at least three deprivations to identify people considered as deprived, while the severe concept adopted in the context of the Europe 2020 strategy sets the threshold at four. The main limitations of this approach are the small number of items and above all the methodological choice based only on the number of deprivations rather than on the combination of the different type of inabilities to meet family needs. Moreover, other items could be added to take into account physical and social environmental indicators, deemed relevant in the analysis of material deprivation. Then, the number of possible combinations of all these multiple aspects becomes increasingly complex.

In this study, we analysed the large dataset provided by EU-SILC survey collected in Italy in 2017 on a sample of N = 22,226 households. The choice of MD variables was driven by the conviction that the analysis of material deprivation should also rely on physical and social environment in which each family lives daily and that affects the quality of life of its members. Therefore, in addition to the 9 variables described above, the following were considered: 10. noise from neighbours or from the street; 11. pollution, grime or other environment problems; 12. crime, violence or vandalism in the area (response modes: Yes/No)[1]. Moreover, some other variables were introduced in the analysis to describe the family clusters. They concern demographic, economic and contextual characteristics of the households: their size, poverty indicator, urbanization level and region.

The main goal is to identify substantially meaningful clusters of Italian households to take into account the multiple aspects of material deprivation conditions. Dealing with categorical variables, suitable algorithms should be adopted. To that end, it is

[1] The consistency of the selected MD variables was tested through Non Linear Principal Component (Promax rotation) which highlighted four different and correlated deprivation dimensions (α=0.934; VAF= 57.86%; λ=6.944): 1) maintenance incapacity (λ_1=2.524); 2) environmental deprivation (λ_2=1.819); 3) deprivation of durable goods (λ_3=1.394); 4) deprivation of household goods (λ_4=1.379).

proposed an application of a Multi-Objective Genetic Algorithm (MOGA) as a clustering technique for categorical data. Finally, the results are compared with those obtained by applying a *K*-means algorithm to latent variables scores.

2 Methods

Categorical data are pervasive in practice. Many real-life datasets are categorical in nature, where no natural ordering within a categorical attribute domain can be found. Most of the clustering algorithms are designed for datasets where the dissimilarity between any two units can be computed using standard distance measures such as Euclidean distance. However, Euclidean distance fails to capture the similarity of data units when attributes are categorical or mixed. In such situations, the clustering algorithms, such as *K*-means, cannot be applied. Some extension of the *K*-means algorithm have been proposed for categorical datasets. Huang [4] proposed the so-called *K*-modes algorithm, in which modes instead means are used to represent the cluster centers. Another extension of *K*-means is the Partitioning Around Medoids (PAM) algorithm [5], or *K*-medoids, where the cluster medoids (i.e., the most centrally located point in a cluster) are determined. A major disadvantage of *K*-means, *K*-medoids or *K*-modes clustering algorithms is that these algorithms often tend to converge to local optimum solutions. Moreover, all these algorithms rely on optimizing a single objective to obtain the partition which may not work equally well for different kinds of categorical data. Hence, it could be profitable to consider multiple objectives that need to be optimized simultaneously. The use of Multi-Objective Genetic Clustering Algorithms (MOGCAs) has emerged as an attractive and robust alternative in such situations. MOGCAs combine the need to optimize different criteria with the capacity of genetic algorithms to perform well in clustering problems, especially when the number of groups is unknown and the dataset to be analysed is very large.

In this paper a MOGCA, integrating the *K*-modes algorithm and simultaneously optimizing two objective functions for automatically partition the large EU-SILC dataset, is applied. A modified version of the Non-Dominated Sorting Genetic Algorithm II (NSGA-II) proposed by Bandyopadhyay et al. [1] as clustering procedure was developed to take into account the specific characteristics of the data. A crucial point in the definition of a MOGCA is the choice of both the encoding of chromosome to represent a solution (partition) and a suitable set of objective functions that are to be optimized simultaneously. In this work a cluster prototype-based encoding of chromosome is adopted for two reasons: a) the large number of units to be clustered does not make possible the use of a different encoding strategy, such as a point-based approach; b) the search for different number of clusters simultaneously. The adopted encoding allows each chromosome to encode a different number of clusters K which may vary in a given pre-specified interval $[K_{min}, K_{max}]$, where K_{min} has to be 2 at least. The chromosome has fixed length K_{max} ($K_{max} << N$) and is coded as a sequence of K_{max} symbols. Each symbol representing a gene may be of two kinds. Type 1: a vector of J coordinates (integer numbers) representing the mode of a cluster.

If units are described in terms of J categorical variables $\{A_1, A_2, \ldots, A_J\}$, the cluster mode is the vector of the attributes each of which corresponds to the most frequent category occurring under the respective variable over all the units belonging to the cluster. Type 2: the character # to mean "don't care". As K must be 2 at least, the symbols # cannot be more than ($K_{max} - 2$). However, chromosomes may possibly not include any "don't care" symbol at all. In general, the chromosome will contain, arranged in any order, K cluster modes and ($K_{max} - K$) symbols #.

Two different sets of fitness functions are used: in the first setting the two functions are the Total Within-Cluster Dissimilarity (*TWCD*) and the Davies-Bouldin (DB) index, in the second one the *TWCD* and the number of clusters K. The Total Within-Cluster Dissimilarity (*TWCD*) is defined as

$$TWCD = \sum_{k=1}^{K_i} \sum_{i}^{N} u_{ik} d(\mathbf{x}_i, \mathbf{c}_k)$$

where $u_{ik} = 1$ if unit $\mathbf{x}_i$ belongs to cluster k, 0 otherwise, $\mathbf{c}_k$ denotes the mode of the k-th cluster and $d(\mathbf{x}_i, \mathbf{c}_k)$ is the Hamming distance between unit $\mathbf{x}_i$ and the centroid $\mathbf{c}_k$ of cluster k, such that $d(\mathbf{x}_i, \mathbf{c}_k) = \sum_{j=1}^{J} \delta(x_{ij}, c_{kj})$ where $\delta(x_{ij}, c_{kj}) = 0$ if $x_{ij} = c_{kj}$, 1 otherwise.

In both settings, the objectives, which are contradictory in nature, must be minimized simultaneously.

NSGAII (Deb et al., 2002) is used as the underlying multi-objective optimization algorithm. An initial random population of chromosomes of size $M = 200$ is created. Then, in the initial population for $i = 1,\ldots,M$, an integer K_i is generated uniformly random in $[K_{min}, K_{max}]$. Therefore, the i-th chromosome encodes K_i cluster modes and each mode is assigned to a gene selected at random within the chromosome. The gene encoding a cluster mode consists of J coordinates each of which is one out of the categories (randomly selected) of the J categorical variables. The genes that are left unassigned are set to the symbol #. The population is sorted based on the non-domination relation. Each chromosome of the population is assigned a fitness which is equal to its non-domination level. A crowding distance-based binary tournament selection strategy [2] is used. The crowding distance operator manages to maintain diversity in the Pareto front. Thereafter, crossover and mutation are used to create a new population of size M, and the process continues. A special crossover and mutation operations are applied to handle the presence of "don't care" symbols in the chromosomes. A two cutting points crossover is adapted. A pair of chromosomes is selected with crossover probability p_c=0.8. Let **R** and **Q** be these two chromosomes. Two integer numbers p and q are chosen at random in the interval $[1, K_{max}]$. If $p < q$ the genes from p through q of the chromosome **R** are exchanged with the genes that in the chromosome **Q** occupy the same positions. However, there is a chance of yielding invalid chromosomes after crossover since the same cluster mode may occur in a child chromosome more than once. Therefore, a penalty function approach is used to handle this situation: an invalid chromosome is given bad fitness values for all the objectives so that it automatically goes out of the competition in subsequent generations. The mutation operator is implemented with a mutation probability p_m=0.01 by generating a new mode or erasing an existing one with equal probability. Whenever mutation takes place, as usually, units are re-allocated to the cluster whose

mode is the nearest one in terms of Hamming distance. Finally, the elitist strategy is implemented. The near-Pareto-optimal chromosomes of the last generation provide the different solutions to the clustering problem.

The multi-objective genetic algorithm generates a set of nondominated trade-off Pareto optimal solutions. None of these solutions can be improved further in any objective value without degrading some other objective value. Among these nondominated set, the final solution is selected using the two cluster validity indices of Dunn and PBM [7], not used as an objective function of the algorithm. Therefore, the cluster modes encoded in this optimal solution are extracted and the partition is obtained assigning each unit to the cluster with the nearest mode in terms of Hamming distance.

3 Main results

The Pareto optimal solutions resulting by applying the MOGCA using both *TWCD* and DB or *TWCD* and *K* as fitness functions were compared. In the first setting, the Dunn and PBM indices suggest two partitions in eight and nine clusters, respectively. Instead, in the second setting the two indices agree in suggesting the same partition in five clusters. These results highlight that the choice of the functions to be optimized represents a key aspect and depends on the data, as stressed in the literature [6].

The partition in five clusters suggested by the above validity indices was analysed to identify substantially meaningful clusters of Italian households. To that end, characteristic categories of MD indicators, demographic, economic and contextual variables are used (Table 1). Taking into account the multiple aspects of material deprivation conditions, the following clusters were detected: 1: Families with maintenance difficulties (23.50%); 2: Not deprived families (42.18%); 3: Moderately deprived families (12.55%); 4: Families with environmental disadvantages (7.57%); 5: Deprived families who own durable goods (14.20%).

Finally, this partition was compared with that obtained by applying a *K*-means algorithm to the latent variables scores (see note 1 p. 2), searching for $K = 5$ clusters and starting from several random solutions. The selected *K*-means solution is the best according to Calinsky and Harabasz index. The two partitions (the one from MOGCA on categorical variables and that from *K*-means on latent variables scores) seem partially consistent (Contingency coefficient = 0.748) and identify some stable clusters which deserve further investigation.

* Test value p<0.000.

[1] Test value is calculated comparing the proportion of a category in the *i*-th cluster and the proportion of the same category in the whole sample. A high test value indicates that the proportion in the cluster differs (positively or negatively) significantly (p<0.05) from that in the sample characterizing the cluster itself. For brevity, Table 1 shows only those categories which differ positively.

LI-CoD Model. From Lifespan Inequality to Causes of Death

Modello LI-CoD. Dalla Lifespan Inequality alle Cause di Morte

Andrea Nigri and Susanna Levantesi

Abstract The evolution of lifespan disparity is gaining a central role in mortality literature. From the beginning of the new millennium, its evolution has led scholars to give more emphasis to longevity and its relationship with causes-of-death evolution. Following this line of research, we propose a novel model aiming to provide the causes-of-death mortality surface, exploiting the relationship between mortality rates by cause-of-death and lifespan variability. Taking advantage of this relationship, and using data from Human Causes of Death Mortality Data Base, our model is able to reconstruct the mortality surface by causes, using a single value of lifespan inequality as input.

Abstract L'evoluzione della lifespan disparity sta acquisendo un ruolo centrale nella letteratura sulla mortalità. Dall'inizio del nuovo millennio, la sua evoluzione ha portato gli studiosi a dare maggiore enfasi alla longevità e al suo rapporto con l'evoluzione delle cause di morte. Seguendo questa linea di ricerca, proponiamo un nuovo modello che mira a fornire la superficie della mortalità per cause di morte, sfruttando la relazione tra i tassi di mortalità per causa di morte e la variabilità della durata della vita. Sfruttando questa relazione e utilizzando i dati dello Human Causes of Death Mortality Data Base, il nostro modello è in grado di ricostruire la superficie della mortalità per cause, usando come input un singolo valore della lifespan disparity.

Key words: Life expectancy, Forecasting, CoD.

1 Introduction

Over the last two centuries, longevity evolution has had a prominent impact on population dynamics, showing a rapid decline in mortality levels in developed countries. These improvements are driven by medical progress, better living conditions, leading to the infant mortality reduction. On the other hand, scientific achievements against chronic diseases ([8], [12]) lowered the adult age mortality after the second-world war, likewise the recent delaying of mortality at older ages ([14]). As a result, life expectancy at birth has increased over time, without any sign of an impending limit in human life boundaries ([5]). This latter behavior seems to be in lockstep with a significant decrease in lifespan variability, which could be due to different causes-of-death (CoD) composition. In light of that, the understanding of evolution of CoD composition is crucial in predicting the aging process and the population health. Concerning forecasting, cause-specific mortality is often based on predicting cause-specific death rates independently. Only a few methods incorporating dependence among causes have been suggested. An attractive alternative is to model and forecast cause-specific death distributions, rather than mortality rates, as dependence among the causes can be directly incorporated ([3]). Unfortunately, these processes are often not straight and show a lack of parsimony and interpretability. Furthermore, they are based on a rigid structure that does not taken into account the revolution of CoD pattern over time. Our paper contributes to the literature proposing a novel statistical tool able to provide the CoD mortality surface, using the relationship between CoD mortality rates and lifespan variability. In particular, given an age, our model is able to reconstruct the mortality surface by causes, using a single value of lifespan inequality as input. Thus, using data for several countries, we try to explain and forecast the remarkable changes in the transition phases that developed countries have exhibited in the period after the second world war, providing age-cause specific action.

2 Longevity indicators

The constant improvement of BPLE suggests that mortality reductions should not be viewed as a disconnected sequence of unrepeatable revolutions, but rather as a regular flow of continuous progress ([6]). Clearly, mortality is linked to social progress in terms of health, nutrition, education, hygiene, and medicine ([7]). Moreover, mortality improvements have been combined with an increase of lifespan equality in which the increase in the age-at-death corresponds to the increase of the compression of the distribution around its modal value ([4]). While life expectancy has been proven to hide heterogeneity in individual mortality courses, lifespan disparity measures

both uncertainty in the age-at-death distribution and heterogeneity[1] ([10]). In the following equations we provide the formal notation and definitions for both life expectancy and lifespan disparity.

- **Life expectancy**
  Let $S(x,t)$ and $\mu(x,t)$ be two continuous functions with respect to age x and time t, respectively representing the survival probability and the force of mortality of an individual aged x at time t in a given population. We denote $e_{x,t}$ the life expectancy at age x and time t, that is defined as follows:

$$e_{x,t} = \frac{\int_x^\infty S(y,t)dy}{S(x,t)} \tag{1}$$

  where $S(x,t) = \exp\left(-\int_0^\infty \mu(x+\xi,t+\xi)d\xi\right)$ are the survival probabilities.

- **Lifespan disparity**
  We denote $e^\dagger_{x,t}$ the lifespan disparity that is an indicator of the lifespan variation representing the life expectancy lost due to death by an individual aged x at time t ([13]). Formally, its functional form is defined as follow:

$$e^\dagger_{x,t} = -\int_x^\infty S(y,t)\ln S(y,t)dy \tag{2}$$

  The lifespan disparity at birth is: $e^\dagger_{0,t} = -\int_0^\infty S(y,t)\ln S(y,t)dy$. Lifespan disparity varies among populations and over time. It measures the dispersion in the age-at-death: when mortality is highly variable, some individuals will die at a much lower age than the expected age-at-death, contributing many lost years to life disparities; conversely, when mortality is highly concentrated around older ages or the modal age, life disparity decreases.

These two variables show latent behaviors that should be represented by incorporating in forecasting the relationship between lifespan inequality and CoD composition. Our approach aims to introduce a new perspective in the forecasting of CoD mortality surface, thus providing more accurate predictions.

3 Data and model

We use data from Human Causes of Death Mortality Data Base that provides death rates specific for ages and causes of death. This database is coded by using the international classification of diseases (ICD), providing different aggregation levels: full list, intermediate list, and shortlist. Each classification has been developed using the same criteria for all countries, ensuring homogeneity and comparability. For our aims,

[1] In addition to life disparity, other inequality measures have been proposed in literature, e.g. the Gini coefficient and the Keyfitz's entropy ([9], [11]) that appear to be linearly related and negatively correlated to life expectancy at birth ([1]).

we use the shortlist that provides the highest level of ICD aggregation, underlining 10 different macro CoD. Afterward, we perform an additional aggregation as follows:

- **Circolatory:** Heart diseases (I00-I52); Cerebrovascular diseases (G45, I60-I69); Other and unspecified disorders of the circulatory system (I70-I99)
- **Neoplasy:** Neoplasms (C00-D48)
- **Diab:** Endocrine, nutritional and metabolic diseases (E00-E90)
- **External:** External causes (V01-Y98)
- **Perinatal:** Diseases of the genitourinary system and complications of pregnancy, childbirth and puerperium (N00-O99) Certain conditions originating in the perinatal period and congenital malformations/anomalies (P00-Q99, R95)
- **Respiratory:** Acute respiratory diseases (J00-J22, U04); Other respiratory diseases (J30-J98)
- **Infectius:** Certain infectious diseases (A00-B99)
- **Digestive:** Diseases of the digestive system (K00-K93)
- **Other:** Diseases of the skin and subcutaneous tissue, musculoskeletal system and connective tissue (L00-M99); Diseases of the blood and blood-forming organs (D50-D89); Mental and behavioral disorders (F00-F99); Diseases of the nervous system and the sense organs (G00-G44, G47-H95)

Let x be the age, t the year and c a specific CoD. Given a certain age x, the aim of the model is to convert a value of lifespan inequality $e^{\dagger}_{0,t}$ into a list of CoD specific rates $m_{c,t}$ as follows:

$$log(\hat{m}_{c,t}) = \beta_c log(e^{\dagger}_{0,t}) + \delta_c \gamma + \varepsilon_c \tag{1}$$

Where: β_c is CoD-specific pattern of human mortality, δ_c the correction of mortality improvement over CoD, γ the parameter to be optimize and ε_c are the errors such that $\varepsilon_c \sim \mathcal{N}(\mu, \sigma^2)$. In the numerical experiment we use the following input data: $x \in \{0, ..., 100\}$, causes: $c \in \{Circ, Diab, ..., Resp\}$, year: $t \in \{1999, ..., 2013\}$.

The projected values of lifespan inequality and total mortality rate(m_t), which constitute the model's input, can be given by a certain extrapolation method or be the target values resulted by official forecasting (e.g. WHO).

In order to obtain the desired CoD mortality rates we define the following steps, starting from $m_{c,t}$ for a given age x, $e^{\dagger}_{0,t}$ and m_t as input:

- We estimate the slope, β_c, of the linear relation between the logarithmic transformation of lifespan inequality and the CoD specific rates over the observation time t. This is done by using the method of the least-squares, by minimizing the sum of squared residuals: $min \sum_c [log(m_{c,t}) - \beta_c log(e^{\dagger}_{0,t})]^2$;
- We estimate the parameter δ_c by computing the singular value decomposition (SVD) of the matrix of regression residuals, R, obtained in the previous step: $SVD[R] = PDQ^T$. Where D and Q are matrices of left and right singular vectors, and P is a diagonal matrix with singular values along the diagonal. The first term of the SVD, is used for obtaining the estimates of δ_c that can be interpreted as the adjustment of mortality improvement over CoD;
- We compute the mortality rates: $\hat{m}_{c,t} = exp\{\beta_c log(e^{\dagger}_{0,t}) + \delta_c \gamma\}$, where $\gamma = 0$

- Give the total level of mortality, m_t, we optimize the CoD mortality rates finding the optimal value of γ where $\sum_c |\hat{m}_{c,t} - m_t| = 0$.

4 Results

The model is applied to the USA data from 1999 to 2013. Figure 1 shows the model fitting with 95% confidence interval in the year 1999. In order to verify the model's

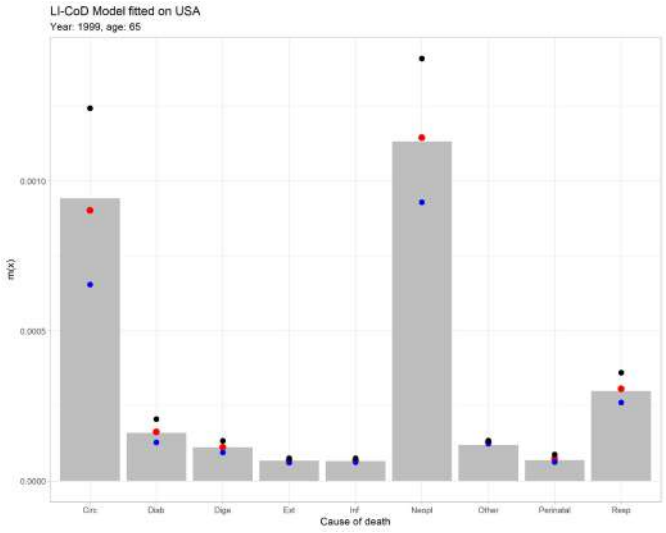

Fig. 1: Model fitting. Predicted values (black dots) and 95% confidence intervals (red and blue dots). Country USA. Year 1999.

accuracy, we perform a backtesting setting the fitting period to 1999-2010 and the forecasting period to 2011-2013. The forecasting results given by the backtesting are compared by the root mean squared error (RMSE) and the mean average error (MAE). Both the values of RMSE and MAE are very low, highlighting the accuracy of the model in predicting CoD mortality rates.

5 Conclusion

In this paper, we provide an innovative model to forecast CoD mortality, able to catch the hidden pattern and the relationship between two summary demographic measures, lifespan inequality and age-specific CoD mortality rates. Our model can have an important application in the context of incomplete data, when the official

Table 1: RMSE and MAE by CoD. Country USA. Years 2011-2013.

CoD	RMSE	MAE
Circolatory	0.000038511	0.000036751
Neoplasy	0.000026127	0.000024954
Diab	0.000007973	0.000007960

Modeling Well-Being through *PLS-SEM and K-M*
Misurare il benessere con il modello PLS-SEM e K-Means

Venera Tomaselli[1], Mario Fordellone[2], Maurizio Vichi[3]

Abstract The concept of "fair and sustainable" well-being (BES) is employed to estimate the effects of 2008-2016 economic crisis on voting behaviour. Many studies suggest overcoming Gross Domestic Product as the only indicator to measure economic growth and development. So, in addition to strictly economic indicators, social welfare and performance of institutions, and public services indicators are used. With the aim to build a composite indicator of well-being, based on BES elementary indicators and domains, *Partial Least Squares-Structural Equation Modeling* and *K-means* clustering simultaneous method is employed to model the well-being classifying territorial micro-areas.

Abstract *Il benessere "equo e sostenibile" (BES) è impiegato per stimare gli effetti della crisi economica 2008-2016 sul comportamento di voto. Numerosi studi suggeriscono il superamento del prodotto interno lordo come unico indicatore per misurare la crescita e lo sviluppo economico. Pertanto, oltre ad indicatori strettamente economici, l'analisi tiene conto degli indicatori BES relativi al benessere sociale ed alle prestazioni delle istituzioni e dei servizi pubblici. Con l'obiettivo di costruire un indicatore composito di benessere, basato su indicatori elementari e domini del BES, il metodo simultaneo Partial Least Squares-Structural Equation Modeling e K-means clustering è utilizzato per l'analisi del benessere e la classificazione di micro aree territoriali.*

Key words: composite indicators, *Partial Least Squares-Structural Equation Models and K-means* method, well-being, territorial micro-areas

1 Introduction

The concept of well-being is very complex and takes into account economic resources, public policies, quality of the environment, and many other topics. Well-being indicators, indeed, are proxies of unobservable, latent dimensions.

By questioning the use of Gross Domestic Product (GDP), the study aims to measure well-being through a multidimensional approach on the basis of the relationships among elementary indicators and domains proposed in the analysis of well-being through BES in order to define the territorial differences of well-being more reliably.

The indicators have been selected from 12 BES domains, grouped in turn into 6 topics: economy and labour market, education, environment, institutional performance, safety and quality of services. The crucial issues are:

- is the economic well-being level the only useful and meaningful measurement to explain the variability of territorial micro-areas?
- are indicators closely related to economic well-being and indicators of well-being related, for instance, to the quality of services and opportunities available in the territory, do not necessarily are correlated?
- is the well-being a composite concept based on a scaling of specific priorities?

In the following section 2, the well-being measurement is discussed; in section 3 the PLS-SEM and K-Means method is presented and in sections 4 the results obtained simultaneously through well-being composite indicator and classification method for the territorial micro-areas are delivered.

2 Well-being measurement

The measures of well-being, economic progress, and social welfare are adopted as drivers for designing public policies by decision makers (Jayawickreme et al., 2012; Layar, 2011; Sachs, 2012). The measures more accurately depict changes not only in individual living standards (Helliwell et al., 2012) but simultaneously also in comprehensive national economic growth (Diener et al., 2009).

Since around 2000 the Organisation for Economic Cooperation and Development (OECD) embarked on a global project to measure the well-being and progress of societies not just and not only through the economic performances. The project was involved in setting up and supporting the Commission on the Measurement of Economic Performance and Social Progress (CMEPSP), established by the President of France, Nicolas Sarkozy in 2008 and led by Stiglitz, Sen and Fitoussi.

The limits of GDP are reviewed in the report of the Commission because the GDP is not believed as a standard of the well-being of societies. The GDP, indeed, does not address economic inequality, happiness, quality of life, wellness, and other crucial societal parameters, and does not integrate environmental services into economic decisions (Stiglitz et al., 2010).

More recently, other scholars (Ven, 2015; Fleurbaey, 2015) have called for a new generation of multifaceted and more comprehensive well-being measures, better able to describe actual living standards and useful for a more accurate design of policies improving efficiency in resources assignment.

A series of measures of well-being, inspired at the Nussbaum-Sen approach to human capabilities and subjective well-being (Nussbaum and Sen, 1993), have been proposed in attempt to go beyond GDP with the aim to broaden the scope of effects in the assessment of policies. For instance, the Human Development Index by UNDP or the Better Life Initiative launched by OECD (2015) and many other approaches are based on the income, health, and education measurements of the countries' performance (for a review, see Fleurbaey and Blanchet, 2013).

From a technical view, many methods are employed to measure the well-being level through composite indicators. Nevertheless, no method is universally valid to select indicators based on theory-driven criteria, measure properly the concept, aggregate and normalise a set of input variables and define a weighting system (OECD, 2008).

The aim is to simplify the analysis of the multidimensional concept according with a formative or reflective measurement model, where elementary indicators are causes or effects of latent variables, respectively (Michalos, 2014; Simonetto, 2012).

Only some studies have focused on the construction of well-being composite indexes to evaluate and compare well-being specifically across the Italian provinces. Mazziotta and Pareto (2019) have obtained a global well-being index by aggregating 11 composite indices with AMPI (Mazziotta and Pareto, 2016) and have ranked Italian provinces for each dimension of well-being and have given an overall ranking.

Also Calcagnini and Perugini (2019) have proposed a composite indicator of well-being for the Italian provinces (NUTS-3) based on the methodology of the regional Index of Regional Quality of Development (QUARS) to analyse the extent to which the socio-economic heterogeneity in individual and contextual features within region affects the well-being among adjacent provinces.

In Italy, indicators of well-being have being used more and more for policy-making reasons at national, but also regional or local levels involving public institutions. From a theoretical point of view, the relationship of well-being assessment with policy-making process in healthcare, education, and training, or local services is the rationale to analyse the well-being measures at local level.

Since the policies of local governmental authorities have a direct and huge impact on the socio-economic context, the assessment of living standards at provincial level allows to evaluate economic, environmental, and social needs of the citizens at any level of government in order to implement and design decentralised policies. Following this, for territorial micro-areas the economic dimension could not be so crucial.

3 PLS–SEM-KM for composite indicator building

Partial Least Squares (PLS) methodologies are algorithmic tools with analytic proprieties aiming at solving problems about the stringent assumptions on data, e.g., distributional assumptions that are hard to observe in real life.

Tenenhaus et al. (2005) try to better clarify the terminology used in the PLS field through an interesting review of the literature, focusing the attention on the Structural Equation Models standpoint.

Given the $n \times J$ data matrix $\mathbf{X}$, the $n \times K$ membership matrix $\mathbf{U}$, the $K \times J$ centroids matrix $\mathbf{C}$, the $J \times P$ loadings matrix $\boldsymbol{\Lambda} = [\boldsymbol{\Lambda}_{\mathrm{H}}, \boldsymbol{\Lambda}_{\mathrm{L}}]$, and the errors matrices $\mathbf{Z}$, $\mathbf{E}$ and $\mathbf{D}$, the PLS-SEM-*K*M model simultaneously identify a SEM model for variables and a partitioning *K*M model for units according to the following three equations:

$$\begin{aligned} \mathbf{H} &= \mathbf{H}\mathbf{B}^{\mathrm{T}} + \boldsymbol{\Xi}\boldsymbol{\Gamma}^{\mathrm{T}} + \mathbf{Z}, \\ \mathbf{X} &= \mathbf{Y}\boldsymbol{\Lambda}^{\mathrm{T}} + \mathbf{E} = \boldsymbol{\Xi}\boldsymbol{\Lambda}_{\mathrm{H}}^{\mathrm{T}} + \mathbf{H}\boldsymbol{\Lambda}_{\mathrm{L}}^{\mathrm{T}} + \mathbf{E}, \\ \mathbf{X} &= \mathbf{U}\mathbf{C}\boldsymbol{\Lambda}\boldsymbol{\Lambda}^{\mathrm{T}} = \mathbf{U}\mathbf{C}\boldsymbol{\Lambda}_{\mathrm{H}}\boldsymbol{\Lambda}_{\mathrm{H}}^{\mathrm{T}} + \mathbf{U}\mathbf{C}\boldsymbol{\Lambda}_{\mathrm{L}}\boldsymbol{\Lambda}_{\mathrm{L}}^{\mathrm{T}} + \mathbf{D} \end{aligned} \tag{1}$$

subject to constraints: *(i)* $\boldsymbol{\Lambda}^{\mathrm{T}}\boldsymbol{\Lambda} = \mathbf{I}$; and *(ii)* $\mathbf{U} \in \{0,1\}$, $\mathbf{U}\mathbf{1}_K = \mathbf{1}_n$. Thus, the PLS-SEM-KM model includes the PLS-PM and the clustering *K*M equations (i.e., $\mathbf{X} = \mathbf{U}\mathbf{C}$ and then, $\mathbf{Y} = \mathbf{X}\boldsymbol{\Lambda}$ becomes $\mathbf{Y} = \mathbf{U}\mathbf{C}\boldsymbol{\Lambda}$).

The proposed methodology shows some important advantages with respect to the other proposed approaches for both cluster analysis and composite indicator construction: it is a new simultaneous approach.

In fact, identifies the best homogenous partition of the objects, represented by the best statistical relationships among latent and observed variables (Fordellone and Vichi, 2018; 2020).

4 Results: well-being composite indicator

The conceptual structure (Giovannini et al., 2012) of the BES considers 9 domains related to aspects that directly influence well-being, plus 3 instrumental or context domains.

In each well-being domain (ISTAT, 2018), elementary indicators and a synthesis through composite indicators related to each domain are integrated.

Our dataset consists in 109 units (Italian provinces) and 16 indicators organized in 9 different domains. Table 1 shows the relationships among MVs and LVs and the loadings estimated through PLS-SEM-KM.

Through the application of PLS-SEM-KM model, we have identified 3 homogeneous groups of Italian provinces. The optimal number of clusters identified corresponds to the maximum value of the pseudo-*F* function (around 1.1).

From this analysis, we can see that the theoretical polarity associated to each observed variable (see Table 1) is well described by the measurement PLS approach.

Whereas only the *Overcrowding of prisons* variable shows a non-significant loading, in fact also the sign is not correct.

Table 1: Measurement models matrix estimated through PLS-SEM-KM.

MVs	LV1	LV2	LV3	LV4	LV5	LV6	LV7	LV8	LV9	WB
MV1	0.795	0	0	0	0	0	0	0	0	0.721
MV2	0	0.750	0	0	0	0	0	0	0	0.619
MV3	0	-0.678	0	0	0	0	0	0	0	-0.917

MV13	0	0	0	0	0	0	0.105	0	0	0.226
MV14	0	0	0	0	0	0	0	0.277	0	-0.088
MV15	0	0	0	0	0	0	0	0.691	0	0.704
MV16	0	0	0	0	0	0	0	0	0.748	0.822

In Table 2 the path coefficients' matrix of the estimated structural-PLS model is shown.

Table 2: Structural model matrix estimated by PLS-SEM-KM.

	LV1	LV2	LV3	LV4	LV5	LV6	LV7	LV8	LV9	WB
LV1-Health	0	0	0	0	0	0	0	0	0	0.324
LV2-Education and training	0	0	0	0	0	0	0	0	0	0.053
LV3-Work-life balance	0	0	0	0	0	0	0	0	0	0.666
LV4-Economic well-being	0	0	0	0	0	0	0	0	0	0.247
LV5-Policy	0	0	0	0	0	0	0	0	0	0.117
LV6-Safety	0	0	0	0	0	0	0	0	0	0.163
LV7-Cultural heritage	0	0	0	0	0	0	0	0	0	0.067
LV8-Environment	0	0	0	0	0	0	0	0	0	0.192
LV9-Innnovation and research	0	0	0	0	0	0	0	0	0	0.198
Well-being composite indicator	0	0	0	0	0	0	0	0	0	0

From the structural model we can see that the Italian provincial well-being is highly affected by the LV3-*Work-life balance* construct (0.666), followed by LV1-*Health* (0.324) and LV4-*Economic well-being* (0.247) constructs. Whereas, the LV6-*Cultural heritage* (0.067) and LV2-*Education* (0.053) constructs are

dimensions with non-significant coefficients. The overall fit of the structural model is good with a $R^2 = 0.74$. In terms of clustering results, the three clusters identified by the PLS-SEM-KM algorithm describe three groups of well-being, i.e., *high*, *medium*, and *low* levels. In this way is very easy to classify the Italian provinces through a "BES ranking".

5 Conclusions

The BES 2018 report by ISTAT has confirmed that in 2015 and in 2016 an improvement in many areas of well-being has been observed, even if territorial differences remain stable both in levels and dynamics.

The differences appear in some cases as real structural differences between North and South of Italy. Then, the different well-being levels measured through a composite well-being indicator in the territories allow to explain the variability in territorial micro areas.

News life-cycle: a multiblock approach to the study of information

Il ciclo di vita delle notizie: un approccio multiblock allo studio dell'informazione

Rosanna Cataldo, Marco Del Mastro, Maria Gabriella Grassia, Marina Marino and Rocco Mazza

Abstract Media are instruments with a high capacity to penetrate inside the socio-cultural fabric. In this paper we examine the informative function of media, focusing in particular to its products the news. The aim of this paper is to study the life cycle of a collection of news, inside a defined medial ecosystem. In particular, we analyze two levels of the medial market, the product (the news), and the channel (the sources). The methodology we chosen is the multiple factor analysis (AFM), which allows us to scan multiple data tables that measure sets of variables collected on the same observations.

Abstract *I media sono strumenti con un'elevata capacitá di penetrazione all'interno del tessuto socio-culturale. In questo contributo prendiamo in esame la funzione informativa dei media, soffermandoci in particolare sui prodotti: le news. Lobiettivo del paper é quello di studiare il ciclo di vita di un collettivo di notizie allinterno di un ecosistema mediale delimitato. In particolare esaminiamo il ciclo di vita delle notizie selezionate applicando un metodo che ci permette di analizzare due livelli del mercato mediale, il prodotto (le notizie) e il canale (le fonti). Il metodo utilizzato é lanalisi fattoriale multipla (AFM), la quale permette di analizzare datasets composti da piú blocchi di variabili raccolte sulle medesime unitá statistiche.*

1 Introduction

News are a product of media in the information market. The aim of this work is to study the life cycle of news inside a defined medial ecosystem of a collection of news. Media are instruments with a high capacity to penetrate inside the socio-cultural fabric. The versatility and adaptability which characterizes them allow to easily adjust to the reference markets orientation. They actually process any genre and depending on their peculiarities and the degree of interaction they allow to realize, they are used to carry out a variety of functions: entertainment, information, promoting sales of both products and services, job training, sharing and social relations too. Its our aim to analyze the informative function in particular: this is fundamental due to the fact that media offer to its public products aimed at the satisfaction of their consumption need, and subsequently create new orientations and ideas (Strmberg, 2004; Anderson, McLaren 2012; Larcinese, 2012; Della Vigna, Kaplan, 2007; Bernhardt et Al., 2008; Chiang, Knight, 2011). We distinguish between hard and soft news: with hard news we refer to news used to describe topics that are usually urgent, important and consequential, like politics, international affairs, and economic news (Reuters Istitute, 2016); Soft news concern entertainment, celebrities and lifestyle (Mills-Brown, 2014). This distinction is essential because the object of our research is hard news. Our contribution to the state of the art is the description of the cycle of life of the news selected on the basis of a method that will allow us to analyze two levels of the medial market, news and sources. The following pages show the work organized as such: In the section (2) we introduce the different modes of gathering and selecting data; in section (3) we propose our methodological approach and the design of our research; and in section (4) we feature the main results and conclusions.

2 Methodological approach

The data-gathering used for the analysis is divided in two phases: 1. firstly, we selected the most popular news to include in the collection; 2. Secondly, we selected the sources and we extracted the frequency of transmission of each singular news from these. In the first phase we used the tool Google Trends in order to identify the news to analyze and gather for the collection: this choice is made in order to align our paper to and give a contribution to the Web Search Studies (Zimmer, 2010; Roberg, 2013; Trevisan, 2014), and also for counting on the great potentialities of this big data tool. Using this tool, we identified, in a time span that goes from January 2018 to July 2018, the 40 news with the highest search frequency each month. We divided these in equal parts between 8 categories of topics: 1. News report; 2. Culture; 3. Economy; 4. Foreign news; 5. Politics; 6. Sciences; 7. Entertainment; 8. Sport. This phase produced a list of 280 news. In the second phase a we used a tool to extract the frequency transmission of news through sources during the referred time span. This tool is Volocom, a web platform that allowed us to use a suite of services

for tracking media. Thanks to this new platform it is possible to search a specific news in query and receive as response its frequency inside one or more designated sources. In order to be effective, research needs two parameters: the selection of sources and the period of reference. As far as it concerns sources, the selection takes into account the main channels that produce news and both off and on-line environments: News agency, Facebook Radio, Facebook News Agency, Twitter Radio, Twitter NewsAagency, TV, Newspapers, Facebook TV, Facebook Newspapers, Twitter tv, Twitter Newspapers, Native digital newspapers, Radio, Facebook Native digital newspapers, Radio site, Twitter Native digital newspapers. In order to describe the news life cycle, it is essential to define the time span that describes transmission. This time frame has been operated with a division in three phases: 1. incubation of the news the 15 days in which the latter starts building up; 2. the moment in which the news is launched, named to; 3. Spreading of the news, the 30 days in which the news travels across different media. Overall, of each news we extracted its frequency during 46 days; t_0, being the fundamental moment of the recording, deserves a series of clarifications. It can be absolute and coincide exactly with the event transmitted by the first subject who spread the news registered by Volocom; or it may be the case that the zero-time its not absolute, but relative to a news that has been covered previously. In this case we refer to the very first moment the subject launched the news as it has been subsequently spread. We queried Volocoms database using API REST interface, programming a cycle of queries in Python. Once we have finished the gathering procedure, we built the data matrix assembling each news on one single string and putting in a column informative sources with the related 46 days. Therefore, the dataset is composed by 16 blocks of columns, one for each source. The methodology chosen is multiple factorial analysis (MFA), that allows to analyze multiple data tables that measures sets of variables collected on the same observation. These methods allow studying the relationship between the observations, the variables, and tables (Escofier and Pags, 1984). This is a generalization of Principal Component Analysis (PCA) and a part of the multitable (or multiblock) PCA family (Smilde et al, 2003). The technique allows: 1. To analyse some variables data tables measured on the same observations; 2. to compute a set of common factor scores; 3. to plot each of the original data sets into a new space to analyse communalities and discrepancies (Abdi et al, 2013). The method breaks up into two phases:

1. In the first phase we have N tables and for each P_n variables collected. First we compute generalized PCA on each of the N tables and extract the first singular value for each table (which is the square root of an eigenvalue). Successively we divide each table by its first singular value, with this procedure we normalize the tables (Abdi et al, 2007).
2. Starting from the concatenated normalized tables, the procedure compute a generalized PCA.

Table 1 Sources' absolute contributions

Contributions (%):			Contributions (%):

3 Results

The reading of the correlations between the variables representing the 46 days examined, and the factors extracted actually help us to create a description of the life cycle of these news. The results that follows are partial and related to a selection of the analyzed sources that will help us to create a division based on types useful for the reading of other channels too. Newspapers show a life cycle in which the various moments are positioned around the positive semi-axis of the first factor, with a distribution spread between the second and fourth sector; Time-zero presents a positive correlation increasing with the first dimension compared to the second; the relations we can read closer to the point help to characterize a type of information that tends to extend in the time span. Communication agencies are another source worthy of study: in this case the variables form two distinct blocks one flattened on the first factor with time zero and the following moments, and another one on the second factor formed by the variables preceding the moment in which the news are launched. The variables furthest from date t_0 are located near the origin, meaning a type of communication that is fast, wearing out rapidly around the point zero. About the social networks sources, in the figure there are the correlations between the moments registered regarding the Twitter official accounts of the information agencies. The correlations of the first axis refer to the days following the emission, while on the second we find the previous days. The most significant points with the highest correlation consist of the moments positioned the closest to t_0. Its evident that in this case the profile that emerges for the previous source its even more defined, the life cycle is sharply divided between the two moments preceding and following the breaking of the news. At the same time the latter tends to wear out in the days closest to its emission, without a period of incubation and insight Now lets take a look at the relations established between the sources. The analysis has shown that the absolute contributions in table 2. On the basis of such values it results that the sources that are involved the most in the defining of the first axis are daily newspaper, communication agencies, radio, digital native publications, TV,

Fig. 1 Correlation plot: a. Newspapers; b. News Agency; c. Twitter News Agency

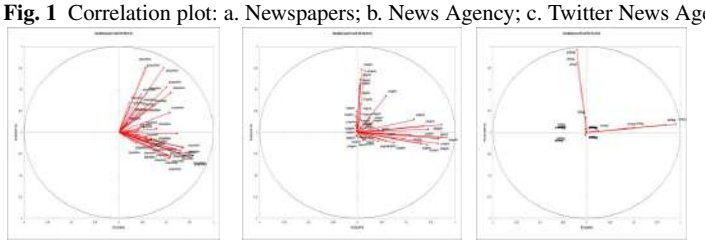

Fig. 2 Sources' coordinates:

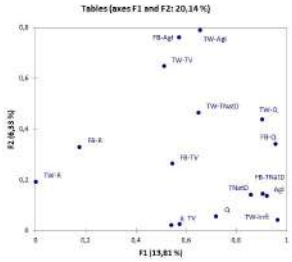

Facebook newspaper, FB digital native publications, TW influencer. While for the second axis the most fruitful sources are FB TV, FB communication agencies, FB Radio, TW newspapers, TW Radio, TW digital native publications, TW TV, TW communication agencies. On the first dimension the information more programmed and structured corresponding to the traditional sources is followed by the digital native publications with the related FB pages and TW influencers. Whereas the second dimension is more coherent, characterized exclusively by social sources. The chart displayed represents the projection of sources on new factorial dimensions, the points that contribute the most to the first dimension are distributed more compactly, while the social sources on the second dimension are more distant between them. This refers a weaker relation between the latter and greater variety between distributions.

4 Conclusion

Going back to the aims of this research, the purpose was to describe the life cycle of news through their journey across the chosen sources. Applying MFA it has been possible to recognize three different kind of cycles, basing on the relations established between each moment, and pair them with different channels:

- Incubator sources, these are characterized by life cycles that tend to extend toward the extremes of the registered time period. The news lives a period of in-

cubation and subsequently is launched on the market where it lasts for the great part of the selected time frame. Sources that can be gathered under this category are the traditional ones (newspaper, TV, radio), with a rich media service offer suitable to manage the different life phases of the news.

- Trigger sources, that launch the news on the market but exert over it a limited control in a brief time span. These sources lack a period of incubation and the tail of the moments following the emission in the market its slightly extended. The present picture is similar to the news agency.
- Flash sources, these cycles are very fast and focused on the moment of the broadcasting of the news. In this case the channel launches the news that is immediately absorbed, and it shortly dissolves inside the network of users. The social sources manage cycle of this kind.

Short-term rentals in a tourist town

Affitti brevi in una città turistica

Silvia Bacci, Bruno Bertaccini, Gianni Dugheri, Paolo Galli, Antonio Giusti, Veronica Sula

Abstract Short-term rents of rooms or apartments in the most important tourist cities have significantly increased in the last decade, also thanks to spread of dedicated smartphone apps and web platforms. These types of accommodation now constitute a significant part of the tourist accommodation facilities, however this under-regulated development has introduced some advantages but also some drawbacks, making it necessary to get an exact measure of this phenomenon. Official statistics are quite lacking in this sector, so we used, as alternative sources of information, two of the main short-term rentals brokerage platforms (AirBnB and Booking) to estimate the extent of the phenomenon in Florence.

Abstract *Gli affitti a breve termine di camere o appartamenti nelle più importanti città turistiche si sono sviluppati considerevolmente nell'ultimo decennio, anche grazie a Internet. Questi tipi di alloggi costituiscono ora una parte significativa dell'offerta ricettiva, ma questo sviluppo sotto-regolamentato presenta oltre a vantaggi anche alcuni inconvenienti. È importante avere una misurazione precisa dei numeri coinvolti per comprendere meglio il fenomeno, anche in vista di una regolamentazione più precisa. Poiché le statistiche ufficiali sono carenti, abbiamo cercato di utilizzare, quali fonti informative alternative, due tra le principali piattaforme di intermediazione web (AirBnB e Booking) per cercare di valutare le dimensioni del fenomeno a Firenze.*

1 Introduction

Short-term rents of rooms or apartments were always existed. In recent years, however, the phenomenon has developed considerably both due to the increasing spread of hit and run tourism and for the emergence of internet platforms (OTA: online travelling agency), such as Airbnb, Booking, etc., which allow easy and rapid intermediation (Griswold, 2016).

At first glance, this under-regulated development may seem a positive fact, at least from an economic point of view, but it has also many drawbacks. First of all, the competition with the traditional accommodation businesses whose managers consider private rentals as unfair competition, given the lower costs and regulatory facilities faced by this type of offer. In addition, there is the issue of the increasing tourist pressure, especially in the central districts of the most important cities, the reduction of the availability of housing for long-term rentals for residential purposes with the consequent depopulation of urban centres, and the increase in the costs of municipalities for services such as urban garbage, water supply, surveillance, etc. (Nieuwland and van Melik, 2018).

To date, these types of accommodation now form a significant part of tourist presence. This requires an estimate of the number of rentals and beds for rent to better understand the real accommodation capacity of a generic tourist location also in view of its more precise regulation. Unfortunately, official statistics are rather lacking in this area; so we decided to use the data highlighted on the sites of two of the most important brokerage platforms to get a more precise idea of the true level of this phenomenon.

Referring to the city of Florence, to collect data from brokerage platforms we used two different strategies. A first method was to consult the Booking website (2020) to collect, in addition to the reviews of the customers on stays, information on the location and other details of the apartments used and the main data about the stay. A different strategy was used for AirBnB website (2020) for which there is a site, Insideairbnb (2020), that collects in-depth information on the whole rental listing published on Airbnb website.

With reference to the month of November 2019, we collected 2585 announcements from Booking on 1 or more apartments (although the vast majority of registrations concern only one apartment), while from Insideairbnb we found 8136 listings. In this case, each registration concerns only one apartment.

The two data sources are partially overlapping, but for the moment it has not been possible to determine the common cases to create a single archive, both because the presentation criteria of the accommodation facilities are very different between the two sources and because the geographical coordinates present in the files are partially altered. For this reason, we used the two data sources separately in our analyses.

2 The accommodation capacity of the Florence municipality

According to official sources, “Tourism statistics” period July-September 2019 (Metropolitan City of Florence, 2020), the accommodation offer in the Florence municipality is made up of 20.9% of hotel facilities and the remainder 79.1% of extra-hotel facilities. However, hotels collect more than 60% of rooms (63.7%) and beds (63.5%). Table 1 provides details about the “official” accommodation offer disentangled by hotel category and type of extra-hotel facilities.

The short-term rent offer represented by guesthouses and non-professional guesthouses captures the 64.5% of the offer of the extra-hotel facilities, rising to 69.9% with historical residences, corresponding to the 40.3% (47.3% with historical residences) of rooms and 36.0% (44.3% with historical residences) of beds. Overall, guesthouses and non-professional guesthouses represent the 51.0% (55.0% with historical residences) of the overall accommodation structures (i.e., hotel and extra-hotel facilities), with only the 14.6% of rooms and 13.1% of beds.

Table 1: Hotel and extra-hotel facilities in the Florence municipality, by number of structures, number of rooms, number of beds, number of bathrooms, period July-September 2019 (Source: Tourism statistics - Metropolitan City of Florence)

Type of structure	***Structures***	***Rooms***	***Beds***	***Bathrooms***
Hotel facilities	390	14853	32926	15640
1 star	*39*	*402*	*845*	*292*

Historical residence	*80*	*588*	*1570*	*632*
Total	**1867**	**23322**	**51826**	**23281**

Although these surveys at provincial level contribute to the production process of the statistical data that ISTAT disseminates at national level, some categories that are part of the "extra-hotel facilities” (i.e., other collective accommodation establishments) are not taken into consideration at this last level (I.Stat, 2020).

However, looking at data about short-term rents coming from Airbnb, the overall situation seems clearly underestimated. In Figure 1 we show the distribution of the short-term rent facilities across the Florence municipality, by census area: the top

panel displays data coming from Booking, whereas the bottom panel refers to data coming from Insideairbnb. The census areas not marked on the maps are sparsely populated non-urban areas.

The two maps show a certain level of overlapping, as already mentioned in the introduction, however data coming from Insideairbnb include a higher number of facilities. In more detail, Insideairbnb took over 8136 active listings that offer more than 18000 beds all around the Florence municipality. Further details about the territorial distribution of the facilities disentangled by census area are provided in Table 2.

The short-term rental facilities are distributed in a very heterogeneous way across the territory (Figure 1 and Table 2). The highest density of structures is observed in the UNESCO area, corresponding to census areas 12, 14, and 13. In particular, census area 14 (where the most famous historical monuments are concentrated, such as Brunelleschi's Dome and Palazzo della Signoria) collects 1241.2 structures per km^2, corresponding to just less than 3000 beds per km^2. Census area 12 follows with a density of 866 structures per km^2 and more than 2000 beds per km^2. Overall, the short-term rental facilities are quite small, with an average of 2.2 beds per structure.

Table 2: Short-term rental facilities, by census area: density of facilities (per km^2), density of beds (per km^2), ratio beds/facilities; period November 2019 (Source: Insideairbnb)

3 Some final remarks

This work is ongoing, but the relevance of the problem and its consequences in terms of political issues in the administration of a tourist destination is quite clear, especially when this tourist destination is a municipality with peculiar characteristics that require specific regulations.

Basically, according to data discussed in the previous section, beds surveyed by Insideairbnb correspond to all those surveyed by the Metropolitan City of Florence survey for the entire sector of extra-hotel facilities (i.e., more than 18000). Moreover, structures surveyed are 1477 according to the Metropolitan City of Florence (Table 1), 1139 according to ISTAT (data not shown here), and 8136 according to Insideairbnb. These figures mean that official statistical sources cover only a small percentage of the entire phenomenon of short-term rental facilities. It is true that these values are not exactly homogeneous neither by date nor by categories included, but the underestimation is so high that it cannot be further neglected. In particular, ISTAT does not cover at all the categories of those who do not carry out these activities in an entrepreneurial way, while the Metropolitan Area data are limited part of the facilities.

For the future work, we intend to perform a comparison between data coming from Insideairbnb and official data related with the city tax of the Municipality of Florence. We also intend to estimate in an accurate way the overlapping among Booking and Airbnb listings.

In perspective, our approach aims at experimenting an integrated system of sources that allows the public administration to follow this important phenomenon, with the least possible delay, to allow the study and definition of new regulations such as to reconcile the needs of the parties involved and, above all, the interest of citizens.

SportIstat: a playful activity to developing statistical literacy

La promozione della cultura statistica attraverso un'attività ludico sportiva: il caso di SportIstat

Alessandro Valentini, Francesca Paradisi

Abstract SportIstat is the acronym of "Sport with Istat", a playful activity proposed in the occasion of scientific dissemination events involving predominantly young public. This activity is part of the context of gamification. The objective is to capture the attention of youth out of the schooling system, to introduce them to the use of quantitative measurement tools, and to develop their critical sense, using the expedient of sport. SportIstat is a combination of sports and statistics, a path divided into stages. The performance reached in the various stages are compared between the different players. Results are illustrated using interactive statistical tools. The activity is modular and can be re-engineered in various contexts with different levels of complexity.

Abstract *SportIstat è l'acronimo di "Sport con Istat", un'attività ludica proposta in occasione di eventi di divulgazione scientifica che coinvolgono un vasto pubblico prevalentemente giovane. Tale attività rientra nel contesto della gamification in quanto ha l'obiettivo di cogliere l'attenzione dei ragazzi in ambito extrascolastico per introdurli all'uso di strumenti di misurazione quantitativi, ed allo sviluppo del senso critico, utilizzando l'espediente dello sport. SportIstat è un percorso combinato di sport e statistica, articolato in tappe. Viene misurata la performance di ogni tappa e illustrato sia il posizionamento specifico che il rendimento complessivo utilizzando strumenti statistici interattivi quali indicatori e grafici. L'attività si sviluppa in maniera modulare ed è reingegnerizzabile in vari contesti.*

Key words: statistical literacy, developing of critical sense, gamification, youth

Francesca Paradisi, Istat; paradisi@istat.it

1 Introduction

The role of Istat is to serve the community through the production and communication of high-quality statistical information, analysis and forecasts. To achieve this goal, one of the key factors is represented by investments for developing statistical literacy, that is intended as (Wallman, 1993) the ability to understand and interpret data and statistics; the capacity to develop and understand data-driven reasoning.
The large amount of statistical information freely accessible and the worsening of the so-called problem fake news (Corselli-Nordblad and Gauckler, 2018) made the need for a strong investment in this area even more urgent.

1.1 Methods for developing statistical literacy

The approach adopted by Istat for the development of statistical culture is broad-spectrum. The method is consistent with the guidelines defined by UNECE for Statistical Institutes (UNECE, 2014), as well as with the international literature on the subject (see for example Ferligoj, 2015; Gal and Ograjensek, 2017). The reference subjects for Istat's initiatives are varied and potentially include all citizens. They range from researchers to policy makers, from respondents to statistical surveys, to journalists, without neglecting the general public. A significant target is represented by students, differentiated according to the school level, from primary schools to university. Istat designs a series of products and initiatives, also in collaboration with scientific companies, such as SIS and with Community (Eurostat) or international institutions. In particular, it promotes participation in the Statistical Olympiad (Pollice e Barbieri, 2019) and in the international competition of ISLP statistical posters. Local activities are also boosted thanks to the Territorial Network for the development of statistical literacy, a network of specialists in the design and implementation of statistical culture promotion activities that operate at the Institute's territorial offices.
The focus of this paper is the use of a non curricular instrument to catch the attention of young people. Methodology is that of gamification.

1.2 Gamification

A recent approach to developing statistical literacy is that of gamification. The general objective of gamification is to foster the active interest of users, that is, their engagement, to modify their behaviour, to convey information in the desired direction. There are many studies concerning the effectiveness of gamification in the field of learning (Mohamad, Sazali and Sallek 2018). The comforting results allowed the development of this approach in the context of statistical literacy

(Zhang. Fang, 2019; Legaki, Karpouzis and Assimakopoulos, 2019). Gamification is also one of the key points of the DIGICOM project, devoted to modernizing the communication and dissemination of European statistics.
Istat also reserves a relevant attention to gamification activities by making available on its institutional website quizzes, puzzles and games. SportIstat is part of this new approach.

2 SportIstat: approach and model

The activity of *SportIstat* (acronym for "Sport with Istat") is designed for developing statistical literacy during scientific events involving a large audience. The model is based on the expedient of sport to attract young people and to introduce them to the use of quantitative tools, and to the development of critical sense (Gal, 2002; Watson and Callingham, 2003). This approach was tested in two occasions: a) during *The European Researchers' Night*, a set of public events dedicated to bringing researchers closer to the public (Perugia and Siena, 27th Sept, 2019); b) during *The Einsein's Island* (Perugia, 30th Aug – 1st Sep, 2019), an international festival of science show.

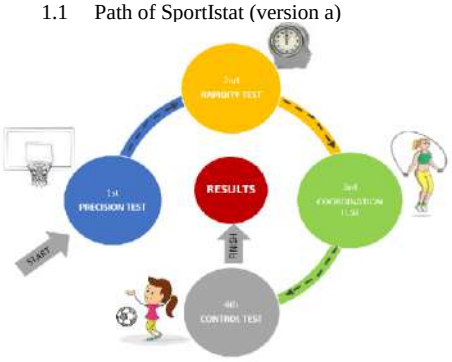
2.1 Materials and methods

SportIstat is an outdoor path inserted in the context of a wider scientific event. A particular care is devoted to the scenario, fundamental to attract the kids. This scenario is a sort of sport village divided into stages, each of which simulating an aspect of sports competition. The path is covered by participants one to one; each one accompanied by an Istat expert with the scope to measure the sport performance and to illustrate results giving statistical messages. Tests are projected to measure the presence of various skills useful for the most part of sport disciplines: precision, rapidity, coordination and control.
The number and typologies of competitions may change depending on the target audience and the space available. For instance, the version a) is modelled in four stages (Figure 1 and Table 1). In version b), in which the available space is very large, the model is slightly different: the total number of stages is 5; a specific stage is dedicated to a statistical test; control test is realized using bowling pins instead of dribbles. In both cases a specific care was dedicated to the output in terms of construction of graphics through the interaction of the participants in order to highlight the individual contribution to the construction of the collective phenomenon. A qualifying point was the use of building bricks to illustrate the content and meaning of the graphs and to make people understand the meaning of the correlation between variables. The prototype of chart made with bricks is illustrated in Figure 2.

Table 1: Detail of the path (model a)

Cod	*Name*	*Objective*	*Score*	*Range*
1	Precision test	To make the most baskets on three throws available. The participant positions himself about 3 meters away from the basket.	0 goal=0; 1 goal =8; 2 goal=16; 3 goal =25	0 – 25
2	Rapidity test	To grasp a falling graduated rod with your hand as quickly as possible. The rod is placed vertically with the zero at the bottom near the participant's fingers.	The interval level (x) ranges from 17 to 31 hundredths of a second. Score is calculated as: 25/14 * (31-x)	0 – 25
3	Coordination Test	To do as many jumps as possible in 20 seconds. Jumps need not be continuous.	One point for each jump up to a maximum of 25 points	0 – 25
4	Control Test	To do as many consecutive dribbles on the ground as possible with one hand, up to a maximum of 25.	One point for each dribble up to a maximum of 25 points	0 – 25

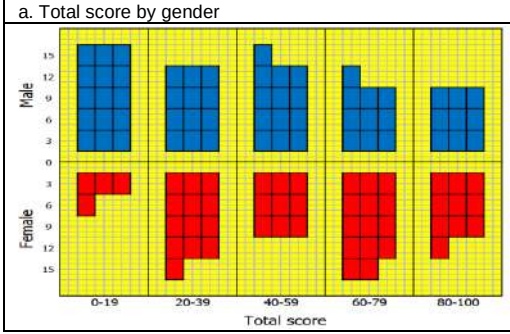
1.1 Path of SportIstat (version a)



1.2 A detail of third step: coordination test

Figure 1: Structure of the path SportIstat and a detail of third step

a. Total score by gender



b. Correlation between Age and reaction time

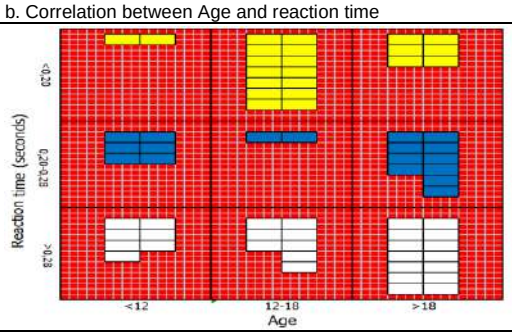


Figure 2: Prototypal chart made with bricks

3 Results

Activities carried out have shown that the SportIstat approach is able to involve a large audience of young people. Youth are attracted by the games and the sports competition. They are enthusiastic both in order to test their individual performance and to compare their scores with other participants having the same covariates (in terms of gender and age).

The path of SportIstat was followed by a total of 650 people: 348 attended event a), 302 event b). Demographics characteristics of participants are quite similar between the two cases in terms of gender: 50% of male in case a); 55% in case b). To be noted a difference by age: the quota of pupils in the ages corresponding to primary and secondary grades is 83% in the first case (a) and 67% in the second (b).

The experience of SportIstat is interesting not only for the project of promoting statistical literacy, but also for the unpublished results on individual performances.

In Table 2 the main results of case a). The total score (which ranges from 0 to 100) is on average 56.3 point. There are significant differences according to demographic characteristics. The score for Male (58.9) is higher than the score for Female (53.7); youth over 15 years (and adults) have a performance (71.3) significantly higher than the ones under 15 (53.5). Another variable that affects the total score is the frequency of sport (in terms of number of time for a week). The 56 participants that do sport more than 4 times a week on average reach a score (62.6) higher than others (55.1). The test with the higher average score is that of control (21.2 in the range 0-25), the score is particularly high (24.9, near to the top) for the 47 participants older than 15 years. Symmetrically the test with the lower score is that of precision (9.5): for this topic the more significant spread is that between male (11.2) and female (7.8). Among other tests, a particularly interesting difference concerns coordination, and is ascribed in the relevant range between younger (11.4) and older (20.4) participants. This should mean that pupils aren't longer able to jump!

Table 2: Average score by sports practice

	Cases	***Average score*** *(range 0-25)*				***Average score Total*** *(range 0-100)*
		Precision	***Rapidity***	***Coordination***	***Control***	
Total	348	9.5	13.0	12.6	21.2	56.3
Gender						
Male	173	11.2	13.4	11.6	22.6	58.9
Female	175	7.8	12.5	13.6	19.8	53.7
Age (years)						
Less than 15	301	9.3	12.6	11.4	20.7	54.0
More than 15	47	10.4	15.6	20.4	24.9	71.3
Weekly sports practice (times)						
Less than 4	291	9.5	12.7	11.8	21.0	55.1
More than 4	56	9.2	14.3	16.6	22.5	62.6

4 Future remarks

The approach of SportIstat is able to give a series of wide-ranging benefits. The expedient of sport, in fact, allows to capture the attention of young people for a few minutes through an activity of gamification, interesting for them and their respective families and friends. This is the occasion to launch a series of important statistical messages that can be transposed unconsciously to the public: the concept of statistical collective, average, correlation and so on; the interpretation of data; the figures. The graphics made with building bricks are very passionate for children and also appreciated by adults for their role of didactic sensory material. Older kids, using IT tools, are also able to create dynamic and interactive graphics: they can thus visualize how the insertion of the data contributes to the continuous evolution of the graphic representation. A good memory of the moment spent with statistics will allow young people to assimilate curiosity towards this world and to take in mind the main concepts, those are the main goals attended.

Finally, SportIstat is a very flexible extracurricular tool that can be exported in various forms and in many contexts thanks to: the possibility to change the number of steps and the disciplines, ductility of materials, soft approach, presence of specialists. For the future it is expected that this instrument will be used in wider areas and with even wider audiences.

Statistical modeling for some features of Airbnb activity

Un modello statistico per spiegare le caratteristiche dell'attività di Airbnb

Giulia Contu and Luca Frigau

Abstract Airbnb is a platform where to rent tourist accommodations. The Airbnb activity is based on hosts. Every three months, Airbnb awards the best hosts with the badge of Superhost taking into account specific aspects such as the number of reservations, the cancellation policy, the response rate and the overall rating expressed by the guests. It is not clear what can really affect host performance and the probability of becoming a Superhost. The aim of this study is to comprehend which aspects can impact host activity and the achievement of Superhost badge. The analysis is realized considering Milan, which is one of the Italian most visited cities. Bivariate odds model and logistic model have been carried out to data. The first results show the impact on host activity of specific aspects as, for instance, the number of reviews, the services provided and the role of the Superhost. Moreover, they evidence the relevance of the overall rating on the probability of becoming a Superhost.

Abstract *Airbnb è una piattaforma online in cui è possibile affittare alloggi turistici. L'elemento base dell'attività di Airbnb è l'host e la sua attività. Ogni tre mesi, Airbnb assegna ai migliori host l'etichetta di Superhost considerando differenti aspetti quali, ad esempio, il numero di prenotazioni, le politiche di cancellazione delle prenotazioni, il tasso di risposta degli host e il giudizio complessivo espresso dagli ospiti. Non è chiaro cosa possa realmente influenzare le performance dell'host e la probabilità di diventare Superhost. Lo scopo di questo studio è comprendere quali aspetti possano influire sull'attività dell'host e sull'ottenimento del badge di Superhost. Si è deciso di analizzare gli host operanti a Milano, una delle città italiane più visitate, e di utilizzare due differenti metodologie: il bivariate odd ratio model e il modello logistico. I primi risultati mostrano l'impatto di variabili quali il numero di*

recensioni e i servizi offerti sulle performance degli host; e l'impatto della variabile giudizio complessivo sulla probabilità di divenire Superhost.

Key words: Airbnb, hosts, superhost badge, VGAM, logistic model.

1 Introduction

Airbnb has been founded in 2008 in San Francisco and in the years has grown significantly. It can be defined as an online platform where it is possible to book single rooms or whole apartments for one or more days [2, 4]. Actually, it operates in more than 65,000 cities and 191 countries and it sells millions of room nights for tourists around the globe [1]. The core of Airbnb activity is constituted by hosts and their activity. Every three months, Airbnb awards the best hosts with the status of Superhost. To become a Superhost is necessary for the previous 12 months: to host at least 10 stays; to honor every reservation; to respond within 24 hours at least 90% of the time; to achieve a 4.8+ overall rating. However, it is not clear if the four variables that Airbnb declares to use in attributing the badge have a direct impact on the probability of becoming a Superhost and on the host activity in general.
In literature, few articles analyzed the role and features of the hosts and Superhosts (see: [5, 6]). Particularly interesting is the study realized by Gunter [3]. His goal was to to comprehend if the variables that Airbnb uses to define the Superhost status can really impact the probability to become a Superhost.The results have shown the relevant impact of overall rating and the existence of a specific rank of variables. In this rank, the first position is occupied by overall rating followed by the cancellation policy, the response rate and the number of bookings.
The aim of this paper is to comprehend which variables can directly influence the activity of hosts and Superhosts. To reach this aim, different kinds of variables will be considered. Specifically, they are the Airbnb variables, the managerial aspects and the characteristics of the accommodation. The analysis will be focused on Milan, one of the Italian cities with the highest number of official tourists. Two different models will be used: the bivariate odds model and the logistic model. The innovative aspects of this study are, firstly, the focus on hosts and their activities and, secondly, the use of Vector Generalized Linear Model (VGLM) in the analysis of tourism data. The main findings evidence the impact of different aspects on the host and Superhost activity.
Five sections comprise this study. The second and third Sections will be related to data and methodologies. The results and implications will be explained in the fourth part. Finally, the last Section will be focused on the concluding remarks, limitation and future developments.

2 Data

The study has been realized using a dataset provided by *Airdna*, a company that manages Airbnb data. Three main groups of variables have been used, as shown in Table 1. The first group includes the variables that Airbnb declares to use to attribute the status of Superhost. The second group is composed of the managerial variables, aspects that can be directly chosen by hosts. The third group includes the variables related to the characteristics of accommodation.

Table 1: Variables of the analysis

Group	Variable	Description
Airbnb	Cancellation policy	Flexible, moderate, and strict
	Number of Bookings	Number of reservations
	Response Rate	% of time a host responds to guests within 24 hours
	Overall Rating	Score related to whole Airbnb experience
Managerial	Max Guests	Maximum number of guests in an accommodation
	Response Time	Amount of time to obtain an answer to their questions
	Extra People fee	Price to add one or more guests
	Minimum Stay	Minimum number of days that must be booked
	Security Deposit	Payment (or not) of the deposit
	Business Ready	Services that can support business travelers
	Instantbook Enabled	To book accommodation without an explicit host approval
	Superhost	The host is or not a Superhost
	Occupancy rate	Reservation Days/(Reservation Days + Available Days)
	Number of reviews	Amount of reviews
Accommodation	Property Type	25 different types of accommodation
	Listing Type	Entire home, private room, and shared room
	Bedrooms	Number of bedrooms
	Bathrooms	Number of bathrooms

3 Models

Two different models have been used. The choice is affected by [3] where a logistic model is carried out to estimate the probability to become a Superhost. The model of this study is the logistic model applied with different level of complexity: the logistic model with one response variable and the bivariate odds ratio model with two response variables. Specifically, a logistic model is defined as:

$$F(\mathbf{X}'\boldsymbol{\beta}) = \frac{e^{\sum_{i=0}^{p}\beta_i X_i}}{1+e^{\sum_{i=0}^{p}\beta_i X_i}} \tag{1}$$

It is estimated by Maximum likelihood estimation. The likelihood function is

$$\mathscr{L}(\boldsymbol{\beta}|Y,\mathbf{X}) = \prod_{i=1}^{n} \left(F(\mathbf{X}'\boldsymbol{\beta})^{y_i} [1 - F(\mathbf{X}'\boldsymbol{\beta})]^{(1-y_i)} \right) \tag{2}$$

To reach the aim of the paper, the variable Superhost has been chosen as response variable; the Airbnb, the managerial and accommodation variables as covariates.
The bivariate odds ratio model is a part of a Vector Generalized Linear Model family functions describe by Yee [7]. It can be defined as a logistic regression model with two different response variables, Y_1 and Y_2. Moreover, it models the marginal distributions of two Y_j and the odds ratio. Specifically, it is defined through:

$$\text{logit } p_j(x) = \eta_j(x), \quad j = 1,2 \tag{3}$$

$$\log \psi(x) = \eta_3(x) \tag{4}$$

where ψ identifies the odds ratio and describes the association between the two responses. It is calculated as:

$$\psi(x) = \frac{p_{00}(x)p_{11}(x)}{p_{01}(x)p_{10}(x)} = \frac{P(Y_1 = 0, Y_2 = 0|X)P(Y_1 = 1, Y_2 = 1|X)}{P(Y_1 = 0, Y_2 = 1|X)P(Y_1 = 1, Y_2 = 0|X)} \tag{5}$$

For the application of this model, occupancy rate and overall rating have been chosen as response variables, whilst managerial and accommodation variables as covariates.

4 Results

The study starts with the identification of the variables that can directly influence the probability to obtain good results in Airbnb activity through the bivariate logistic model. The impact on occupancy rate and on overall rating of the managerial and accommodation variables have been analyzed. Tables 2 and 3 show that in Milan managerial variables and characteristics of the accommodation impact significantly on the probability to reach high results in terms of Overall rating and Occupancy rate. Some variables, as Instant book and Response rate, have a significative impact not only on the two response variables, but also on the odds ratio.
Then, through a logit model, it is investigated which variables can influence the probability to obtain the status of Superhost. The results show how in Milan all Airbnb and managerial variables influence the probability to obtain the badge of Superhost, as shown in Tables 4 and 5. On the contrary, only the accommodation variables have not a significant impact on this probability, as shown in Table 6.

Table 2: Impact of the managerial variables on occupancy rate (Occ.) and overall rating (Over.)

	Occ.	Over.	(Occ.= 1,Over.= 1)
Intercept	−1.80 ***	−0.22	0.73 ·

Overall Rating	4.56	***	0.39

5 Conclusions

The analysis highlights how the best results in terms of occupancy rate and overall rating were obtained with the highest scores in business ready, number of reviews, instant book, response rate, listing type and property type. Moreover, the results suggest that the Airbnb variables, the managerial variables and the accommodation variables influence the achievement of badge. In general, the findings evidence the necessity for hosts to offer high-quality services, to support guests before and during the experience, to enhance writing reviews.

Table 5: Impact of managerial variables on the probability to be a Superhost

Tertiary students with migrant background: evidence from a cohort enrolled at Sapienza University

Background migratorio e percorsi universitari: osservazioni su una coorte di studenti iscritti a Sapienza Università di Roma

Giudici Cristina, Vicari Donatella, Trappolini Eleonora

Abstract The participation of foreign and international students in the Italian tertiary education shows a strong positive trend in the last decades, and has recently drawn attention in the literature. The aim of this study is to examine disparities in timing of graduation of a cohort of full time students which have been enrolled at Sapienza University in the a.y. 2012/2013 and graduated within twice the theoretical duration of the programme of study, considering both their citizenship and country of prior education. Although migrant background is not necessarily indicative of a disadvantage, the analysis suggests the existence of a link between migrant background and longer time to complete the programme of study, mostly in Bachelor's programmes.

Abstract *La presenza di studenti stranieri ed internazionali nel sistema universitario italiano ha conosciuto nel tempo una tendenza ampiamente positiva, con un interesse crescente da parte della letteratura. Il presente studio è volto ad analizzare i tempi di conseguimento della laurea per una coorte di studenti iscritti alla Sapienza nell'a.a. 2012/13 e laureati entro il doppio della durata legale del corso, distinguendo per cittadinanza (italiana e straniera) e paese di conseguimento del titolo di accesso all'Università (italiano o estero) e stratificando per classi di laurea. L'analisi suggerisce l'esistenza di un legame tra background migratorio e tempi di conseguimento del diploma, in particolare nelle lauree triennali.*

Key words: University students, migrant background

1 Introduction

The Organization for Economic Co-operation and Development has recently pointed out the massive expansion of the number of mobile students enrolled in tertiary education programmes worldwide, going from 2 million in 1998 to 5.3 million in 2017, with an annual increase of 5%. English-speaking countries are the most attractive destinations, and Asian students constitute the largest group of international students across the OECD countries (OECD, 2019).

The increase of international enrolment is particularly high at master and doctoral level, driven by a variety of push and pull factors. Actually, in many countries, the ever-growing demand for tertiary education may be associated with low education capacity in the origin country, and a growing number of students may look for educational opportunities abroad. On the other hand, social and economic factors are contributing to make international student mobility more affordable than in the past: the presence of an immigrant community already present in the country of destination, the existence of previous colonial ties, the use of a common working and teaching language, the job prospects after graduation are among the most motivating factors for studying abroad, together with the increasing investment by Universities in the quality of education (Norton and Fatigante, 2018).

In the literature, international students are generally assumed to be people moving to a country for the purpose of study and accessing University programmes with a foreign prior degree which would formally entitle him/her to be enrolled.

The term foreign student is often used as an approximation of international student, but they should be distinguished by taking into account also the country of citizenship, because foreign citizens may enter university with a national educational background and, conversely, international students may be national citizens.

The participation of students with a migrant background in the Italian Higher Education Institutions has been progressively growing and shows a strong positive trend in the last ten years. According to national statistics, 55% of the students enrolled as foreign citizens (almost 80,000 in 2017) is already resident in Italy and obtained the last educational degree from an Italian institution: this is the case, for instance, of the children of immigrants. The remaining 45% are international students, who accessed the Italian university system with a diploma obtained abroad (MIUR, 2018).

To our knowledge, in the Italian context, no studies exist on tertiary education, where international and second-generation students are distinguished. The few studies focusing on the first/second generation (Lagomarsino and Ravecca, 2014, Vaccarelli, 2016, Bertozzi, 2018) and on international students (Norton and Fatigante, 2018 and references therein) in the Italian University, underline the need of investigating student pathways in terms of access, academic pathways, success (or dropout), integration (well-being) and university-work transition.

Sapienza University of Rome is considered the largest in Europe with over 100,000 students and it is characterised by the largest number of both international and foreign students in Italy. Thus, it may be considered as a representative case for the analysis of tertiary students with migrant background in Italy.

The aim of the study is to analyse the timing of graduation for a cohort of graduate students, distinguishing by migrant and educational background and stratifying by medical, social-humanistic and technical-scientific programmes of studies.

2 Data and methods

Data come from Sapienza University administrative archives and are collected by Infosapienza on 13,061 full time students enrolled during the a.y. 2012/2013 in Bachelor's (7,873) and Master's (5,188) degrees and graduated within twice the theoretical duration of their programme of study, following the approach suggested by OECD (2019).
For comparability reasons, students enrolled in single-cycle Master's programmes with a legal duration of more than two years (Laurea Magistrale a ciclo unico) have not been included in this study.

Student demographic and socio-economic characteristics include age, gender, country of birth, citizenship, scholarships, graduation date and broad classes of study programme (medical, social-humanistic and technical-scientific.) A dummy variable also provides information on the country (Italy/abroad) where the student has obtained the *prior education,* i.e., the qualification (high school diploma or bachelor degree) which formally entitles him/her to be enrolled at Sapienza (as Bachelor or Master student, respectively). An international student is defined *stricto sensu* as a student who obtained his/her prior education abroad.

Table 1 outlines four categories of students based on their citizenship and country of prior education.

Table 1: *Categorization of students according to their citizenship and country of prior education*

Country of prior education	***Italian Citizenship***	***Foreign Citizenship***
Italy (non-international student)	*Italian Student* (*IS*)	*Foreign Student with Italian Educational Background* (*FS-IEB*)
Abroad (international student)	*Italian Student with Foreign Educational Background* (*IS-FEB*)	*Foreign Student with Foreign Educational Background* (*FS-FEB*)

International students include both Italian and foreign students who obtained their prior education abroad; analogously, non-international students include both Italian and foreign students who obtained their prior education in Italy. In addition to *Italian Students* (IS), i.e., Italian citizens with Italian prior education, the other three groups include *Foreign Students with Italian Educational Background* (FS-IEB), *Italian Student with Foreign Educational Background* (IS-FEB), and *Foreign*

Students with Foreign Educational Background (FS-FEB). FS-FEB should be distinguished by FS-IEB because the latter are supposed to better handle the Italian education system and to master the Italian language. Note that FS-IEB may also include long term residents or even students born in Italy. Analogously, IS-FEB moved from another country to study in Italy, but they may be supposed to know the Italian language and to be well integrated in the Italian education system.

Globally, our data include 12,564 Italian students, 192 FS-FEB, 275 FS-IEB and 30 IS-FEB. Table 2 shows the percentages of Bachelor and Master students by citizenship and country of prior education: 1.8% and 1.5% of Bachelor and Master students, respectively, obtained their prior education abroad. In both Bachelor's and Master's programmes the majority of foreign citizens have Italian educational backgrounds.

The cohort has been followed for twice the theoretical duration of the programme of study, i.e., 3+3 years for Bachelor's and 2+2 years for Master's, and a regression analysis of survival data has been performed, based on the Cox proportional hazards model. In the following survival analyses, Italian Students with Foreign Educational Background (IS-FEB) have not been included because of their limited number.

Table 2: *Percentages of Bachelor and Master students by citizenship and country of prior education*

Country of prior education	***Bachelor's***			***Master's***		
	Italian Citizens	***Foreign Citizens***	***Total***	***Italian Citizens***	***Foreign Citizens***	***Total***
Italy	*99.63%*	*58.33%*	*98.2%*	*99.96%*	*59.69%*	*98.5%*
Abroad	*0.37%*	*41.67%*	*1.8%*	*0.04%*	*40.31%*	*1.5%*
Total	*100%*	*100%*	*100%*	*100%*	*100%*	*100%*

3 Preliminary results

Figure 1 shows survival functions for the cohort of students enrolled in 2012/13 and graduated within twice the theoretical duration of their programme of study, for both Bachelor's and Master's programmes, by country of prior education.

Three years after entering university, more than 50% of bachelor students are still in education and the percentage increases for international students. For Master's programmes no substantial differences emerge in the survival patterns between Italian and international students. The analysis by citizenship (Figure 2) shows similar results, with a lower gap.

Table 3 shows hazard ratios estimated from the Cox regression model for bachelor students by programme of study adjusted for age, gender and categories. Male gender and higher age at the enrolment are generally associated with longer time of graduation. Looking at categories, students with foreign citizenship generally take longer to graduate than Italians (IS), and this is more pronounced when students have a foreign educational background (FS-FEB) than an Italian one (FS-IEB). Foreign educational background is confirmed to be slightly associated to

the graduation delay for medical and social-humanistic degrees. Results for Master students are not reported for space reasons; although globally the analysis confirms what was found for Bachelor students, the results are less evident, probably for the greater heterogeneity of the student population.

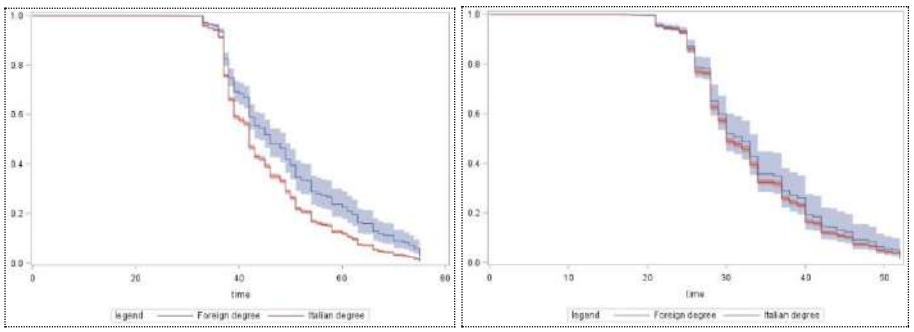

Figure 1: *Survival function (in months) for a cohort of full time students enrolled in 2012/13 in Bachelor's (on the left) and Master's (on the right) programmes and graduated within twice the theoretical duration of the programme of study, by country of prior education (95% CI).*

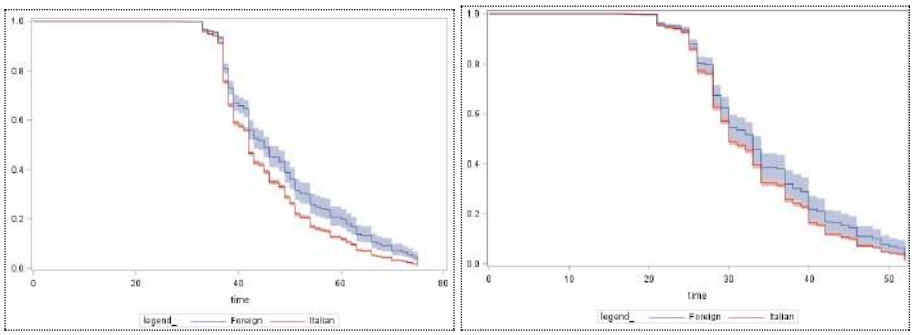

Figure 2: *Survival function (in months) for a cohort of full time students enrolled in 2012/13 in Bachelor's (on the left) and Master's (on the right) programmes and graduated within twice the theoretical duration of the programme of study, by citizenship (95% CI).*

4 Concluding remarks

Although migrant background is not necessarily indicative of a disadvantage, the analysis suggests the existence of a link between migration and lower student performance in the Academic context, which need to be further analysed. Notably, we need to examine academic paths of those students who have not graduated within a reasonable period. As pointed out by OECD (2019), delay graduation or dropping out are not necessarily symptoms of student or institutional failure. A strong labour market demand may lead a student to start working before attaining his degree. Nonetheless, specific difficulties associated with displacement, such as language barriers, socio-economic disadvantage, or lack of social integration, should not be underestimated.

The Causal Effect of Immigration Policies on Income Inequality

L'effetto causale delle politiche migratorie sulla disuguaglianza del reddito

Irene Crimaldi, Laura Forastiere, Fabrizia Mealli and Costanza Tortù

Abstract This work evaluates the effect of immigration policies on the income inequality. The employed methodology has been recently introduced in [10]. It takes into account network interference among units, in the presence of a multi-valued individual treatment. The estimation strategy is based on the usage of a Joint Multiple Generalized Propensity Score, which properly guarantees balance with respect to both individual and network characteristics. Results suggest that a highly restrictive political approach leads to a higher income inequality index.

Abstract Questo lavoro valuta l'effetto delle politiche di immigrazione sulla disuguaglianza del reddito. La metodologia impiegata è stata recentemente introdotta da [10]: tiene conto della interferenza tra le unità, in presenza di un trattamento individuale multidimensionale. La procedura di stima è basata sul Joint Multiple Generalized Propensity Score, che consente di ottenere un adeguato bilanciamento rispetto a covariate sia individuali sia di rete. I risultati mostrano che politiche migratorie più restrittive portano ad un maggiore coefficiente di disuguaglianza del reddito.

Key words: causal inference, interference, complex networks, multi-valued treatment, multiple network exposure, immigration policies

1 Introduction

Policy evaluation studies intend to assess the effect of an intervention. This goal often results to be challenging, since most empirical scenarios involve complex treatments, which have not been randomly assigned over the population and, moreover, the analysis might be also affected by the presence of interference among units. This last phenomenon arises when the treatment of one unit has an effect on the response of another unit [2]. For instance, the political attitude of a country towards a relevant issue may influence the neighboring countries. Furthermore, evaluating the impact of a policy often requires the definition of a multi-valued treatment: a complex policy might be multi-faceted and, therefore, vary over multiple dimensions.

This work evaluates the impact of governments' stance towards immigration on the Gini index for income inequality. The employed methodology is the one proposed in [10], which in turn finds its roots in [4]. These works both refer to the branch of the growing statistical literature about causal inference under network interference, which extends the Rubin Causal Model for policy evaluation studies admitting first-order spillover effects. Specifically, the model proposed and studied in [10] allows to account for interference between units, in observational studies where the treatment varies over multiple categories. We here define a multi-valued characterization of an immigration policy looking at the restrictiveness of the national regulations, which are explicitly addressed to migrants, and of the control mechanisms, which monitor adherence to the regulations. Furthermore, we model interference between countries according to a specific indicator, that we call *Interference Compound Index*.

2 The Model

Let us consider a population $\mathscr{N}$, with N units. Denoted as K the number of treatment levels, let $Z_i \in \{1,\dots,K\}$ be a categorical variable representing the treatment assigned to unit i and Y_i^{obs} the observed outcome for the same unit. By $\mathbf{Z}$ and $\mathbf{Y}^{obs}$ we denote the corresponding vectors of the whole sample $\mathscr{N}$. Moreover, $\mathbf{X}_i$ denotes a vector of P covariates (or pre-treatment variables). We assume that the relations between units are fully described by the observed *weighted* undirected network $\mathscr{G} = (\mathscr{N}, \mathbb{E}, \mathbb{W})$, where $\mathscr{N}$ is the set of nodes (the units), $\mathbb{E}$ is the set of edges, indicating links between the units, and $\mathbb{W}$ is the set of the weights on the edges, that is $\mathbb{W}$ collects the quantities I_{ij}, each representing the weight of the link between i and j. We denote as $\mathscr{N}_i$ the set that includes all the nodes j which are in the neighborhood of i, that is all the units j such that exists a link between j and i. In this framework, the standard SUTVA assumption, which includes the no-interference hypothesis, is replaced by an alternative assumption, known as Stable Unit Treatment on Neighborhood Value Assumption (SUTNVA), which grants first order spillover effects:

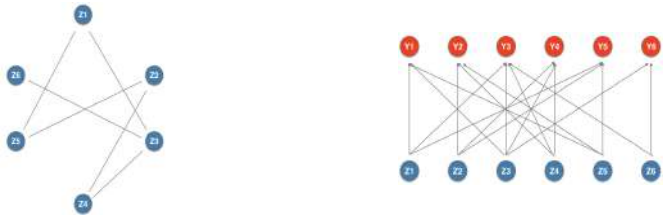

Fig. 1 Relations between units and the corresponding interference structure

Assumption 1 (SUTNVA).

1. No Multiple Versions of Treatment (Consistency)*: $Y_i(\mathbf{Z}) = Y_i(\mathbf{Z}^1)\ \ \forall \mathbf{Z}, \mathbf{Z}^1$ such that $\mathbf{Z} = \mathbf{Z}^1$, that is, the mechanism used to assign the treatments does not matter and an alternative assignment does not constitute a different treatment.*
2. Neighborhood Interference*: There exists a function g_i such that, for all $\mathbf{Z}_{\mathcal{N}_{-i}}, \mathbf{Z}^1_{\mathcal{N}_{-i}}$ and $\mathbf{Z}_{\mathcal{N}_i}, \mathbf{Z}^1_{\mathcal{N}_i}$ with $g_i(\mathbf{Z}_{\mathcal{N}_i}) = g_i(\mathbf{Z}^1_{\mathcal{N}_i})$, we have*

$$Y_i(Z_i, \mathbf{Z}_{\mathcal{N}_i}, \mathbf{Z}_{\mathcal{N}_{-i}}) = Y_i(Z_i, \mathbf{Z}^1_{\mathcal{N}_i}, \mathbf{Z}^1_{\mathcal{N}_{-i}}).$$

We denote as $\mathbf{G}_i$ the variable which results from applying the function g_i on the i's neighbors' treatment vector: $\mathbf{G}_i = g_i(Z_{\mathcal{N}_i})$. This variable, known as *neighborhood treatment*, measures the unit's indirect exposure to the treatment and represents a numerical synthesis of the treatment vector which characterizes the neighborhood of i. Figure 2 provides a graphical intuition of the interference mechanism, in a toy example: it shows the observed network and the corresponding spillover mechanism that the network links generate. Note that when the individual treatment is multi-valued, the neighborhood treatment is multivariate (specifically, it covers K dimensions) and it quantifies the individual indirect exposure to all treatment levels. Therefore, we can map the indirect exposure by means of the *Neighborhood Treatments Exposure Matrix* (NTEM) $\mathbf{G}$, which is defined as a $N \times K$ matrix that collects the individual neighborhood exposure to all the treatment levels. In particular, the generic element $G_{i,z} \in \mathbb{G} \subseteq \mathbb{R}$ indicates the indirect exposure of unit i to the treatment level z. Consequently, each row of $\mathbf{G}$ represents the neighborhood treatment of the generic unit i, $\mathbf{G}_i \in \mathbb{G}^K$. For instance, we can define the element $G_{i,z}$ as

$$G_{i,z} = \sum_{j \in \mathcal{N}_i} I_{ij} \delta_{zj}, \tag{1}$$

where δ_{zj} is a dummy variable that equals 1 if $Z_j = z$ and 0 otherwise. In this setting, each unit i is exposed to a *joint treatment* $(Z_i, \mathbf{G}_i)$: the *individual treatment* Z_i, which is a categorical variable with K levels, and the *neighborhood multi-treatment* $\mathbf{G}_i$, which is a K-variate variable. Hence, potential outcomes, for each unit i, are indexed by the joint treatment: $Y_i(Z_i, \mathbf{G}_i) = Y_i(Z_i = z, \mathbf{G}_i = \mathbf{g})$. As a consequence, the propensity score has to be defined with respect to this particular joint treatment.

Definition 1 (Joint Multiple Generalized Propensity Score (JMGPS)). The JMGPS is the probability of being jointly exposed to a K-variate individual treatment equal to z and to a K-dimensional neighborhood treatment equal to $\mathbf{g}$, conditioning on baseline covariates. That is,

$$\begin{aligned}\psi(z,\mathbf{g};\mathbf{x}) &= P(Z_i = z, \mathbf{G}_i = \mathbf{g}|\mathbf{X}_i = \mathbf{x}) \\ &= P(\mathbf{G}_i = \mathbf{g}|Z_i = z, \mathbf{X}_i^g = \mathbf{x}^g)P(Z_i = z|\mathbf{X}_i^z = \mathbf{x}^z) \\ &= \lambda(\mathbf{g};z,\mathbf{x}^g)\phi(z;\mathbf{x}^z),\end{aligned} \tag{2}$$

where $\lambda(\mathbf{g};z,\mathbf{x}^g)$ is the neighborhood propensity score and $\phi(z;\mathbf{x}^z)$ is the individual propensity score. $\mathbf{X}_i^z$ and $\mathbf{X}_i^g$ are vectors collecting covariates that affect the individual and the neighborhood treatment, respectively.

The estimation strategy is based of the usage of JMGPS and proposes a parametric approach for imputing missing potential outcomes, for the possible characterizations of the joint treatment. Please refer to [10] for a more detailed description of it.

3 Empirical Analysis

We make use of the above methodology in order to assess the causal effect of immigration policies on the income inequality. Specifically, we focus on a subset of 22 OECD countries, which are located in Europe, and we assess their political attitude towards migrants, evaluating its effect on the (lagged) Gini index for income inequality. We deal with country-year observations $i = (c,t)$, $i \in \mathcal{N}$, where c refers to a generic country and t indicates a given year, $t \in \{1980,\dots,2010\}$. We merge three main sources of data: (i) The IMPIC (Immigration Policies in Comparison) Dataset, which properly measures the restrictiveness of many specific immigration policies implemented by OECD countries between 1980 and 2010 [6]; (ii) The CEPII Gravity Dataset, which provides information about similarity and proximity measures involving country-year profiles [5]; (iii) The World Development Indicators Dataset, that includes country-year indexes [1]. In this empirical setting, SUTVA may be violated: the political receipt that each country implements with respect to immigrants has an impact on the international equilibrium and the global social system. The idea is that immigrants avoid highly restrictive countries and decide to go in places that are similar to their first choice with respect to some characteristics, but more politically welcoming. We assume that the extent to which each country can be influenced by another country is modeled by a suitable indicator, that we call Interference Compound Index (ICI) and that summarizes the macro-components which reasonably rule the spillover mechanism:

Definition 2 (Interference Compound Index (ICI)).

$$ICI_{cc',t} = \alpha \times IG_{cc'} + \beta \times IC_{cc',t}$$

where $IG_{cc'} \in [0,1]$ is the *geographic proximity indicator* which measures the geographical proximity between country c and country c' and $IC_{cc',t} \in [0,1]$ is the *cultural similarity indicator* that measures how much each pair of countries are culturally similar at time t. The constants α and β, with $\alpha+\beta=1$, are the weights that determine the extent of which each component contributes to the global index.

We vary the interference input weights so to check the robustness of our results, under different assumptions about the network structure.

We now define the treatment variable, that "quantifies" the immigration policy, which has been implemented by national governments. The IMPIC Dataset provides indicators which measure the country-year restrictiveness towards migrants with respect to *regulations* and *control* mechanisms. Let reg_i be the reported value of the restrictiveness in terms of regulations of the generic country-year profile $i=(c,t)$ and $cont_i$ represent the corresponding value in terms of control. Denoting as med_{Reg} and med_{Cont} the medians of the regulations and control indicator, respectively, we classify the national political approach towards immigration with respect to the distribution of the two indicators:

Definition 3 (Nominal Treatment Categories).

- Z_i=A if $\text{reg}_i \leq \text{med}_{Reg}$ and $\text{cont}_i \leq \text{med}_{Cont}$: this category identifies profiles that are barely restrictive with respect to the two mechanisms.
- Z_i=B1 if $\text{reg}_i > \text{med}_{Reg}$ and $\text{cont}_i \leq \text{med}_{Cont}$: this category detects profiles which implement restrictive regulations but weak control strategies.
- Z_i=B2 if $\text{reg}_i \leq \text{med}_{Reg}$ and $\text{cont}_i > \text{med}_{Cont}$: this category indicates a welcoming attitude in terms of regulations but intense control protocols.
- Z_i=C if $\text{reg}_i \geq \text{med}_{Reg}$ and $\text{cont}_i \geq \text{med}_{Cont}$: this category denotes an highly restrictive policy towards migrants with respect to both regulations and control.

With respect to this definition of the treatment variable, and given the ICI formulation, we can define the neighborhood treatment as $\mathbf{G}_{ct}$ as

$$\mathbf{G}_{ct} = \begin{pmatrix} G_{ctA} \\ G_{ctB1} \\ G_{ctB2} \\ G_{ctC} \end{pmatrix} = \begin{pmatrix} \sum_{c' \in \mathcal{N}_{ct}} ICI_{cc',t}\,\delta_{Ac't} \\ \sum_{c' \in \mathcal{N}_{ct}} ICI_{cc',t}\,\delta_{B1c't} \\ \sum_{c' \in \mathcal{N}_{ct}} ICI_{cc',t}\,\delta_{B2c't} \\ \sum_{c' \in \mathcal{N}_{ct}} ICI_{cc',t}\,\delta_{Cc't} \end{pmatrix},$$

where $\delta_{Ac't}, \delta_{B1c't}, \delta_{B2c't}, , \delta_{TCc't}$ are dummy variables such that $\delta_{Ac't}=1$ if $Z_{c',t}=A$ and 0 otherwise; $\delta_{B1c't}=1$ if $Z_{c',t}=B1$ and 0 otherwise; $\delta_{B2c't}=1$ if $Z_{c',t}=B2$ and 0 otherwise; $\delta_{Cc't}=1$ if $Z_{c't}=C$ and 0 otherwise. Consequently, the joint potential outcomes are defined as $Y_{ct}(Z_{ct},\mathbf{G}_{ct})$. As said before, the outcome variable of interest, Y_i, is the Gini index for income inequality: it is bounded between 0 and 1 and higher values are associated to more unequal societies.

The estimation strategy is based on the Joint Multiple Generalized Propensity Score. We separately estimate the two propensity scores, relying on the factorized nature of the JMGPS: we estimate the individual propensity score, referred to the

categorical variable Z_i, that is $\phi(z;\mathbf{x}^z) = P(Z_i = z|\mathbf{X}_i^z = \mathbf{x}^z)$, fitting a standard Multinomial Logit Model; moreover, we estimate the neighborhood propensity score following the approach which has been proposed by [11]. Under continuous treatments (in our setting the neighborhood treatment is a multivariate continuous variable), we can estimate the propensity score assuming a functional form for the treatment of interest, such that the functional parameters depend on individual covariates. In particular, we assume that the (transformed [1]) neighborhood treatment $\mathbf{G}_i^*$ is normally distributed as

$$\mathbf{G}_i^* \sim MN(\mu_{\mathbf{G}_i^*}, \Sigma_{\mathbf{G}^*}) \tag{3}$$

where $\mu_{G_{i,z}^*} = \alpha_{G_z^*} + \beta_{G_z^*}^T \mathbf{X}_i^g + \beta_{G_z^*}^T Z_i$.

4 Key Results

We evaluate the impact of immigration policies on the Gini index for income inequality, dealing with a treatment of four categories and exploiting the pairwise comparisons between the treatment levels. Note that, for dealing with possible reverse causality issues, we introduce a one-year lag process in the analysis: that is, baseline covariates of a given country at time t affect its own joint treatment exposure at time $t+1$, which in turn affects the outcome at time $t+2$. Furthermore, we include in the propensity score estimation the no-lagged value of income inequality (evaluated at time t), so to control for the country-specific baseline outcome and more accurately identify the effect of the treatment. We take into consideration four scenarios depicting the interference mechanism to check the robustness of results with respect to different *a-priori* assumptions about the dependency structure. In particular, we check the following configurations of the influence weights: i) $\alpha = \beta = \frac{1}{2}$, *(gc)*: both geographical proximity and cultural similarity affects the interference between units, and contribute in determining the global interference compound index with equal weight; ii) $\alpha = 1, \beta = 0$, *(g)*: only *geographical proximity* drives interference; iii) $\alpha = 0, \beta = 1$, *(c)*: interference is prompted by cultural similarity only and iv) $\alpha = 0, \beta = 0$, *(noint)*: *no interference* mechanism comes into play. Table 1 reports the estimated treatment effects and their 95% Confidence Interval (computed using bootstrap), while Figure 2 represents the box plots and forest plots, referred to the distribution of the estimated effects.

We can see that highly restrictive political approaches cause significantly higher income inequality indices. In particular, severe control mechanisms prompt inequality (B2-A,B2-B1). Observing the results, we can also state that ignoring the possible spillover mechanism leads to a downward bias in the estimates, thus relying on the SUTVA makes the size of the effects becomes smaller (*noint*). This conclusion is stable in all the contrasts of interest. Allowing for the presence of interfer-

[1] We have applied a preliminary transformation over each component of the neighborhood treatment so that the normality assumption is plausible.

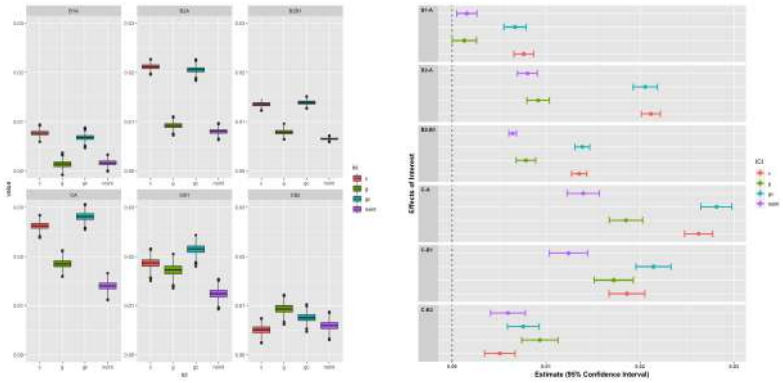

Fig. 2 The causal effect of immigration policies on the Gini index for income inequality: Colors signal the different assumption about interference: *gc*(lightblue), *g*(green), *c*(red), *noint*(purple)

ence increases the magnitude of the effects, and their robustness, with respect to the no-interference scenario. In particular, introducing the cultural similarity in the mechanism of dependencies points the way to an enhancement in terms of effects' intensities (c) (unless in the C-B2 comparison). Geographical proximity instead, mitigates the impact of interference on the results (g). These considerations hold in all the considered comparisons.

5 Concluding Remarks

This work presents an innovative approach for exploring the causal relationship between the national immigration policies and income inequality. The employed methodology proposes a multi-valued characterization of the treatment variable and accounts for first-order spillover mechanisms. Results suggest that implementing severe policies has a negative impact on the income inequality, intensifying the dis-

crepancies between individuals. Specifically, enacting severe control mechanisms on migrants leads to a higher Gini index for income inequality.

incremento delle iscrizioni all'interno degli atenei italiani, riducendo la selettività dei corsi e aumentando l'eterogeneità dei laureati. In questo modo, non solo un titolo accademico è diventato insufficiente a garantire un'occupazione remunerativa e prestigiosa, ma il crescente numero di laureati ha peggiorato fortemente le condizioni lavorative preesistenti. Utilizzando diverse fonti di dati, i.e l'indagine AlmaLaurea, le comunicazioni obbligatorie del ministero del lavoro e i dati amministrativi dell'Università di Firenze lo scopo del presente lavoro è quello di analizzare le condizioni lavorative dei laureati UNIFI al fine di valutare l'efficacia dei corsi universitari intrapresi dagli stessi. In questo estratto è presentata un'analisi preliminare dei risultati ottenuti.

Key words: Field of education; occupational outcome; university graduates; mixture cure models; Italy.

1 Introduction

Education is one of the fundamental factors of development [1]. Education human capital contributes to the economic growth in both developing and developed countries and has a positive and significant effect on labour productivity [2,3]. Thus, graduates' professional careers represent a tool to measure quality and effectiveness of university courses by providing an overview of the relationship between higher education and subsequent graduate employment [4,5]. The evaluation of students' occupational status at different times -from six months to many years after graduation- is important to assess the system's performance and contribute to its progressive improvement [6,7].

In the twenty-first century the Italian university system has experienced an expansion of enrolments benefiting from the Bologna Process. Moreover, after the significant increase in the number of graduates over the period 2001-2007, the number of new students started to decline in 2008 with the beginning of the economic crisis. The decline continued till 2012, when the number of graduates began to increase again, especially in northern and central Italian universities [8,5]. The expansion of higher education in Italy reduced the selectivity of courses increasing the heterogeneity of graduates. Thus, an academic degree may no longer be sufficient to access the most prestigious and remunerative occupational positions [9]. According to Rostan and Stan [5] two important theories may explain the characteristics of Italian graduates' employment and work conditions [10,8]. Firstly, the Italian economy seems to lack the characteristics, such as firms' size, innovation capacity and technology, to valorise and reward qualified human capital [11,12,13,14,15, 4,5]. Secondly, the expansion of higher education in Italy is often not associated with the demand of highly qualified human capital. In this perspective, the growth of the education system has led to an over supply of graduates, especially in some fields, worsening the employment and working conditions of degree holders [14,5]. The deterioration of employment conditions has resulted in stronger competition among graduates entering the labour market, where

selection processes started requiring a number of additional criteria. These go beyond the minimum job-related qualifications and more often focus on the type of institution attended at secondary or tertiary [15].

Nevertheless, much of the variation among graduates in occupation and earnings outcomes are related to disciplinary areas, with graduates from humanities and social sciences often penalized in terms of employability [16,17]. In fact, some qualifications adapt more easily to the demands of the market and are focused to develop human capital skills, whereas others are less sensitive to professional practice [7]. In Italy, Ballarino and Bratti [17] showed that in the decade 1995-2004 graduates in the 'hard' sciences obtained better rewarded occupations in terms of earnings and occupational status and were less likely to be unemployed or overeducated compared to graduates in the 'soft' social sciences and humanities.

Another important indicator of the performance of higher education institutions is the job-education mismatch. According to the existing literature, there are different ways to measure study mismatch. In general, the most part of studies focused on the qualifications or skills mismatch, which happens when a job-seeker may have to downgrade to find a job, but often this is different from field of study mismatch, which occurs when workers educated in a particular field work in another [18,19,20,21,22]. According to the OECD [22] Italy is one of the countries where more than 45% of workers are mismatched with respect to their field of study (FoS).

Relying of various sources of data, i.e Almalaurea, the Mandatory Notices of the Ministry of Labour datasets and the administrative database of University of Florence (UNIFI) students, this work aims to provide an overview of UNIFI graduates' employment and labour market participation. In order to outline the employment situation of UNIFI graduates, we will focus on three main aspects of the job experience, that is, the graduates employment condition at one, three and five years after graduation, the most common types of contract, the time needed to obtain a permanent position and the education-job match. Every objective will be evaluated comparing graduates from different FoS.

2 Data and methods

Three data sources will be integrated in the analysis of UNIFI graduates: the Mandatory Notice of the Ministry of Labour, the administrative database on UNIFI students and the AlmaLaurea Survey on Occupational condition of UNIFI graduates. The first source is an administrative dataset provided by the Ministry of Labour that reports information on all job contracts signed by graduates (except self-employment spells) in the years after graduation. The administrative source provides different information related with the job activity, such as the type of contracts held (open-ended, fixed term, short term, permanent, etc.), the number of working days per contract, the contract effective date, graduate age and gender, economic sector, etc. The second source contains a wide range of student's information: enrolment data, graduation data, previous education experience, high school, the course of study description and field of study. The third source is the AlmaLaurea Survey on

Occupational condition that provides information on post-graduate education and working career path of UNIFI first- and second-level graduates and five-years masters. On annual basis, the AlmaLaurea survey ensures a more than significant photograph of the employment path of graduates but is often characterized by a high nonresponse rate.
For the analysis of employment conditions of graduates, contingency tables and general descriptive statistics will be considered in order to identify the most important determinants of degree holder job career. In addition, mixture cure models will be employed in order to analyse time needed to obtain a job position, explicitly modelling the survival function as a mixture of 2 types of graduates: those who obtained a permanent position and those who did not.

3 Preliminary results

All the preliminary results presented were obtained from the database of Mandatory Notice of the Ministry of Labour and the administrative database on UNIFI students. The datasets were merged by a probabilistic record linkage. The archive contains data on about 262250 contracts signed by 46931 UNIFI graduated from 1 January 2008 to 31 December 2016. All the information refers to UNIFI students that obtained their degree between 2008 and 2016.
Trying to catch a snapshot of occupational outcomes of UNIFI graduates, Table 1 shows the percentage of signed contracts from 2008 to 2016. Overall, more than 60% of contracts were signed after graduation, the 37.17% within 3 years from graduation and almost the 29% more than 3 years after graduation.

Table 1: Number of signed contracts between 2008 and 2016

Number of signed contracts	N	%
While studying and ended	78,369	29.88
While studying and not ended	11,170	4.26
Within 3 year after graduation(3 years since gradutation)	97,469	37.17
More than 3 years after graduation	75,242	28.69
Total	262,250	100

Graduate employment can be analysed according to the type of contract graduates have. Focusing on the contract signed after graduation and on those signed while studying (or during university) the most common contract among UNFI students (bachelor and master level graduates and five-years masters) was the temporary one (59.13%); only the 10.35% of contracts were permanents. The 19.81% of contracts belongs to the category “Others” that includes “atypical” or “non standard” employments. Looking at the details bachelor and master graduates permanent contracts was, respectively, the third (8.77%) and the fourth (8.59%) most common.

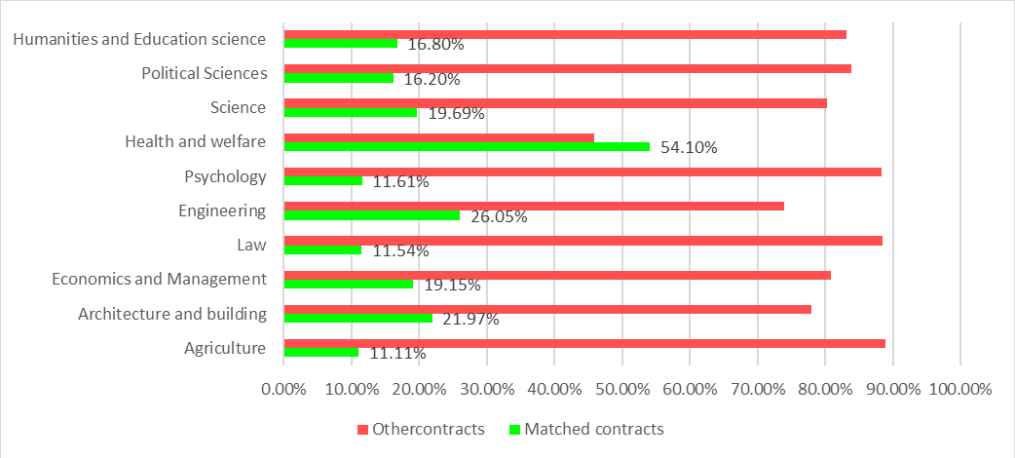
Looking at the difference by FoS, the average number of days of contract seems to differ across disciplinary areas and between bachelor and master students, but a high variability is observed for all the disciplinary areas. The average number of days increases for bachelor and master, except for Psychology that shows the lowest number of days for bachelor and master among all FoS. In the master group, Economics and Management, Health and Engineering show the highest average of days of contract.

Table 2: Average number of days of contracts and FoS (SD)

Field of study	Bachelor's degree	Master's degree and five-year master
Psychology	119.579(358.345)	118.39(336.86)
Humanities and Education science	122.104(312.233)	145.455(380.79)
Political Sciences	140.769 (378.678)	174.389(438.68)
Agriculture	142.23(301.814)	166.873 (309.85)
Science	153.767(314.434)	179.332(341.37)
Architecture and building	156.242(333.150)	113.45(340.22)
Economics and Management	167.152(341.708)	228.448(466.73)
Law	179.646(453.224)	164.977 (378.04)
Engineering	181.267(355.936)	259.618(495.81)
Health and welfare	213.424 (627.291)	228.811(852.59)

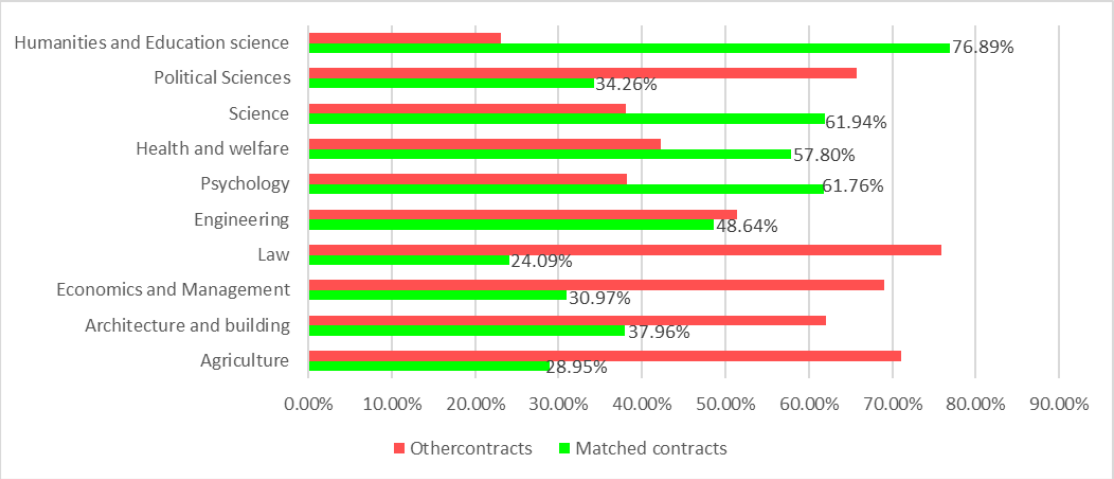
Qualification and skill mismatch was explored according to the ISTAT employment and work qualification list. In the list, employments are classified according to 9 main groups. Among bachelor graduates job-study mismatch can be identified looking at the percentage of contract belonging to the "TECHNICAL PROFESSIONS", whereas second cycle and single cycle are evaluated according to the "INTELLECTUAL, SCIENTIFIC AND HIGHLY SKILLED PROFESSIONS". As shown in Figures 1, among bachelor graduates only Health and Welfare seems to present the lowest percentage of mismatched contracts. In general, all FoS show a lower match between job and education attained in terms of skill and qualification (22.22%).

Figure 1: Study mismatch among first cycle graduates.



For master holders, Humanities and Education, Science, Health and Welfare, Psychology are less likely to be mismatched whereas the lowest percentage of matched contracts is showed by Law and Agriculture, as shown in Figure 2.

Figure 2: Study mismatch among secon and single cycle graduates.



4 Preliminary conclusions

Preliminary results revealed that graduates professional outcomes, in terms of average number of contract days, type of contracts and study mismatch seem to differ across disciplinary area. Further analysis are needed to consistently evaluate UNIFI graduates professional outcomes. Mixture cure model will be employed in order to analyse time needed to obtain a job position, explicitly modelling the survival function as a mixture of 2 types of graduates: those who obtained a permanent position and those who did not.

The joint effect of childcare services and flexible female employment on fertility rate in Europe

L'effetto congiunto dei servizi di assistenza per l'infanzia e della flessibilità lavorativa femminile sul tasso di fecondità in Europa

Viviana Cocuccio and Massimo Mucciardi

Abstract This research aims to deepen the effect of childcare services jointly to the flexible female employment on Total Fertility Rate (TFR) within the different European states contexts. In the 2002, the Barcelona European Council set objectives with regard to the availability of high quality and affordable childcare facilities for pre-school children, to improve the employment female rate and the TFR. Considering a spatial approach, the authors analysed how the current European situation in terms of childcare and employment policies are decisive on TFR levels

Abstract *Questo lavoro si propone di approfondire l'effetto dei servizi di assistenza per l'infanzia congiuntamente alla flessibilità del lavoro femminile sul Tasso di Fecondità Totale (TFT) nei differenti contesti nazionali europei. Considerando che già nel 2002 il Consiglio U.E. di Barcellona ha sancito gli obiettivi di elevate qualità e accessibilità dei servizi di assistenza alla prima infanzia al fine di migliorare il tasso di occupazione femminile e il TFT. Considerando un approccio spaziale, gli autori hanno analizzato quanto l'attuale situazione europea in termini di assistenza all'infanzia e di politiche occupazionali sia determinante sugli attuali livelli di TFT*

Keywords: Fertility, Childcare, Flexible Female Employment, Spatial Analysis

1 An overview of childcare services, flexible female employment and fertility in Europe

Many researchers have shown how new childcare policies are positively determinant on the female employment and, consequently, on the grown of Total fertility Rate (TFR) (Rindfuss et al., 2011). With "childcare policies", we mean

policies that support families like family allowances, public and private childcare services, parental leaves and tax exemptions. About the childcare services (CS) and the reproductive behaviour of the European regions, some researcher explain the evident stabilization of the phenomenon of fertility decline in Europe in the last decades (Lutz and Skirbekk, 2007). Besides the cultural causes of adaptation, however, there is the efficiency of early childhood care services on the growth of the fertility rate. According to this hypothesis, the surveys which were in the Eurobarometer 2006 (Testa, 2006), show that people who said they haven't fulfilled their desires on the childbearing, often said they didn't have the availability of a parental leaves and childcare, thus the presence of formal or informal childcare resources are determinant on the decision-making whether to have or not have a child. For instance, a cross-national study of 21 OECD countries shows a statistical positive correlation between the fertility behaviour of the European female employment and the presence of formal childcare services in their territory (Blum, 2012). After 1980 policies were introduced and directed at the reconciliation of work and family life as paid parental leaves and the TFR was grown. Let's briefly analyse some European cases. The Scandinavian countries represent an example of this good influence of CS on TFR, as it is proven by some recent literature. Rindfuss et al. (2007) with the use of comparative and spatial statistical models, has shown how in Norway there was a growth of childbirth rate for women of child-bearing age equal to 0.5 and 0.7 in correspondence with the implementation of child policies-care aimed at preschool children. That was a real welfare response favourable to the female worker and consequently to the family. Because of the aging of the population, Germany has decided to prevent the catastrophic socio-economic consequences of this phenomenon by implementing policies in Nordic style. One of these policies was the choice to realize the right of childcare for all preschool children by 2013. One of these consists to ensure that all children under the age of 3 have access to childcare services. A fertility study in Germany by Bauernschuster et al., (2012) shows that there is a correlation between the existence of more CS and the growth of local fertility rates, especially in the countries with a high level of education and less conservative cultural attitudes. Therefore, not only in the Scandinavian countries but also in countries which are similar to Italy but have culture and social conditions such as Germany, the strategy of implementation of early childcare policies present itself as a winning solution to the problem of low fertility. A recent paper by P. Baizàn (2009) supports the hypothesis of the positive correlation between early childhood care policies and growth in fertility rates, also in the Spanish case. This study highlighted important territorial differences growth: public CS increase more frequently in the regions of Spain where there was a higher rate of female employment, followed by a growth in fertility rates in these regions. In Russia there was an important demographic decline from 1990 to 2009, caused by emigrations of young aged people for the urban and rural unemployment and high death rates. Answering to this decline, Russia approved many new policies in the 2000s. New additional measures of public support for families with children had a positive impact on the TFR, through an increase of the per capita income, which allowed a decline in youth emigration. There were pro-natal measures and incentives for families with second and subsequent births since 2007, for the mothers

especially who are non-workers and have one or more children following the first. Following these policies to support the birth rate, Russia had experienced a “true demographic explosion. About the Russian case, the research of Miljkovica and Glazyrina (2008) on TFR in Russia shows us the unemployment phenomenon as a negative determinant on the percentage of fertility. Infact, as the level of unemployment increases, there is a decrease of the family income that make grown the perception of uncertainty that influence the procreative choice. At the contrary, France is an anomalous case given by the apparent similarity of the French context to neighbouring nations with low TFR. France recently has exceeded the TFR rates historically typical of the Scandinavian countries: in 2015, French’ TFR was equal to 1.96 while the Swedish one was 1.85. In France, policies in favour of the birth rate are not limited to classic monetary incentives such as the "baby bonus" but there are measures that counteract the progressive aging of the population through concrete services and work facilities that support families who embrace the choice of procreation. First of these policies was to guarantee ‘free kindergartens’ distributed throughout all the territory. Generating children in France is an event calculated in terms of merit for professional and pension purposes: for the calculation of the pension the period of maternity and leave for breastfeeding or other early childhood care is counted in favour of the female worker and contributions are paid by the state. This policy is the result of an ideological battle contaminated by pro-nativist values and gender equality supported by the state and the feminist movement. According to the study of Toulemon et al. (2008), the virtuous rate of fertility in France can be explained by the policies supporting fertility aimed directly at supporting the working mother and the not working one and many other political initiatives to combat youth unemployment. These can favourite the reconciliation of family and working time and should be replicable in other similar countries.

2 An attempt to estimate using a spatial approach

In order to identify the joint effect of CS and flexible female employment (FFE) on TFR, we use a geographically weighted regression (GWR) approach (Fotheringham et al., 2002). In the current state of research, the variables considered at member states level (NUTS0) are: average age of women at childbirth (year) (W_AGE_M); part-time female employment (W_E_PRT) (%); children aged 0-3 who use childcare services for less than 29 h a week (%) (CH_LESS). All the data is extracted from Eurostat dataset (2019) and are calculated considering the averages for the period 2014-2017. We analysed the results in two steps: first considering the global model (OLS regression); then considering the local model (GWR). To evaluate the spatial variability of the regression coefficients we refer to the Geographical Variation Test (Nakaya, 2015). As it is easy to see from the results obtained from the OLS model (table 1), the variable W_AGE_M is negatively correlated with the TFR. This correlation is probably due to the extension of the training education period and to the time taken to find employment, confirming the

Picchio's thesis (Picchio M. et al., 2018). Another classic thesis seems to be confirmed by our results. More specifically, the variable W_E_PRT is positively correlated with the fertility rate, thus the reproductive behaviour should be conditioned by the part-time female employment. This result probably explains that women need to feel more economic and social secureness to make this decision, but they prefer to spend time for family care too. Moreover, the prospection to have children is correlated with the use of CS too (see CH_LESS variable) which involves only less hours a week (less than 29 hours).

Table 1: Estimates and test for the OLS and GWR model[1]

Variable	OLS	Min	Lower quartile	Median	Upper quartile	Max
Intercept	3.54**	-1.315	2.549	2.808	3.135	8.089
W_AGE_M	-0.072**	-0.221	-0.059	-0.048	-0.039	0.101
W_E_PRT	0.008**	-0.006	0.006	0.007	0.008	0.068
CH_LESS	0.007*	-0.010	0.002	0.004	0.006	0.014

Global regression results (OLS): AICc=-20.66; Adj-R-square=0.25; *=p<0.05; **p<0.01
GWR results: AICc=-27.12; Adj-R-square=0.54; GWR ANOVA Test: F=3.86
GVT test results[#]: -88.14 (W_AGE_M); -8.56 (W_E_PRT); 3.37 (CH_LESS)
[#] Positive value of GVT suggests no spatial variability (Nakaya, 2015).

It is important to highlight how the variables W_AGE_M and W_E_PRT have a spatial variability respect to the variable CH_LESS which has a homogeneous impact on fertility on the European territory (see the positive GVT value in table 1). For the W_AGE_M and W_E_PRT variables, the GWR model detects a spatial variability of the coefficients (see the range of the coefficients from the min to the max value in table 1). Although there are some variabilities in the estimates, for the variable CH_LESS spatial model (GWR) does not reject the null hypothesis of absence of spatial variability. This should mean that the presence of CS is a crucial element on the reproductive choice, regardless of the territorial contest. Instead, as regarded the determinants W_AGE_M and W_E_PRT, the GWR model reveals a territorial influence of these regressors on the TFR. These variables affect the TFR differently according to the European local context.

As it's known, analysing the spatial distribution of the TFR at European level[2], it's higher in Scandinavian countries, in Turkey and French, while the lower European TFR are in the Mediterranean part of Europe and in Poland, where the policies of childbirth and the FFE probably are not efficient to reconcile the work and family-caring time. From the territorial point of view, the FFE is present mostly in the Scandinavian states, UK and Netherland. It is less common in France, Turkey, Greece, German and Iberian and Baltic nations. Probably, this is just the useful time to help women to reconcile the part-time working and family care time and the

[1] The data was appropriately geocoded and processed using GWR 4.0 (estimates) and Arcgis 10.2 software (maps). Furthermore, for methodological reasons we exclude Iceland from the analysis.

[2] The maps of the TFR, W_AGE_M, W_E_PRT and CH_LESS variables are not shown for reasons of space but are available on request

services for childcare services for 0-3 year-old-children are used for few hours a week according to the part-time, seems to be more used in northern and west European states. Examining the childcare variable, it's possible to see how data confirms thesis of Sonja Blum's survey (Blum, 2012) that showed how the public childcare policies have almost everywhere an important role in family's decision-making on their demographic behaviour. Also other studies confirm our results: we refer, for example, at Baizàn's analyse (Baizàn, 2009), who underline the positive effect on fertility of formal childcare for children under the age of 3. However it will be necessary to investigate better, considering the joint effect between these two effects (CS and FFE). According to Gesano's study (Gesano, 2017) in a socio-political context that pushes women to extend the period of training to hyper-specialize and compete for managerial work positions, it becomes natural to postpone the age of the first birth. To limit this, the presence of efficient early CS becomes essential. In particular, Gesano's study shows how the average age of woman at the first birth is low in the provinces of Eastern European countries, while it is particularly advanced in Sardinia (Italy) and other regions of central and southern Italy and Spain. The results of ~~a~~ the research by Gustaffson and Kalwij (2006) consolidate this view: it seems that higher educational level of the woman makes lower chances of birth before the average age of woman at birth and at births subsequent to the first. This means a negative relationship between fertility and education level of woman. This dynamic reduces the demand for the quantity of children, which allows women to postpone childbirth and increase investment in human capital in a few children (i.e. higher quality demand). In conclusion, from our maps results (figure 1) it is possible to see the jointly influence of the regressors on TFR in some European countries. There are nations where some regressors have ~~a~~ stronger influence on TFR and other regressors that have a poor influence on the TFR. This spatial methodology allows us to show how different are the phenomenon as the CS and the FFE with the average age of giving birth, probably influence the reproductive choice in different local way. However a research on new models is currently in progress by authors on these topics to deepen the influence of the factors analysed by Gesano and Gustaffson and Kalwij, who are not considered on this European fertility research because of the lack of availability of territorial and/or temporal data. It would be interesting, for instance to correlate the average age of women at childbirth with the extension of the educational period on the female employment.

The Left Behind Generation: How the current Early School Leavers affect tomorrow's NEETs?

La generazione degli emarginati: Quanti di coloro che abbandonano la scuola oggi si trasformano nei NEET di domani?

Giovanni De Luca, Paolo Mazzocchi, Claudio Quintano, Antonella Rocca

Abstract The youth labour market in Italy is among the most problematic ones. Indeed, across European countries, Italy shows the highest share of young people (16-34 years), not in Employment, Education or Training (NEETs). Furthermore, while at European level, the share of high educated is one of the lowest ones, Italy is among countries with the highest share of Early School Leavers, which are those who leave education after the achievement of compulsory education or even less. In line with a great amount of literature on human capital, highlighting the relationship between the level of education attained and the performance in the labour of market, this paper aims at analyse the link between the decision to leave prematurely the studies and the future status of NEETs in Italy. At this end, the authors estimate a time-varying correlation model to a four-weekly time series ad hoc constructed by Labour Force Survey.

Abstract *A livello europeo, l'Italia è il paese con la più elevata percentuale di giovani NEET (giovani tra i 16 ed i 34 anni che non lavorano, non studiano né svolgono alcun tipo di attività di formazione). In Italia, inoltre, la quota di giovani laureati è la più bassa mentre la quota di coloro che smettono di studiare dopo il conseguimento della sola scuola dell'obbligo, o anche prima (Early School Leavers), è tra le più alte. In linea con un ampio filone della letteratura sul capitale umano, che ricollega le difficoltà di inserimento dei giovani nel mercato del lavoro al loro basso profilo educativo, questo lavoro analizza il legame tra la decisione di lasciare prematuramente gli studi ed il conseguente status di NEET di Italia. A tal fine, gli autori stimano un modello di time-varying correlation su una serie storica costruita sui dati dell'Indagine forze di lavoro per il periodo 2007-2017.*

Key words: Early school leavers, NEETs, Youth unemployment rate

1. Introduction

Young people suffer a particular condition of disadvantage in the labour market in comparison to their older peers. When they leave school, they meet many obstacles to find a job for the lack of job experience and in many cases for the absence or an inefficiency of the instruments regulating the School-to-Work transition. This latter refers to the time from the end of the studies until the achievement of a stable job. In Italy, this period is very long, and its causes cannot be ascribed only to the high levels of unemployment. Indeed, in Italy the ratio between the youth unemployment rate and the adult unemployment rate, defined as the young people relative disadvantage, is one of the highest ones.

As the difficulties met by young people in the labour market may induce, besides unemployment, inactivity, the most appropriate indicator in order to study the youth condition on the labour market is represented by the NEET rate. It expresses the percentage of young people Not in Employment, Education and Training (aged 16-34 years). In the last years, a great amount of literature has underlined the relevant role of education as main human capital factor in determining the employability chances of individuals. Looking at the level of education, Italy shows the lowest share of tertiary educated among young people while the share of who leave school after completing compulsory school or before (Early School Leavers, ESLs) is one of the highest one. In this paper, we try to verify to what extent the highest share of NEETs in Italian young population depends on the high share of ESLs.

The structure of the paper is as follows: Section 2 introduces the framework of analysis; Section 3 shows the methodology while Section 4 presents the main results. Some conclusive considerations follow.

2. The framework of analysis

The high share of NEETs among the young population is certainly due to the high vulnerability of young people in the labour market. However, this phenomenon shows a great variability across Europe. Indeed, in 2017, the share of unemployed in the age class 18-24 ranged from the 43.6% of Greece to the 6.8% of Germany. Italy with 34.7% was just overcome by Greece and Spain. Conversely, according to NEETs, Italy, with 25.5%, shows the highest share, against a EU-28 mean of only 14.7%. The causes of so high share of NEETs in countries like Italy are certainly due to the difficulties met by young people to enter the labour market. This depends on individual characteristics and macro-economic factors linked to the labour market and the institutions in force on it. However, as a great amount of literature

highlights, these difficulties are also due to the education system, its inability to attract and keep young people and to transmit the skills and competences requested by employers (Pastore, 2014). Indeed, among the factors strongly increasing the chance to be employed for an individual, the level of education plays a crucial role (Becker, 1967). It is therefore not surprisingly that the highest share of unemployed and inactive can be found among low educated. Within the objectives contained in the United Nations 2030 Agenda for Sustainable Development Goals (SDGs), the Goal 4, Quality of Education, refers at subpoint 4.3 to the reduction of ESLs to less than 10%. However, among EU countries, many of them are very far from this objective. In 2017 the share of ESLs ranged from the 18.3% of Spain to the 3.1% of Croatia. Italy, with a share of 14%, just follows to Spain, Malta and Romania, against a mean value at EU-28 level of 10.6%.

Repeated failures in job search may induce to two different conditions. The first one is unemployment and consequent risk of falling into a trap of low-paying, temporary, unstable, or part-time jobs (Caroleo et al. 2018; Pastore 2014). The second possible consequence consists in discouragement, which is when people do not look for a job simply because they believe the search will fail, provoking inactivity (Finegan 1978; Furlong 2006). Unemployed and inactive individuals acquire the NEET status which, therefore, better than the youth unemployment rate is useful to highlight the youth condition on the labour market.

Therefore, in order to investigate on the causes of the NEET status, it is crucial to identify the causes in terms of the different connected characteristics.

The left side of Fig.1 shows the share of NEETs and of ESLs who are inactive. In Italy inactive are at least the 50% of total NEETs among males while among females they reach almost the 70%. This outcome highlights the remarkable difference between Italy, on the one side, and the other countries like Greece and Spain, on the other side. These latter countries share with Italy the high levels of youth unemployment rate, but while in Spain and Greece the high share of NEETs is mainly the result of high levels of unemployment, in Italy the determinants are not only explainable in terms of unemployment.

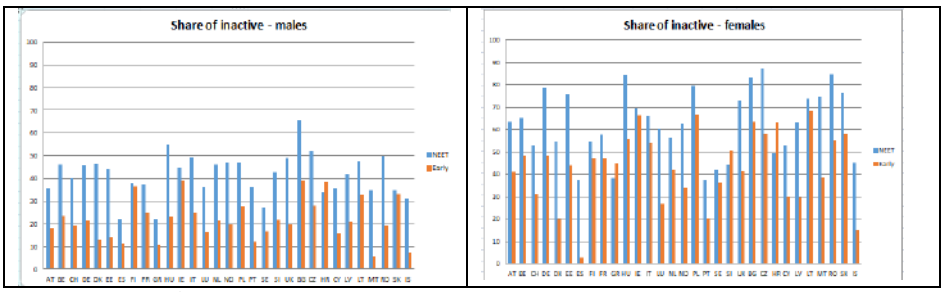

Figure 1: *Share of inactive on total NEETs by gender in EU countries in 2017.*
Source: Ad hoc elaboration on Labour Force Survey Data (2017).

Since the individuals' employability chances, and therefore the probability of becoming NEET, is affected by the level of education system, in Fig. 2 we have reported, on the left side, the share of ESLs who have become NEET and, on the

right side, the share of NEET who are ESLs. Even in this case, data highlight relevant differences across countries. The share of ESLs who have become NEET is very high in Italy, reaching the 45% among males and the 70% among females. Looking at the total of NEETs, those who are also ESLs are more than 40% among males and just a little bit less among women. Across EU countries, only Hungary and Denmark show highest percentages. Therefore, in the following we try to investigate on the relationship between NEET and ESL rates in terms of correlations on ad hoc constructed time series. The analysis is limited to the Italian data.

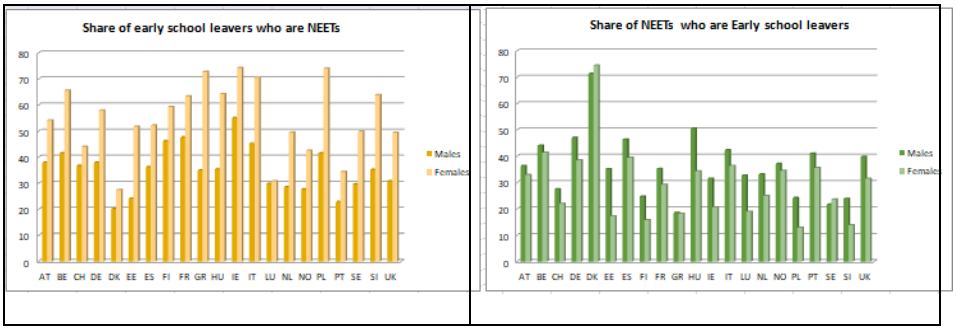

Figure 2: *Share of ESLs on total NEETs and share of NEETs on total ESLs by gender in EU countries in 2017.*
Source: Ad hoc elaboration on Labour Force Survey Data (2017).

3. The statistical methodology

In order to understand how the condition of ESL can lead to NEET status, starting from the Labour Force Survey, we have constructed an ad hoc time series based on four-weekly observations from 2007 to 2017, for a total number of 143 observations. Then we have investigated the dynamic relationship between NEET and ESL rates based on the estimation of a time-varying correlation. Indeed, given that in the life-cycle of an individual, after leaving school, the NEET status can occur immediately or after a certain temporal lag, we have estimated the correlation between $NEET$ and ESL, at time t and lag k

$$Corr_{t,k}(NEET, ESL) = \frac{Cov_{t,k}(NEET, ESL)}{\sqrt{Var_t(NEET)}\sqrt{Var_{t-k}(ESL)}}$$

with k = 1, 13. The two lags correspond, respectively, to a four-week and on-year periods.
The time-varying nature of the correlation has been captured using a moving-window with size s = 26, that is a two-year window, such that at time t

$$Cov_{t,k}(NEET, ESL) = \frac{1}{s-1}\sum_{i=t}^{t-s+1}(NEET_i - \overline{NEET}_{t:t-s+1})(ESL_{i-k} - \overline{ESL}_{t-k:t-k-s+1})$$

where $\overline{NEET}_{t:t-s+1}$ is the average of the 26 observations of the variable NEET from time t backward to $t-25$ and $\overline{ESL}_{t-k:t-k-s+1}$ is the average of the 26 observations of the variable ESL from time $t-k$ backward to $t-k-25$. Finally, $Var_t(NEET)$ and $Var_{t-k}(ESL)$ are the variance estimated using again 26 observations.

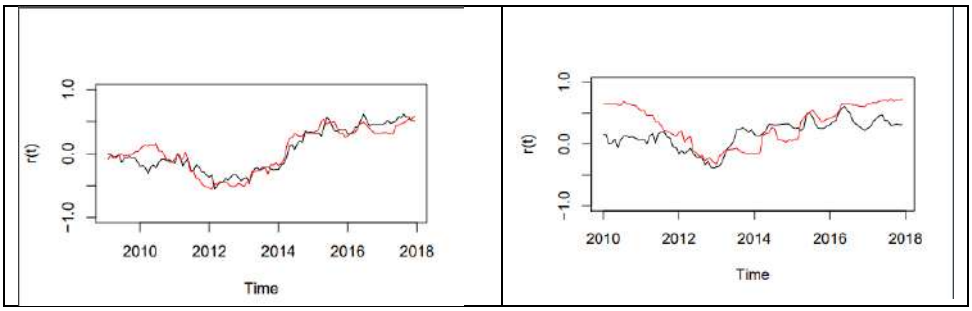

Figure 3: *Moving-window time-varying correlation based on lag=1 (left) and lag=13 (right). The red line is for females and the black one for males.*
Source: Ad hoc elaboration on Labour Force Survey Data (2017).

4. Results

Looking at the results of the rolling correlation, the lag 1 plot, on the left side of Fig.3, shows a null correlation at the beginning of the period in analysis, followed by a negative correlation in the years of the economic crisis, approximately between 2011 and 2014. Finally, starting from 2014, the association between the two variables is positive and increasing, in light of the low descending trend of ESLs and of the slightly decreasing pattern of NEETs of these last years. In any case, the NEET trend shows a persistence on higher levels than the situation prior to the crisis. No particular differences arise when we consider the gender perspective: at the end of the sample period, both for males and for females a positive and increasing dependence is detected. At lag 13, the relationship between NEET and one-year-lagged ESL does not show any relevant difference for male gender, even if the minimum and maximum values are less extreme. For women, there is evidence of a positive correlation at the beginning of the period, which decreases towards zero and finally becomes positive and increasing.

5. Conclusions

High share of NEETs represents a huge loss for a country economic growth. Among European countries, Italy shows the highest share of NEETs. One of the most important actions to take in order to reduce the high share of NEETs consists in stimulating young people to attain higher level of education, which can improve their skills and employability. A recent study demonstrated that the different capacity of the European countries to recover by the great recession can be explained through the strong role played by higher levels of education, which can reduce unemployment and inactivity (Pompei and Selezneva, 2018). In this paper, we tried to identify the main peculiarities of the condition of young people in Italy, where the share of NEETs is the highest one, despite the fact that the youth unemployment rate, even if high, is not maximum. The analysis shows that, besides the major propensity to inactivity, characterizing especially young women, the link between the NEET status and the low level of education is very strong. Compared to the other EU countries, in Italy the probability that an ESL becomes NEET is one of the highest ones. It is also higher than the Spanish one, where the share of ESLs is maximum and the levels of youth unemployment rate higher. After Denmark, Hungary and Spain, Italy shows also the highest share of low educated NEETs. The results of the rolling correlation add to this first results other relevant evidence. The connection in terms of correlation between the status of ESL and the status of NEET is very high and, especially for females, this relationship is even increased in these last years, when the economic crisis has been widely overcome. In a gender perspective, we can highlight that the differences between men and women, initially negligible, tend to amplify. Being young represents a factor of penalization on the labour market. However, when other conditions of vulnerability add, such as being low-educated, the difficulties dramatically arise. Finally, being female further increases the previous disadvantage, making still more difficult escape from a future of long-term unemployment or inactivity, that is from the NEET status.

The probability to be employed of young adults of foreign origin

La probabilità di essere occupati dei giovani adulti di origine straniera

Alessio Buonomo, Francesca Di Iorio and Salvatore Strozza

Abstract Our study focuses on a sub-sample of the 2011-2012 ISTAT survey on 'Social Condition and Integration of Foreign citizens' (SCIF). A Probit model is implemented in order to analyse the determinants of the probability to be employed of the young adult (aged 18-34) foreign population. Our findings prove the central role played by gender and citizenship at birth, without significative effects of migratory generation. The importance of the cultural integration emerges for women.

Abstract *Su un sotto-campione dell'indagine ISTAT del 2011-2012 su "Condizione e integrazione sociale dei cittadini stranieri" è stato implementato un modello Probit al fine di analizzare le determinanti della probabilità di essere occupati dei giovani adulti (18-34 anni) stranieri o di origine straniera. È confermato il ruolo centrale del genere e della cittadinanza di origine, mentre la generazione migratoria non appare significativa. Tra le donne emerge l'importanza dell'integrazione culturale.*

Key words: Employment, Foreigners, Migratory generations, Probit model, Italy

1 Introduction

Foreign immigration to Italy has a history that began more than 40 years ago (Strozza 2016). Since the end of the nineties, literature has focused attention on immigrants' descendants (Ambrosini e Molina 2004). Scholars proved that students with non-Italian citizenship are more likely to have lower levels of education, poorer

[1] Alessio Buonomo, University of Naples Federico II; email: alessio.buonomo@unina.it
Francesca Di Iorio, University of Naples Federico II; email: francesca.diiorio@unina.it
Salvatore Strozza, University of Naples Federico II; email: salvatore.strozza@unina.it

performances, and a greater probability of moving towards vocational schooling than Italian counterparts (Strozza 2008; Dalla Zuanna et al. 2009; Conti et al. 2013; Buonomo et al. 2018). The lack of fluency in the language of the majority population represents an important obstacle for children of immigrants to succeed in their schoolwork. These evidences imply that their insertion into the labour market will be more difficult compared to nationals (Meurs et al. 2008). Specifically, some studies proved that they have higher risk of unemployment and precarious employment (Kristen et al. 2008; Meurs, et al. 2008).

The aim of this contribution is to evaluate, through a Probit model, the relevance of different determinants on the probability to be employed among foreign and naturalized people aged 18-34, focusing our attention in assessing possible differences between first generation immigrants and children of immigrants born in Italy or immigrated in Italy before age 18 (hereafter 1.5 generation).

2 Data used, descriptive statistics and method of analysis

The survey on 'Social Condition and Integration of Foreign citizens' (SCIF) was conducted in 2011-2012 and released in 2016. It is a new and unique sample survey on this subject, designed by the Italian National Statistical Institute (ISTAT) in the system of multipurpose household surveys. The survey collects data on households with at least one foreign (or foreign origin) citizen and provides original information on foreigners living in Italy. In particular, many immigrants' characteristics and behaviours are considered: family, marriage, fertility, education, employment history, working conditions, religious affiliation, etc. This survey has a cross-sectional asset and it covers a sample of about 12,000 households. Our target sample refers to people aged 18-34 (6,342 unweighted observations).

We considered the weighted data in order to reproduce the main characteristics of the universe. Using a vector of weights resized to the total sample size, we observe that 58.5% of the target sample is employed with evident differences by gender (the percentage of employed is equal to 74.6% among men and only 44.6% among women) and migratory generation (62.6% among first generation immigrants against 48.6% among 1.5 generation). The difference in the employment rate by migratory generation could however depend on the different age structure of the two groups considered.

Many factors can be associated with employment probability. Considering the available information, we selected as possible explanatory factors 13 covariates grouped in two types of variables: individual characteristics (including intentions), and indicators of integration condition. The following individual covariates are included in the analysis (in brackets some weighted percentages): gender (males are 46.4%); age (continuous, we included the square term); area of residence (62.2% in the North, 23.9% in the Centre and 13.9 in the South of Italy); marital status (in three categories: single are 50.2%, married 43.7% and other conditions 6.1%); presence of children (56.3% without children); educational level (in three categories: 10.0% without education or with primary education, 52.3% with low or middle secondary education,

and 37.7% with complete secondary or tertiary education). We added a dummy variable that expresses the desire to have a child in the next 3 years (49.7% desire a child) in order to consider future intentions of the target sample. Migratory generation was summarized in another dummy variable that divides first generation of immigrants (70.9%) from children of immigrants born in Italy or immigrated before age 18 (1.5 generation). We used citizenship at birth, instead of the current one, in order to identify ethnic minorities even among the people who have acquired Italian citizenship. We considered three more numerous countries in our sample, while all the others were aggregated by geographical and economical macro-areas (table 1).

Table 1: Citizenship at birth by main countries and macro-areas. Absolute weighted values and percentages

Citizenship at birth	***N***	***%***
Albania (ALB)	755	11.91
Romania (ROM)	1,567	24.70
Morocco (MOR)	573	9.04
Rest of Eastern EU (EST_EU)	301	4.74
Rest of Eastern non EU Europe (EST_NEU)	747	11.77
Rest of Africa (AFR)	651	10.26
Asia (ASIA)	1,061	16.74
Latin America (LATAM)	530	8.36
More Developed Countries (MDCs)	157	2.48
Total	6,342	100.00

Following Blangiardo and co-authors (2013, 2018), we included three different dimensions of integration: cultural (knowledge and frequency of use of the Italian language, healthcare, eating habits, etc.), social (the active participation in social and public life), and political (the attention given to issues in Italian politics and their opinion regarding the importance of acquiring Italian citizenship). Each of the three indicators has a variation range between -1 (absence of integration) and +1 (maximum integration), with an average value of the total sample equal to 0.
Given the nature of the dependent variable, i.e. the probability to be employed, we choose to implement a Probit model (among others Hosmer and Lemeshow, 2000).

3 Results and discussion

Estimated coefficients are reported in table 2. Three different models are proposed. Model 1 include all the covariates described above excepted for variables on age and the dimensions of integration. It serves as the basis for the following models. The probability of be employed is higher for first generation immigrants compared to the 1.5 generation. As expected, females have negative effect on the estimated probability. Compared to single individuals, married have lower estimated probability to be employed while this is higher for separated or divorced individuals. Area of residence and education turn out not statistically significant at 5% level. The association between employment and the desire to have a child in the next three

years is positive. Considering the citizenship at birth (benchmark category is Albania), just Romania (positive), Morocco (negative) and others African nationalities (negative) significantly affect the response variable.

In Model 2, with the introduction of variables on age and its squared term, the coefficient associated to first generation assume a negative significant impact as well as the presence of children. This is the result of the age distribution, since the first generation is made up of older people and constitutes the greater part of the target sample. Moreover, age have expected positive (and age squared negative) effect on the estimated probability. The first generation coefficient become non-statistical significant in Model 3 with the introduction of variables on integration. Among them, only cultural integration has a significant (positive) effect. The remaining coefficients do not undergo significant changes compared to Model 2. This final model shows how the probability of be employed is linked mainly to gender, to the family context, the area of origin and the level of cultural integration,

and obviously to age. Education level and area of residence, as well as migratory generation, do not seem to play a significant role.
We repeated the analysis presented in Model 3 on males and females subsamples. The significant gender differences in the determinants of the probability of be employed are highlighted. The Probit model shows significant effect for variables associated to family context only for females: marital status (negative for married women), presence of children (negative for women having children) and desire to have a child (positive for women that desire a child). Citizenship at birth shows significant coefficients for the same categories in the three Models. At the same time the analysis carried on by gender using Model 3 highlights that several categories of citizenship at birth affects the response variable in different way in their respective sub-samples with respect to the reference group (Albanians). In particular, in the male subsample only Moroccans, other Africans and MCDs have significant negative effect. These evidences have a different meaning being probably due to high unemployment in the case of Africans and low activity rate in the case of citizens of MDCs. For the female subsample there is an advantage in terms of probability of be employed by the Romanians and a negative effect by Moroccan compared to the Albanians.

Figure 1: Estimated probability to be employed and 95% Confidence Interval by gender, migratory generation and citizenship at birth when all categorical variables are set to benchmark level and continuous variables at the mean.

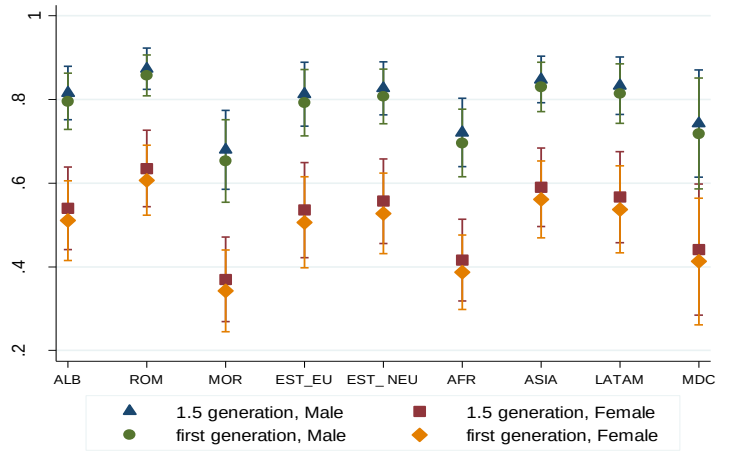

Figure 1 depict the estimated probability to be employed by gender, migratory generation and citizenship at birth, when the other dummies or polychotomous variables are at the reference level and the remaining variables at the mean. Gender differences are confirmed separately by citizenship at birth: for all citizenship at birth, except for MDCs, women always have values of the estimated probability of be employed clearly lower than those of the male counterpart. All other things being equal, it seems that there aren't significant differences in the possibility of access to employment for young adults of foreign origin distinguished between those of the first generation and those who are children of immigrants.

Described results gives a first insight on the probability to be employed of young-adults foreigners. It will be necessary to verify, for example, the quality of the occupational status level and the importance of over-education comparing the results among both migratory generations and citizenship at birth. This analysis is mainly devoted in evaluating the contribution of the SCIF survey, further investigation will require also the evaluation of a different source of data (for instance, Labor Force Survey). In any case, our contribution provides some policy implications. In particular, the results reveal the central role played by investing in (cultural) integration in order to favour the placement in the labour market of the host country of foreign (female) young-adults residents in Italy.

The risk of inappropriateness in geriatric wards: a comparison among the Italian regions.

Rischio di inappropriatezza in ambito geriatrico: un confronto tra le regioni italiane.

Paolo Mariani, Andrea Marletta, Marcella Mazzoleni and Mariangela Zenga

Abstract Italy could be considered one among the oldest countries in Europe and this situation is becoming increasingly relevant in the future decades. This scenario will lead the Italian Health System to cope with a significant increase in healthcare consumption. This work will analyse the ordinary acute admissions in the geriatric wards of the Italian hospitals using the Hospital Discharge Data. Specifically, the aim is to describe the risk of inappropriateness of the hospitalizations related to chronic diseases among the Italian regions. A risk of inappropriateness index will be proposed to compare the Italian regions into the period 2012-2015.

Abstract *L'Italia può essere considerate una tra le nazioni più anziane in Europa, e questa situazione non può che aumentare nelle prossime decadi. Questo scenario porta il Sistema Sanitario Nazionale italiano verso un maggiore consumo di risorse per la salute. Questo lavoro si propone di analizzare i ricoveri ordinari in acuto nei reparti di geriatria degli ospedali italiani attraverso i dati delle dimissioni ospedaliere. In particolare, lo scopo è quello di descrivere il rischio di inappropriatezza per i ricoveri per malattie croniche tra le regioni italiane. Verrà proposto un indice di rischio di inappropriatezza per comparare le regioni italiane nel periodo 2012-2015.*

Key words: Italian Geriatric Wards, Chronic diseases, Inappropriateness risk.

Introduction

In the last decades, the proportion of elderly population has increased across all European countries, showing the highest growth rate amongst groups of all ages. Italy could be considered one among the oldest countries in Europe: in fact, the population aged 65 and over is 22.6% of the Italian population with an aging index of 168.7% as stated by ISTAT in 2018. Moreover, a high percentage (49.6%) of elderly people shows at least one of chronic/chronic degenerative disease. Moreover, in 2012 the Italian regions have been undergone to spending review in relations to the high cost of healthcare review (Ministero della salute, 2012). Given by the Italian spending review in healthcare, the acute hospitalizations in geriatric wards decreased by 3.9% from 2012 to 2015.
This work proposes a synthetic index to measure the risk of inappropriate hospitalization that is applied to the Italian regions, so they are classified into three groups based on the distance from the national average behaviour.

Definition of inappropriate hospitalization

In this work, we pay attention on the measure of inappropriateness in the hospitalizations for elderly patients admitted in the Italian geriatric wards. From a healthcare point of view, several authors (Tsang and Severs, 1995; Inglis et al., 1995; Houghton et al., 1996; Beringer and Flanagan, 1999; Leah and Adams, 2010; Mayo and Allen, 2010) proposed to use a definition based on patients' clinical details by a team of doctors. Glasby and Littlechild (2001) proposed to use also the patients' opinion.
In this case, we adopt the definition of inappropriateness hospitalization as stated by the Italian Healthcare Ministry. In 2001, the Essential Assistance Levels (LEAs) were introduced with the aim to rationalise the use of resources in the healthcare sector and they were related to the Diagnosis-Related Group (DRG). The concept of appropriateness was defined with the aim to improve the quality of provided health services and the proper use of resources. An indication of potential inappropriateness of the healthcare was represented by a high variability in the demand and supply of healthcare services at a regional level. In this way, 108 DRGs with a high risk of inappropriateness for hospitalization of acute diseases were defined to monitor and verify effective delivery of performance in the national territory. The 2010-2012 Pact for Health (Patto per la Salute, 2009) has been drawn up. According to this reform, the aspect of appropriateness plays a major role in hospital care. This reform defines a set of indicators to be used to control the achievement of an appropriate service delivery and performance in healthcare system. The indicators system affords to the regions to define standards of organisational appropriateness for the purpose of self-assessment in order to optimise the delivery of healthcare. Some standards have been defined at regional level indicating the threshold values within which to permit

inpatient admissions. A comparison of the regional values of the indicators can identify regional critical areas and it could help the central level to intervene.

Data and Methodological Approach

The data used in this paper consists of the ordinary admissions of the patients aged 65 years or older to every geriatric ward in every acute care hospital operating in the 20 Italian Regions in 2012 and 2015.
The Italian Healthcare Ministry provided the data. Individual Hospital Discharge Charts (HDC) are reported in the dataset including patient information (gender, age, residence, etc.), the treatments received during hospitalization including information such as Disease Related Group (DRG), principal and secondary diagnoses and procedures, date of admission, and so on.
Patients are aged 84 years on average. Approximately 42% of patients were male. The ten percent of patients were admitted to the department of geriatric medicine through emergency admission. Approximately 57% of patients were admitted for surgery. Chronic patients represented approximately 33% of all patients. Moreover, 24% of the admitted patients had a principal diagnosis of circulatory system, 22% as respiratory system problems, and 16% problems of the nervous system. Approximately 73% of patients left the geriatric ward to return home, of whom about 3% were voluntary discharge; 13% died while in hospital and the remaining 14% transferred. The length of Stay is about 11 days. The Elixhauser comorbidity index diseases (Elixhauser et al., 1998) for the geriatric hospitalizations is about 1.3 comorbidity.
The Ministry of Health measures the rate of DRGs at Inappropriateness risk as the number of Inappropriate hospitalizations per Not Inappropriate hospitalizations (Ministero della Salute, 2010):

$$RI_{t,i} = \left(\frac{Number\ of\ Inappopriate\ Hospitalization}{Number\ of\ Not\ Inappopriate\ Hospitalization}\right)_{t,i}$$

for the *i-th* Italian region in *t-th* year. To compare the *i-th* region in t_1 and t_2 years, a number index is used:

$$DRI_{t_2,i/t_1,i} = \frac{RI_{t_2,i}}{RI_{t_1,i}}.$$

Moreover, considering Italy as a benchmark, the regions could be divided in three groups according to $I_i = (DRI_{t_2,i/t_1,i})/(DRI_{t_2,ITALY/t_1,ITALY}) \cdot 100$ if:

- $I_i \leq 100$ the *i-th* region shows a better performance in reduction of inappropriateness respect to Italy;
- $100 < I_i \leq 100 + std(I)$ the *i-th* region presents a limited worst performance in reduction of inappropriateness respect to Italy;

- $I_I > 100 + std(I)$ the *i-th* region presents a worst performance in reduction of inappropriateness respect to Italy.

Some evidences

Table 1 reports the rate of DRGs at Inappropriateness risk by the Italian regions in 2012 and 2015. In 2012 for Italy, for 100 Not Inappropriate Hospitalizations exist 11 Inappropriate Hospitalizations. Sardegna has the highest rate of DRGs at Inappropriateness risk (0.21), followed by Puglia (0.16) and Lombardia (0.15), while Valle d'Aosta is the region with the lowest rate of DRGs at Inappropriateness risk (0.04), followed by Piemonte (0.0593) and Marche (0.0599). In 2015, the Italian rate of DRGs at Inappropriateness risk decreased by 20%. Almost each region shows decreased rate of DRGs at Inappropriateness risk, except for Piemonte, Friuli-Venezia Giulia, Umbria and Molise. Again, Sardegna shows the higher rate of DRGs at Inappropriateness risk (0.18), followed by Lombardia (0.12) and Puglia (0.11). Calabria has the highest percentage of decreasing, going from 0.10 to 0.03 (-71.13%), while Friuli-Venezia Giulia has the highest percentage of increasing, going from 0.065 to 0.089 (+36.92%).
In the comparison in I_i, ($std(I)$*=29.57)* six regions (Group 1: Toscana, Marche, Campania, Puglia, Calabria and Sicilia) show better performance in reduction of inappropriateness respect to the Italian situation, even if different situations are present. For example, Marche shows lower rate of DRGs at Inappropriateness risk in 2012 and 2015 and the reduction in it is greater respect to Italy. On the contrary, Puglia and Campania have bad performances in terms of the rate of DRGs at Inappropriateness risk in 2012 and 2015, far below the Italian situation, but the reduction in inappropriateness results to be greater respect to Italy. The regions in the limited worst group (Group 2) are Valle d'Aosta, Lombardia, Trentino Alto Adige, Veneto, Liguria, Emilia Romagna, Lazio, Abruzzo, Basilicata and Sardegna. In the worst perfomance group (Group 3) there are Piemonte, Friuli-Venezia Giulia, Umbria and Molise.
This result is widely reflected on the Italian regional spending review (Ministero della salute, 2012).

Conclusions and future works

The study of the inappropriateness dynamics of the geriatric hospitalization recommends a more careful examination by temporal and spatial aspects. In this analysis, some regions showing better performance have been undergone heavy actions by the National Health Care System reducing costs. On the other hand, other regions showing undesirable values were subject to attention by the Italian government in these last years.

Future research is based on the investigation of the possible causes of inappropriateness that could be nested both in the comorbidity and in the different styles of health management that are currently in the hands of the individual regions.

The role of the accumulation of poverty and unemployment for health disadvantages

Il ruolo delle traiettorie di povertà e occupazione negli svantaggi di salute

Annalisa Busetta, Daria Mendola, Emanuela Struffolino and Zachary Van Winkle

Abstract Health inequality is an important aspect of how advantages and disadvantages are distributed within societies. We extend previous research by considering how trajectories of poverty and employment affect self-reported health among young adults. We use data from the German Socio-Economic Panel, restricting the analytical sample to those who were 25 to 45 year-old in 2005. We calculated the indexes that account for persistence and intensity of poverty and employment on 10-year-long individual-level employment and household-level poverty trajectories. Ordinal logit regression models show that both long-lasting poverty and short periods out of employment are detrimental for men's health. In contrast, only more recent episodes in poverty have a negative effect on women's health.

Abstract *Le disuguaglianze di salute sono cruciali per la distribuzioni di vantaggi e svantaggi. Questo lavoro esamina come le traiettorie di povertà e occupazione influenzino la salute percepita tra i giovani adulti. Utilizzando il German Socio-Economic Panel e considerando un campione di 25-45enni al 2005, abbiamo misurato su 10 anni la persistenza e l'intensità della povertà e dell'occupazione. I modelli di regressione logistica ordinali mostrano che sia la povertà di lunga durata che i brevi periodi di disoccupazione sono dannosi per la salute degli uomini; mentre per le donne solo degli episodi di povertà più recenti mostrano un effetto negativo.*

Key words: in-work poverty, gender, health, life-course, index, persistence

Introduction

Health inequality is an important aspect of how advantages and disadvantages are distributed within societies. Individual health can be affected both positively and negatively by life course events in different domains, such as work and family (e.g., Marmot, 2015). Most mechanisms linking individual life courses to health outcomes depend on exposure to specific risks, require time to show up, and can have cumulative effects (Dannefer, 2003). Empirical research that adopts a longitudinal perspective shows that long-lasting exposure to poverty over the life course and changes in income and economic status are associated with poorer health (e.g., Gunasekara et al., 2011). Similarly, employment trajectories characterized by unemployment as well as precarious and poorly paid jobs are associated with poor health in mid-life (e.g., Cullati, 2014; Devillanova et al., 2019). Not only do differences in material standards of living, access to healthcare, and disposable financial resources account for the association between precarious life courses and health, but also the psychological and behavioural implications of unemployment and poverty.

Recent reviews on socioeconomic inequalities in health have identified limitations in the existing literature that can be addressed by adopting longitudinal analytical approaches and the life course perspective (Corna, 2013). Specifically, there has been so far little recognition of how the association between socio-economic position and health are—at least partly—constituted by labour market and family experiences across the life course. Additionally, a deep understanding of these dynamics requires to consider how gendered they are. We extend upon previous research and assess how longitudinal trajectories of poverty and labour market attachment independently and mutually affect self-perceived health among young adults. We devote particular attention to gender differences.

We focus on Germany, where the increase in in-work poverty between 1985 and 2017 was one of the largest in the EU (Eurostat, 2018) and for which high quality longitudinal data are available (SOEP-German Socio-economic Panel). At this stage, we will consider a cohort of young individuals whose life courses unfolded between 2005 and 2014. To assess how trajectories of poverty and employment impact health, we reconstruct separate sequences of household poverty and individual labour market attachment. We then adopt two recently developed indexes that capture cumulative effects of repeated poverty spells in terms of their severity and recentness (Busetta et al., 2019; Mendola et al., 2011). We therefore go beyond "point in time" approaches that consider how the transition from a permanent to a temporary job affects health and address how trajectories of poverty and labour market attachment affect health in a holistic manner.

Data and methods

Data. We used data from the German SOEP, a nationally representative household panel. We restrict the sample to those born between 1969 and 1980 who therefore were 25 to 34 year-old in 2005 (women=717, men=584). For each individual, we constructed an "employment trajectory" and a "poverty trajectory".

Dependent variable. Health is measured in 2015, that is at the end of the 10-year observational window, using a question that asks respondents to self-rate their own general health (herein SRH). We recoded SRH into four categories in each panel wave: very good (13.86% of the sample), good (49.97%), fair (25.89), and bad/very bad (bad, henceforth, 10.28%). SRH has been shown to be a valuable predictor of more detailed measures of health status (Jylhä, 2009).

Main dependent variables. Employment and poverty patterns are our main predictors for SRH. For employment trajectories, each time-point between the first observation in 2005 and the last in 2014 was coded with 0 if the individual was inactive/unemployed and 1 if he/she was employed. For poverty trajectories, each time-point where coded with 1 if the respondent's household income was below the poverty line (i.e. 60% of the median of equivalised household income distribution) for that year and with 0 otherwise. We then calculated the index of longitudinal poverty proposed by Mendola et al. (2011) on the poverty trajectories. The index takes into account the pattern and the severity of poverty experience, as it (i) gives the highest weight to each pair of consecutive years spent in poverty (and an increasingly higher weight to closer spells of poverty), i.e., they contribute more to increase the value of the overall measure) and (ii) puts more emphasis to poverty episodes experienced during years of low poverty incidence in the general population; (iii) puts more weight the more severe poverty spells are (i.e., when household income is far below the poverty line). To summarize employment trajectories to proxy individuals' labour market attachment, we propose an adaptation of the index proposed in Busetta et al. (2019) that considers individual and contextual labour market conditions simultaneously. By adopting this modified index, we account for the continuity of employment (vs. unemployment) and the "intensity" of employment, by weighting each employment episode by the numbers of hours worked (percentage of a full-time week, 40h/week). In addition, the employment index incorporates the probability of remaining in employment and the detrimental effect of years spent out of employment. Next to poverty and employment indexes, we calculated two ancillary indexes (so-called "closeness" effects) that account for how recent poverty and employment spells are to the measurement of self-rated health. Note that the income variable was lagged to preserve the correspondence between the employment status and income reference period.

Modelling strategy. We run a set of ordinal logit regression models for SRH, for men and women separately. Following a forward-stepwise criterion, they include: (1) the poverty index, (2) the poverty index and its closeness effect, (3) the labour market attachment index, (4) the labour market attachment index and its closeness

effect, (5) both the poverty and labour market attachment indexes and their closeness effect and the interaction between the indexes.

Control variables. All models are adjusted for a set of observable individual and household characteristics: age, age-squared, number of years in education (logarithm), being born in East Germany, and number of children in the household (age 18 and below) are measured at the onset of individuals' sequences. Another set of variables accounts for the change in the number of children in the household and for the share of years spent in singlehood and divorce across the 10-year observational window.

Main results

Table 1 shows the results (as betas) of a set of ordered logistic regressions for the probability of bad health for women and men separately.[1] Models 1a and 1b estimate the effect of the poverty persistence index: longer and closer periods spent in poverty increase the probability of reporting bad health for men. For them, the poverty index is no longer statistically significant after adjusting for the closeness effect of poverty (models 2a and 2b), which—by emphasising the more recent poverty episodes—captures all the effect of poverty patterns. The closeness effect of poverty is also statistically significant for women (model 1b). With regard to employment trajectories, stronger attachment decreases the likelihood of bad health for men but not for women (models 3b and 3a respectively). Similar to poverty, the effect of the overall trajectory of employment disappears once the effect of recent employment spells (model 4b) are taken into account. Finally, the interaction between the poverty and employment trajectories is not statistically significant for both for men and women, while closeness effect of poverty and of employment are significant for both groups (models 5a and 5b). Explanations for gender differentials in our relationships of interest are not straightforward. Although in Germany several steps towards gender equality have been made, the division of labour remain highly gendered, especially after childbirth. The so called "1.5-bread-winner model" prevails so that weak labour market attachment might affect men's health but not women's as for men the social norms associated with their primary role of breadwinner are stronger. However, when it comes to household poverty, the negative effect of the closeness of poverty affects women as well, as they are highly involved in the process of coping with poverty irrespective of their own position in the labour market and especially in presence of young children.

[1] As robustness checks, we replicate the models by (i) dichotomizing the outcome variable ("bad"/"very bad" vs. "very good"/"good"/"fair"), (ii) keeping the categories "bad" and "very bad" separated, (iii) estimating generalized ordinal logit models for the outcome with five categories; (iv) including interaction between closeness effects of poverty and employment. The results are highly stable and consistent with those presented in Table 1.

Conclusions and next steps

In this study, we investigate possible spill-over effects of poverty and employment trajectories on health. We adopt a longitudinal view that accounts for the persistence and intensity of poverty as well as of labour market attachment. Our preliminary results show considerable gender differences. For men having spent several years in poverty and out of the labour market has a negative effect on health, especially when these events occurred in the last few years before the self-reported assessment. However, we did not find an interaction effect between poverty and employment trajectories. For women, we only find a significant effect of poverty episodes experienced more recently in time. Possible explanations for the gendered differential effects of poverty and employment trajectories can be found in how the cultural and institutional contexts shape the role of men and women in the family and the labour market. Further, gender roles might influence men's and women's reporting behaviour also depending on how the employment status of partners affects respondents' perceived health (e.g., Oksuzyan et al., 2019). In the next steps, we will deepen our understanding of these dynamics by expanding the current analytical design to incorporate observations from older birth cohorts and consider how welfare state and labour market changes (such as the Hartz reforms started in 1998) strengthened or weakened the association between poverty and employment trajectories and health across social groups in East and West Germany.

Unemployment and fertility in Italy: A panel analysis.

Disoccupazione e fecondità in Italia: un'analisi panel.

Gabriele Ruiu and Marco Breschi

Abstract The effect of increasing unemployment on the decision to have children is not clear from both theoretical and empirical points of view. We focus our empirical analysis of the relationship between fertility and unemployment on a peculiar context represented by Italy. The demographic behaviour in this Country challenges the most influential theoretical predictions developed in social sciences. Implementing a panel ARDL analysis, our results indicate that a negative long run relationship exists between the two variables, but some surprising results are obtained when the short-run is considered.

Abstract *L'effetto della disoccupazione sulla fecondità non è chiaro sia dal punto di vista teorico sia da quello empirico. L'analisi della relazione tra queste due variabili svolta nel presente contributo è focalizzata su un contesto molto particolare come l'Italia. Il comportamento fecondo nel Paese rappresenta infatti la sfida per eccellenza nelle scienze sociali. I risultati di un'analisi panel ARDL indicano che tra le due variabili esiste una relazione negativa di lungo periodo, mentre nel breve periodo emerge una situazione più eterogenea tra le regioni.*

Keywords: Unemployment; Fertility; ARDL technique; panel analysis.

1 Introduction

The relationship between unemployment and fertility is widely debated in both economics and demography. In particular, the effect of increasing unemployment on the decision to have children is not completely clear, from both theoretical and

[1] Gabriele Ruiu, Department of Economics and Business, University of Sassari; gruiu@uniss.it

Marco Breschi, Department of Economics and Business, University of Sassari; breschi@uniss.it

empirical points of view. For men, unemployment implies not being able to access previously accessible goods due to the reduction of income. Therefore, if we are willing to accept the idea that having a child may be modelled as an economic decision, the prediction is inevitably that a sharp reduction in the demand for "children" will be observed. For women, in addition to this income effect, another force pushes in the opposite direction. Indeed, unemployment implies that the opportunity cost of having a child (i.e., the wage that one has to give up net of the possible maternity allowance) suffers a drastic decline, thus favouring fertility choices (substitution effect). Therefore, only when the latter force compensates the income effect, there will be an overall increase of fertility in times of crisis, while the opposite will happen when the substitution effect is overwhelmed by the income effect. However, Regions with low female participation rates experience a higher incidence of households in a situation of zero earnings when men lose their jobs. Therefore, the positive substitution effects should be negligible in these regions with upsetting effects on fertility. Pro-cyclical relationships have been confirmed by several empirical studies that use macro-level data [1, 8]. However, there are also empirical works, especially those analysing data before the late 1980s, which have found a counter-cyclical tendency in fertility [6, 5].

Considering the Italian case, [4] have shown that the direction of the relationship between unemployment and general fertility rates in Northern Italy is different from that of Southern regions. Specifically, they found that in Northern and Central Italy, the effect of unemployment is negative, while the opposite is true for Southern Italy (although in the latter case the results were weakly statistically significant). They conclude that this difference may be due to regional heterogeneity in the pervasiveness of the underground economy. In particular, it is well known that Southern Italy is characterised by the highest level of underground economic activity. This means that the level of unemployment, as measured by official statistics, may not reflect the real economic situation of this part of the Country. It should be noted that, the empirical results of [4] are obtained by pooling together all the regions belonging to the same macro-area and estimating a dynamic regression model for each area. In other words, this approach does not consider regional heterogeneity. We believe that Italy represents a peculiar context for analysis for several reasons. First of all, the country is (together with Spain, Portugal, Greece, Cyprus, and Malta) characterised by the lowest total fertility rate (TFR) in the World. In addition, given that female participation in the labour market in Italy is among the lowest in Europe, the positive relationship between unemployment and fertility challenges the predictions made by neoclassical microeconomic models. Furthermore, Italy has often been depicted as the least secularised among the developed countries. Hence, the Second Demographic Transition theory cannot help explain the low fertility rate. In the following section we will present data and methodology. In the third section, we will show and comment the obtained results-

2 Data and methods

We calculated the time series of quarterly GFR for each Italian region in the period 1992 (fourth quarter)-2017 (fourth quarter) using official data produced by ISTAT. The log of GFR is used as a dependent variable in an ARDL panel estimation where both the log of the male unemployment rate (hereafter *unem_male*) and the log female unemployment rate (hereafter *unem_female*) are the main explicative variables. In figure 1, it is reported the evolution of both the general fertility rate and of the total unemployment rate in the considered period.

Going into greater detail on ARDL panel techniques, we implement both the Mean Group (MG) and Pooled Mean Group (PMG) estimator, proposed respectively by [9] and [10]. In addition to distinguishing between short-run and long-run effects, these techniques make it possible to deal with time series that have different orders of integration; however, the series must not be second order stationary. Our battery of stationarity tests (not reported here) shows indeed that male unemployment is integrated of order one, while the other time series are integrated of order zero. The PMG model enables to estimate regional specific short-run coefficients and heterogeneous (region by region) speed of adjustment to the long-run equilibrium values, allowing error variances to be heterogeneous across regions, while the long-run slope coefficients are restricted to be homogeneous across regions. With $LGFR_{it}$ indicating the log of general fertility rate in region i at time t and with x the log of the unemployment rates in region i at time t-j, the PMG could be written as follows:

$$LGFR_{it} = \sum_{j=1}^{p} \lambda_{ij} LGFR_{i,t-j} + \sum_{j=3}^{q} \eta_{ij} x_{i,t-j} + m_i + \varepsilon_{it} \qquad (1)$$

For i=Apulia, Basilicata, … and t=1992q4,…2017q4

m_i is a unit-specific effect. In equation 1, j=3 is exemplificative of a model in which we assume that the short-run effects on fertility produced by the increase in unemployment are exerted with a lag of three quarters. This has been done to consider the potential effect of economic uncertainty on delaying conception to better times. Thus, this should have a negative effect on fertility, at least nine months later. However, we estimated the model also allowing j=4, j=5, and j=6. ε_{it} is a white noise error term. p and q (i.e. the number of lags of both dependent and independent variables) are usually decided by adopting the AIC criteria.

The model can be reparametrized as a VECM system:

$$\Delta LGFR_{it} = \theta_i \left(y_{i,t-1} - \beta' x_{i,t-4} \right) + \sum_{j=1}^{p-1} \lambda_{ij} \Delta GFR_{i,t-j} + \sum_{j=3}^{q-1} \eta_{ij} \Delta x_{i,t-j} + m_i + \varepsilon_{it} \qquad (2)$$

Where β is the long-run parameter and assumed to be equal across i. θ_i are the error correction parameters, which can be interpreted as the speed of adjustment when a shock perturbs the long-run equilibrium. As usual in econometric literature, the operator Δ indicates that the variables are differenced. The main difference between PGM and MG is that the latter does not impose long-run homogeneity. In particular, the MG estimator obtains the long-run parameters from autoregressive distribution lag models estimated separately for each unit i, while for the whole panel the long-run parameter is computed as the arithmetic mean of the individual β_i. MG is less efficient than PMG when the assumption of homogeneity holds. In the latter case we have also that the PMG is both consistent and efficient and thus

should be preferred to MG. We will implement both estimations and use the Hausman to decide between the MG and PMG estimators.

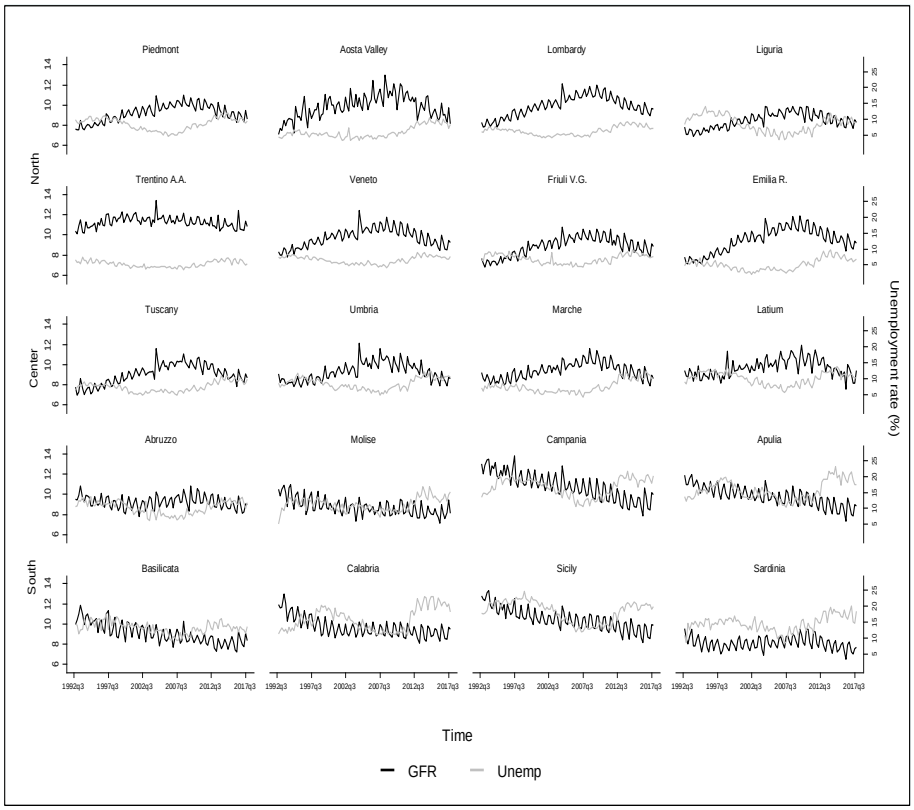

Figure 1: General fertility rates and unemployment rates in Italian Regions, 1992-2017

3 Results

Table 1 shows the results associated with long-run coefficients of both the PMG and MG model and the averaged error correction term.

Table 1: The relationship between fertility and unemployment

Error Correction Term	-0.149 (0.021)***	-0.205 (0.027)***

Nr of lags selected	(5,1,1)	(5,1,1)
Hausman test	Chi-square st. 4.20 sig:0.012	

Lags were selected by minimizing the AIC indicator. Max lags allowed: 8. Standard errors in parentheses; Sig: *$p < 0.10$, ** $p < 0.05$, *** $p < 0.01$

According to the Hausman test (reported at the end of the table), PMG should be preferred to MG. It is worthwhile noting that only the long-run coefficient associated with male unemployment is larger than that associated with female unemployment. This evidence gives some support to the idea that Italy is a country where the traditional male breadwinner model is still strong, and is coherent with the findings of [3,4] regarding the stronger correlation for male unemployment and fertility with respect to the same correlation calculated for female unemployment.

For a 1% increase in the male unemployment rate we have a decrease in the GFR of about 0.13%. Considering that Southern Italy tends to be characterised by an unemployment rate of more than the 10%, this suggests that the reduction of unemployment in these regions may produce a considerable gain in fertility in the long run. The error correction term is negative and highly statistically significant. If this term is not different from 0, then one may conclude that there is no evidence of a long-run relationship. Accordingly, our result suggests that when the long-run equilibrium is disturbed, about 15% of the shock is absorbed in the following quarter. Table 2 reports the short-run coefficients associated with the unemployment rates for each region.

The short-run specification also includes dummies for the quarters and a dummy for the recession period 2008-2013 (not reported to save space). The results depict a very heterogenous situation across Italian regions. We are able to confirm the results obtained by [4] about the positive relationship between male and female unemployment rates and fertility only for Abruzzo and Apulia. However, the same result has been found in Trentino Alto Adige (Northern Italy) and in Umbria (Central Italy). In the remaining Northern Regions, the relationship is negative. This excludes the hypothesis suggested by [4] about the possible role of the shadow economy, given that according to the estimation carried out by [7], Trentino Alto Adige is characterised by the lowest incidence of shadow economy in Italy. Therefore, at least for this region, a possible explanation could be that when unemployment is expected not to be persistent, couples who have postponed their first birth, are at risk of not having children and this may induce them to lower the desired "quality" of the child [2], thus partly counteracting the negative income effect. Perhaps, the depicted mechanism is weaker in Southern regions where female participation in the labour market is lower and unemployment tends to be longer. Therefore, when men lose their job, the zero earning situation is more frequent, also causing an immediate negative effect. This explanation seems to be consistent also with the findings obtained by [3]. According to these results, the economic uncertainty that derives from the persistence of joblessness negatively impacts fertility intentions with an effect that is stronger for men than for women (even in dual earner family). It remains to establish why this is not true for Abruzzo and Apulia. Perhaps, an investigation at individual level may help to better understand the obtained result.

University drop out and mobility in Italy. First evidences on first level degrees

Abbandono degli studi universitari e mobilità in Italia.

Prime evidenze sulle lauree di primo livello

Nicola Tedesco and Luisa Salaris

Abstract Italian university system presents a widespread inefficiency in the management of training processes which has – among others - a significant impact on the ratio between enrolled and graduated students. Dropout is an important issue which could be considered as an indicator of criticality of the training system. Using data from MIUR "Anagrafe Nazionale Studenti" from MIUR (ANS), the present work aims to measure the levels of dropout in Italy among a cohort of students (2011-2012) enrolled in a bachelor course (Level I) and followed for a period of 5 years. The analysis is carried out by means of Logistic 2-levels Model, to investigate the possible the determinants of the probability of student dropout, together with the role played by student mobility.

Abstract *Il sistema universitario italiano presenta una diffusa inefficienza nella gestione dei processi formativi che ha, tra gli altri, un impatto significativo sul rapporto tra gli studenti iscritti e laureati. Importante risulta il tema degli abbandoni che possono essere considerati come un indicatore della presenza di criticità nel sistema formativo. Grazie all'uso dei dati provenienti dall'Anagrafe Nazionale Studenti del MIUR (ANS), il presente lavoro ambisce a misurare i livelli di abbandono in Italia nella coorte degli studenti (2011-12) iscritti ad un corso di laurea triennale (Livello 1) seguita per un periodo di 5 anni. L'analisi è stata condotta attraverso l'uso di un modello logistico a 2 Livelli, per investigare le possibili determinanti dell'abbandono, assieme al ruolo giocato dalla mobilità.*

This paper has been supported from Italian Ministerial grant PRIN 2017 "From high school to job placement: micro-data life course analysis of university student mobility and its impact on the Italian North-South divide.", n. 2017HBTK5P. CUP: B78D19000180001

Key words: dropout, mobility, university, cohort, multilevel model

1 Introduction

That of University dropout is a relevant issue not only for student, but it is also represent a relevant topic for the evaluation of higher education system performances. Its incidence is highly variable and depends on the different methods of teaching delivery and the time needed to complete the studies. These aspects make it an issue that all European countries, despite with some differences in changing contexts. In Italy, high levels of university student dropout are generally observed, and this is partially related to the fact that Italian university system suffers from a low level of efficiency. Despite an important number of students every year decide to enrol at the University, there is a low number of graduates. Another relevant peculiarity of Italian system is that an enrolled student can indefinitely remain in this "enrolled" status and this occurs even if he/she does not achieve CFU (University Training Credits). As it is easy to understand this condition poses many problems for the estimation of dropout.

Prior studies have reported that the determinants of dropout are different: economic, need to get a job, wrong choices (see [1], [2], [3], [4]); but the possible role of student mobility has been never considered as a push/break factor.

The primary aim of this paper is measure student dropout in Italy, while instigating the possible determinants of this phenomenon based on the data provided by the MIUR student registry (Anagrafe Nazionale Studenti, ANS). Moreover, according to the fact that in Italy a consistent level of mobility is observed, in particular from Southern regions to Northern ones, in this work the possible role of mobility within the dropout dynamics is explored and considered into the analysis.
In section 2 the used data and methods are described together with the definition of key concepts for analysis, i.e. that of dropout and of mobility. In section 3 presents the results of data analysis according to the following two steps: firstly, the events in the career trajectories of students occurred during a period of 5 years are reported; secondly, thank to the application of Logistic 2-level Models the possible determinants of student dropout are investigated, where respectively region of residence and region of university of enrolment were considered as Second Level variables.

2 Data and methods

The data comes from the MIUR student registry ANS. The studied population is the cohort of students that during academic year 2011-2012 enrolled in a bachelor

course (Level I). The university career of these student cohorts was followed for a period of 5 years. We observed outcomes at the first level degree and in the possible access to the second level. The ANS data set contains the micro-data on the individual students enrolled in all Italian universities, on their university careers and the events occurred in their administrative career. In this study, the following individual information were considered: gender, region of residence and type of diploma. The cross-checking information on municipality of residence of the student and on municipality of the university site led to a classification of enrolled students as "non-mover" or "mover", where students belonging to the last group are those that are enrolled in University that is located in a different region to that of their residence. This variable allows to include in the analysis the possible role of mobility and to explore if the status of "mover" has an increasing/decreasing effect on student dropout. The analysis considers regional level mobility as it proves to be a more stable movement compared to mobility occurring within provinces which could be affected by commuting phenomenon. The analysis longitudinally considers the changes in the student status at every academic year. The considered student statuses are the following: stay enrolled, formal drop out, re-enrolment in another course of study, do not confirm the enrolment.

Data were analysed in two steps. Firstly, we observed the status of each student every a.y. to measure real drop out (net of re-enrolment); secondly, we modelled the probability of dropping out as success event (formal drop out and do not confirm the enrolment) vs failure (take the degree and enrol to a course of the II level, re-enrolment in another course of study and stay enrolled). Every year a student can change his/her status. All status that represent the permanence in the university system are aggregated as "enrol", the others as "drop out" to obtain a dichotomous dependent variable (drop out vs enrol).

3 Data analysis

The first step of the analysis regards the reconstruction of student trajectories over a period of 5 academic years. Table 1 firstly reports the outcomes of cohort of 2011 Italian students (269,309 subjects). During the first year of observation 41,180 dropout are recorded. The number of dropouts in subsequent year increases up to 58,110 in 2014. 2015 data was not considered in the analysis (see note).

Table 1 also shows the behaviour of the cohort of dropping out student in 2011 in subsequent years. In 2012, a great number of students that dropped out in 2011 (18,529, 45.0%) started a new university career. This behaviour persists in subsequent years, but with a low magnitude. So, it is evident that drop out in 2011 and 2012 are clearly a repositioning in the choice of university course.

In Table 2 the evolution of dropping out considering the student status of mover/not-mover is considered, focusing on regional movers, who are those students that are resident in a different region other than that of the chosen university. Region dimension was preferred to provincial one as the latter could reduce the estimation of real number of movers. In many geographic areas of Italy, it is easy to observe

mover-students between provinces, but a large proportion of this mobility is generated by commuter students, because their residence is not so far from the university but is still in another province. Accordingly, despite a regional approach might be reductive, as it does not consider spatial variability due to internal regional movements, it still represents a first useful attempt to investigate the possible role of mobility and to think about alternative measure that will be implemented in future steps of this research (i.e. a proximity indicator (according to distance and time to reach university).

Table 1: Enrolled students and dropout in Italy in 2011-2015 a.y.

Outcomes	***2011***	***2012***	***2013***	***2014***	***2015***
Enrolled	228,096	-	-	-	-
Drop out (registered every year)	41,180	48,463	52,742	58,110	175,735*
Dropping-out cohort of 2011					
Drop out	41,180	22,651	18,368	16,789	15,575
Re-enrolled		18,529	3,847	1,579	1,214

*The data of 2015 is extraordinarily high because it contains first-level graduates who decided not to enrol into a II level degree in 2015.

Table 2: 2011 cohort student enrolled in 2011 according to mobility status

Outcomes	***2011***	***2012***	***2013***	***2014***	***2015****
Mover	50,787	82,980	92,353	126,657	144,770
of which drop out	6,912	38,839	48,068	54,492	100,613
Not Mover	218,522	186,329	176,956	142,652	124,539
of which drop out	34,268	9,624	4,674	3,618	75,122
Dropping-out cohort of 2011					
Mover	6,912	20,396	17,945	16,624	15,721
Not Mover	34,268	1,819	423	165	34

*The 2015 data consider I level graduates who decide not to enrol in the II level degree in 2015.

The number of movers has increased every year. In 2011, 50.787 student begin their academic career moving to another region. In 2012 this number increase significantly as in 2014, when the first graduates at I level enrols at the second level degree. It is interesting to observe how the number of mover student dropout is greater only after one a.y. (38.839), while between not-mover students is higher in the first year and then decrease consistently.

The analysis of the cohort of dropouts shows that among not-mover students most of them leaves studies in the first year (2011) to reorient their own academic career (as shown in Table 1). If a student is a mover, the great part of dropout delays by one year (in 2012 20.396), probably because his own condition of mover encourages the choice to stay enrolled also for parental influence [3].

Table 3: 2-levels logistic model for the probability to drop out according to sex, mobility status, type of diploma and region of residence (2^ level units). Cohort 2011.

Covariates model 1	***OR***	***SE***	***p***	***95% Confidence Interval***	
Sex (base=Female)					
Male	1.14	0.013	0.000	1.12	1.17
Regional mover (Base=No)

High school diploma (Base = Scientific High School)					
Other High School	1.37	0.023	0.000	1.33	1.42
Classical High School	1.02	0.018	0.160	0.99	1.06
Abroad High School	1.13	0.042	0.000	1.06	1.22
Professional High School	1.81	0.042	0.000	1.73	1.90
Technical High School	1.54	0.021	0.000	1.50	1.59
Variance (regions)	0.1566	0.051		0.08	0.30

Table 4: 2-levels logistic model for the probability to drop out according to sex, mobility status, type of diploma and university of enrolment (2^ level units). Cohort 2011.

Covariates model 2	***OR***	***SE***	***p***	***95% Confidence Interval***	
Sex (base=Female)					
Male	1.15	0.013	0.000	1.13	1.18
Regional mover (Base=No)					
Yes	0.98	0.015	0.149	0.95	1.01
High school diploma (Base = Scientific High School)					
Other High School	1.39	0.024	0.000	1.34	1.44
Classical High School	1.05	0.018	0.011	1.01	1.08
Abroad High School	1.19	0.044	0.000	1.11	1.28
Professional High School	1.81	0.042	0.000	1.73	1.89
Technical High School	1.52	0.021	0.000	1.47	1.56
Variance (universities)	0.4831	0.0092		0.10	0.13

To preliminary investigate the role of some important covariates, we build a 2-level logistic regression model. The dependent variable is the probability to drop out. The considered covariates are sex (male, female), mobility status (yes, no) at the first observation year of the cohort 2011, type of high school diploma. The mobility status is a condition that can change every year. But to simplify data analysis, we decided to consider only the initial mobility status.

In model 1 (Table 3) the region of residence of the student was introduced as second level variable. In this way we can measure the variability of the dependent variable due to the geographical breakdown. The variability explained by region of residence is quite important. Among covariates male has a greater probability to dropout (OR=1.14), the opposite for movers (OR=0.83). Except for student with classical high school, for the others is higher the probability of dropout.

In model 2 (Table 4) we substitute the 2-level variable and we introduce the university of enrolment. The parameters estimated does not change compared to model 1, but it grows considerably the variance component (0.4831).

4 Conclusion and further developments

The cohort analysis (Tables 1) showed that dropout is a relevant problem of Italian university system. However, in the first year, the possibility of not confirming their enrolment is clearly an opportunistic behaviour adopted by an important share of students. In fact, if a student drops out he/she does not have to pay enrolment fees as he/she can sign up again to another course. The analysis of dropping-out cohort shows it clearly (Table 1).

Regional mobility influences the propensity to drop out (Table 2). If a student is a mover, he decides to drop out after one a.y. (probably because the status of mover delays his decision to drop out). If a student is not mover the decision to drop out is immediately, probably to re-orient his own choice.

Model results suggest that if we consider universities as 2-level units, we can better explain the variability of the probability of drop out. Probably the different offer of university courses, the different organization, the reputation of some specific university locations creates differ conditions that significantly influence the experience of university students.

These are preliminary results. The university career of a student is characterized by different events. Each student in fact can enrol to a first level course, drop out, enrolment in another course, take a degree. Later the student can enrol to second level course, drop out, to enrol in another course, take a second level degree. All these possible events suggest to analyze data with Multilevel Multistate Models. This will be our next step.

Worthiness-based Scale Quantifying
Re-interpretare scale ordinali equi-distanziate

Giulio D'Epifanio[1]

Abstract The construction of an ordinal scale Y, to be associated to a performance index in evaluating social-agents, is outlined which is quantified, adopting an "intrinsic worthiness" criterion, standardized on a chosen reference-agent, eg that which is intended as representing a (actual or perhaps hypothetical) "best practice". The usual practice of using the equispaced scale is re-interpreted. The ordinal levels of Y are identified by design through scheduling a hierarchical sequence of increasingly stringent "goals to be achieved". The index, to be associated to Y, borrows the structure of the Yaari-Quiggin functional, from the RDEU theory. But, the concept of "value increases", in advancing on the scheduled goals, is meaningfully re-interpreted herein, besides utility-based meaning, as "social worthiness". These "value increases" may be extracted, fully normalized on the data-behavior of the chosen "reference social-agent", upon a probabilistic formal setting using data-analysis (perhaps pseudo-Bayesian) tools. Thus, the ordinal levels of Y remain quantified, alternatively to various other approaches.

Abstract Si delinea la costruzione di una scala ordinale (da associare ad un indice di prestazione), quantificata adottando un principio di "merito intrinseco", normalizzata sulla scelta di un agente di riferimento, ad es. quello il cui comportamento è da intendersi come una "buona pratica", reale o ipotetica che sia. I livelli ordinali of Y sono identificati, per disegno, attraverso la pianificazione di una seguenza di obiettivi da raggiungere, progressivamente più severi. L'indice, associato alla quantificazione di Y, è formalmente strutturato sul funzionale di Yaari-Quiggin, ripreso dalla teoria RDEU. Ma il concetto di "incremento di valore", nelle transizioni sulla catena di obiettivi, è qui reinterpretato come "merito sociale", piuttosto che utilità. Questi incrementi potranno essere operativamente estratti previa formalizzazione in un quadro probabilistico, attraverso strumenti di data-analysis.

Key words: indexing, social agent evaluation, scale quantifying, worthiness

1 Introduction and methodological outline

[The higher level question] Some agent-schools $\{A_1, A_2, \ldots, A_q\}$ have to be benchmarked, from the view of the National Instruction Authority (the policy maker), with respect to *"the ability to address students*[1] *in achieving outcomes in learning"* on a certain outcome scale Y which classifies student-performance (eg by using a certain *learning test*) on the outcome-levels labeled as: "*very bad*" , "*bad*", "*almost enough*", "*sufficient*, "*more than sufficient*", "*good*", "*excellent*"). The policy-maker (PM) demands the agent-assessments be standardized on the behavior of a certain school A^* (the reference agent), perhaps chosen by experts to represent an actual instance of "*what should be intended as a, reasonable and desirable, best practice*". Performance-data are reported in table (1). More complex ex. are in [3].

level of performance Y:	I	II	III	V	V	VI	VII
actual agents:							
agent A1	0	16	24	31	12	0	4
agent A2	4	28	65	107	26	1	3
agent A3	4	42	71	102	33	0	2
agent A4	4	71	112	194	53	0	4

(a) Data by the agents to be benchmarked

Y:	I	II	III	IV	V	VI	VII
reference agent A^*	12	157	272	434	124	1	13

(b) Data by reference stand. agent A^*

Table 1: Example data

The PM[2] would need now an evaluation-machinery (the index) which, whenever applied to any agent A, it takes into input the performance-data of A to provide a certain performance-value, on a properly quantified ordinal scale Y, so that such a value is meaningful upon the conceptual framework which the PM has adopted, conditional on a set of design specifications. These specifications also including the choice of reference-agent A^* on the which the PM would normalize its evaluation-machinery.

[Ordinal scaling] In order to design an ordinal scale Y, on the which the evaluation-machine has to be constructed, we refer to the following scheme. Suppose that the PM, in pursuing its purposes, has been able to schedule a sequential hierarchy of, increasingly stringent, (Guttman-like ordered) goals[3]

[1] in a specified social domain $\mathcal{D}$, e.g. "18 year old female with a certain social background"

[2] To him, in setting value-levels, it seems be excessively "naive" considering equi-distanced scale; but, not clearly structured levels-score choices seem difficult to be justified in institutional benchmarking. On the other hand, economic utility-based interpretations seem lacking of meaning in social assessments (for an operative-research-based approach, see [2]). Worse still, merely data-analysis-criteria based methods (eg see [4]), "*di per se*" seem of little relevance at the PM's higher level question (eg see also [6]).

[3] Guttman order: $O_l \preceq O_{l+1} \Leftrightarrow$ "whenever goal O_{l+1} is achieved, also O_l has been achieved"

$$O_0 \preceq O_1 \preceq O_2 \preceq ... \preceq O_l \preceq ... \preceq \ldots \preceq O_{L-1} \preceq O_L := O_{Full}, \qquad (1)$$

Assume that a verbal ordinal scale for the outcome exists so that (unless of recoding it as a sequence of integers $0, 1, \ldots, l, \ldots, L$) the intrinsic meaning is established through the following identification[4]: $O_l \leftrightarrow (Y \geq l)$, $l := 0, \ldots, L$, where $O_0 := (Y \geq 0)$ represents the "tautological-goal" (ie the dummy goal always achieved by anyone). Therefore, an ordinal scale $Y \in \{0, 1, ..., l, ..., L\}$ remains identified with goals sequence (1) from the which it will inherit semantics, and vice versa.

[The formal evaluation machine] Suppose that the PM is able to assign, for any transitions in advancing sequence (1), the value-increase[5] $\omega_l := \Delta_{l-1}Val := Val(O_l) - Val(O_{l-1}) \geq 0$, $l := 1, \ldots, L$. Here, $Val(.)$ denotes a (non-negative, not decreasing in value by crossing goals-sequence (1)) value-function, which is initialized at $\omega_0 := Val(O_0) = 0$. The utility-value theory would provide the formal platform (e.g. see [1], pp. 559) from the which it could be inherited (as an instance of a more general class of Yaari-Quiggin-like value-functionals, eg see [1]) the following index-structure:

$$A \in \{A_1, .., A_q\} :\mapsto W[A] := \sum_{l:=1}^{L} \omega_l \cdot (1 - F_Y[p[A]](l)) = \sum_{l:=1}^{L} s(l; \omega) \cdot p_l[A] \quad (2)$$

unless of parameters list $\omega = (\omega_1, .., \omega_L)$ of value-increases on the transitions between adjacent levels of Y (ie in advancing performance on the scheduled ordered goals-sequence (1)). Here, $p[A] := (p_0, p_1, \ldots, p_L)[A]$ denotes the relative distribution which describes the behavior of agent A; $F_Y[p]$ the cumulative distribution such that $F_Y[p(A)](l) = p_0(A) + p_1(A) + \cdots + p_{l-1}(A)$; $s(l; \omega) := \omega_1 + \omega_2 + \cdots + \omega_l$ the Y-levels-quantifier.[6]

[The core methodological question] At the higher-level of the PM's decisions, the practical question now arises, which has an intrinsic methodological interest with regard to the operative way for specifying parameters ω_l, $l := 1, \ldots, L$, which will enter index structure (2) above, in a way that they will be actually meaningful and useful to the PM in evaluating social performance, besides formal utility-based settings.

[What it is proposed herein] Value-increases parameters ω_l on chain (1), which will enter (2), are re-interpreted with the meaning of "social worthiness-

[4] it is set here the logical identification of proposition *"goal O_l is achieved"* with that of "*the outcome-level of Y is at least l*"

[5] Here, $\omega_l := \Delta_{l-1}Val$ may be interpreted as the reference-value which would be gained by any social agent (due to its political activity in addressing the governed individuals) which is able to improve the condition-level of a certain "*standard individual*", from the current $(l-1)$th level to the next lth one

[6] Formally, $s(.; \omega)$ can be viewed as the quantification-function of the ordinal-levels $0, 1, \ldots, L$ of Y, which is obtained by (Choquet-)integrating value-increases ω_l, so that:$s(0; \omega) := Val(O_0) = 0 \leq s(1; \omega) := Val(O_1) = \omega_1 \leq s(2; \omega) := Val(O_2) = \omega_1 + \omega_2 \leq \ldots \leq s(L; \omega) := Val(O_L) = \omega_1 + \omega_2 + \cdots + \omega_L$

increases", by recalling a "principle of intrinsic worthiness". These increases are then specified upon a probabilistic formal setting, which may be also advanced enough to include complex contexts (eg see [3]). Hence, parameters ω_l could be numerically elicited from the reference-agent A^* data, conditionally on the PM's design-specifications, perhaps using pseudo-Bayesian data-analysis tools (eg as in [3]). The methodological point of arrival (unless of more complex extensions and advancing) is that an ordinal quantified scale Y (by Choquet-integrating increases ω_l) will remain operatively quantified, fully normalized on that specific "meaning of worthiness" which is intrinsic into the PM's choice of assuming, as reference-behavior among various alternatives, the behavior of agent A^* (eg a presumed "best-practice") .

2 Worthiness based indexing

Recalling (eg see [3]) the criterion of intrinsic worthiness[7], the "increases of worthiness"$\omega_l := \Delta_{l-1}Val(.)$ may be interpreted as follows. Let $\mathcal{P}^*$denote the population of the (real or perhaps virtual) individuals which are governed by the "reference agent" A^*.

> For any actual individual i (eg a student of a school in tab.1a), which has achieved goal O_{l-1} moving up goals-chain (1), *the higher* the $\mathcal{P}^*-$standardized risk of failing the next goal O_l, *the greater* the $\mathcal{P}^*-$standardized "increase of worthiness" $\Delta_{l-1}Val(.)$ which such an individual i gains whenever it also achieves goal O_l.

By adopting now a probabilistic interpretative setting, such a $\mathcal{P}^*-$standardized risk could be related to non-transition probability[8] $Pr\{Y = l-1|Y \geq l-1; \mathcal{P}^*\}$, up to some monotone transformation $\varphi_l(.)$ (eg see [3]). Thus, by setting value-increases as:

$$\Delta_{l-1}Val := \omega_l^* := \varphi_l(Pr\{Y = l-1|Y \geq l-1; \mathcal{P}^*\}),\ l := 1, \dots L \qquad (3)$$

[7] Consider hierarchical chain of goals (1). Given that a certain goal O_{l-1} has been achieved, the greater the resistance, with reference to the evaluation framework, to also achieve the next pursued goal O_l, by continuing to improve, the greater the increment of value $\omega_l := \Delta_{l-1}Val(.)$ due to the "intrinsic worthiness" of who, effectively, is able to achieve it.

[8] of course, $Pr\{Y=l-1|Y\geq l-1;\mathcal{P}^*\}=\frac{Pr\{Y=l-1;\mathcal{P}^*\}}{Pr\{Y\geq l-1;\mathcal{P}^*\}} = \frac{p^*_{l-1}}{p^*_{l-1}+p^*_l+\dots+p^*_L}$.

Example, by data-table (1b): $\omega_0 = Pr\{O_0\ fails\} = 0$, $\omega_1 = Pr\{O_1\ fails\} \simeq \frac{12}{12+157+272+434+124+1+13}$, $\omega_2 = Pr\{O_2\ fails|O_1\ achieved\} \simeq \frac{157}{157+272+434+124+1+13}$, $\omega_3 = Pr\{O_3\ fails|O_2\ achieved\} \simeq \frac{272}{272+434+124+1+13}$, $\omega_4 \simeq Pr\{O_4\ fails|O_3\ achieved\} = \frac{434}{434+124+1+13}$, $\omega_5 = Pr\{O_5\ fails|O_4\ achieved\} \simeq \frac{124}{124+1+13}$, $\omega_6 \simeq Pr\{O_6\ fails|O_5\ achieved\} = \frac{1}{1+13}$. Then (let here $\varphi_l(.)$ be the identity), by accumulating value-increases yields:

level-score of Y:	0	1	2	3	4	5	6
	0	0.011846	0.168689	0.490964	1.249705	2.148256	2.219685

it yields index structure (2) to be instanced as[9]

$$A :\longmapsto W[A;\, \omega^*] := \sum_{l:=1}^{L} \varphi_l(\frac{Pr\{Y = l-1; \mathcal{P}^*\}}{Pr\{Y \geq l-1; \mathcal{P}^*\}}) \cdot (1 - F_Y[p[A]](l)) \qquad (4)$$

From the which, the re-ranged on interval $[0, 100\%]$, normalized version[10]

$$A \in \{A_1, .., A_p\} :\longmapsto W^*[A;\, \omega^*] := \frac{W[A;\, \omega^*] - W[A_{worst};\, \omega^*]}{W[A_{best};\, \omega^*] - W[A_{worst};\, \omega^*]} \qquad (5)$$

3 Advancing and notes on equidistant scaling

[***Multi-domain indexing***] The PM might want consider worthiness-based performance difference, among the social agents, conditional on status $x := X \in \{x_1, \ldots, x_r, \ldots, x_R\}$ of the governed individuals, normalized on standard agent A^*. Here, $\{x_1, \ldots, x_r, \ldots, x_R\}$ represents a set of *"reference domains"*. A global worthiness-index, integrating on domains X from (4), could have the following structure:

$$A \longmapsto \sum_{r:=1}^{R} q_r \cdot W_{x_r}[p_r([A]; \omega_r(\mathcal{P}^*)] = \sum_{r:=1}^{R} q_r \cdot \{\sum_{l:=1}^{L} \varphi_l(\frac{\exp(\widehat{a}_l + \hat{b}_l x_r)}{1 + \exp(\hat{a}_l + \hat{b}_l x_r)}) \cdot (1 - F_{Y|x_r}[p[A]](l))\}$$

where parameters $\hat{a}$ and $\widehat{b}$ were determined, using a sequence of logistic models to model value-increases (3) conditional on status x, given reference-population $\mathcal{P}^*$associated to A^*. Here, $q_r \geq 0$ weights[11] ($\sum_{i:=1}^{R} q_r = 1$) the reference domains. A more complex example is presented in [3].

[***Equi-distanced quantifying***] Process any individual, governed by standard-agent A^* in a certain condition-domain $\mathcal{D}$ (ie in reference-population $\mathcal{P}^*_{|\mathcal{D}}$), sequentially against goal-achievement detectors associated to goals-hierarchy

[9] Here, a continuous monotone functions $\varphi_l(.)$ could be chosen for specifying some types of design-requirements (e.g. the additivity) on the worthiness-scale.

[10] Here, the performance of agent $A \in \{A_1, .., A_p\}$ is graduated on the percentage of gained worthiness, in advancing from the complete social-failure (represented by distribution $p[A_{worst}] := (1, 0, \ldots, 0)$ associated to the "worst-virtual agent" named A_{worst}) toward the full achievement of the social overall-goal (represented by distribution $p[A_{best}] := (0, 0, \ldots, 0, 1)$ associated to the best virtual agent named A_{best})

[11] the weights should represent the political relevancy of the "social reference domains" to the overall purpose of the PM

(1). Then[12], recalling worthiness-increments (3), the value-increases will be provided (for simplicity use identity $\varphi_l(t) = t$) by:

$\omega_l^* = \frac{q_1 q_2 \cdots q_l (1-q_{l+1})}{q_1 q_2 \cdots q_l (1-q_{l+1}) + q_1 q_2 \cdots q_l \cdot q_{l+1}(1-q_{l+2}) + \ldots + q_1 q_2 \cdots q_l \cdot q_{l+1} \cdots q_L} = \frac{(1-q_{l+1})}{(1-q_{l+1}) + q_{l+1}(1-q_{l+2}) + \ldots + q_{l+1} \cdots q_L}$

Suppose now that, in particular, A^* has been chosen (to be put into example-table 1b) such that transition probabilities $q_l := Pr\{Y > l-1 | Y \geq l-1; \mathcal{P}^*\} = q,\ l := 1, \ldots L$ ($0 < q < 1$ constant) were invariant through chain (1). Then, it will happen[13] that worthiness increases $\omega_l^* = 1-q,\ l := 1, \ldots L$ remain constant. Thus, normalized on A^*, it will be induced an equi-distanced scale, with some curious interpretation[14]with respect to the PM's choice of considering A^* as a "best practice".

[12] Let $q_l := Pr\{Y > l-1 | Y \geq l-1; \mathcal{P}^*\}$, $l := 1, \ldots, L$, denote the "transition probability" which an individual, once arrived at level $(l-1)$th of Y, is also able to pass over beside. Of course, the expected "social behavior" of A^*, with respect to outcome-classifier $Y \in \{0, 1, \ldots, L\}$, is represented by parameters $p[A^*] := (p_0, p_1, \ldots, p_L)[A^*]$, where $p_0 := 1-q_1$, $p_1 := q_1(1-q_2)$, ..., $p_l := q_1 q_2 \cdots q_l(1-q_{l+1})$,.., $p_L := q_1 q_2 \cdots q_l \cdot q_{l+1} \cdots q_L$; here, $p_l[A^*]$ represents the probability of definitively remaining at level lth of Y.

[13] $\omega_l^* = \frac{1-q}{(1-q)+q(1-q)+q^2(1-q)+\ldots+q^{L-1}(1-q)+q^L} = \frac{1-q}{1-q+q-q^2+q^2-q^3+\ldots+q^{L-1}-q^L+q^L} = 1-q$

[14] Vice versa, the choice of using an equi-distanced ordinal scale for Y would be equivalent, in our interpretative setting in schools evaluations, to choose as reference standard-agent A^* that "virtual" school (the distribution $p[A^*] := (1-q, q(1-q), \ldots, q^{L-1}(1-q), q^L)[A^*]$ to be put into example-table 1b) whose students constitute that reference population $\mathcal{P}^*$ where everyone, subjected to a sequence of k-outcome-formatted learning-tests (intended as goal-achievement detectors on goals-hierarchy (1)) until a goal is failed, tries to guess, among the k (k constant positive integer) proposed answers, the correct one. That is to say that, in particular using a sequence of $k := 2$ outcome-formatted learning-tests, it would be "*as if*" any student in $\mathcal{P}^*$ would respond according to the random outcome from tossing a certain coin.

Young people in Southern Italy and the phenomenon of immigration: what is their perception?

I giovani del Sud Italia e il fenomeno dell'immigrazione: quale percezione?

Nunziata Ribecco, Angela Maria D'Uggento and Angela Labarile

Abstract In Italy, the issues of immigration, integration and perception of the phenomenon are extremely topical and have prompted a rather heated debate. Lacking official data on the citizens' "sentiment", a survey was carried out through a questionnaire addressed to about 1,200 students attending the Apulian high schools. The aims are mainly two: to ascertain possible misperceptions or information gaps and to better understand young people's opinions about the positive or negative effects of the immigrants' presence in our communities, and their behaviour to facilitate the integration process. Some relevant misperceptions are highlighted, and the respondents' perceptions are detected by means of exploratory analyses, heterogeneity indexes and multiple correspondence analysis.

Abstract *In Italia, i temi dell'immigrazione, integrazione e percezione del fenomeno risultano estremamente attuali e originano accesi dibattiti. In mancanza di dati ufficiali sul "sentiment" dei cittadini, è stata svolta un'indagine attraverso la somministrazione di un questionario che ha coinvolto circa 1200 studenti delle scuole superiori della Puglia. L'obiettivo è duplice: individuare eventuali bias informativi, nonché conoscere la percezione degli intervistati circa la presenza di immigrati nella propria realtà territoriale e gli atteggiamenti per favorire il processo di integrazione. In particolare, la ricerca evidenzia la presenza di bias rilevanti; la percezione degli intervistati è stata analizzata dal punto di vista della eterogeneità mentre l'analisi delle corrispondenze multiple delinea tre profili.*

Key words: immigration, misperception, heterogeneity indexes, multiple correspondence analysis.

1 Introduction

Perceptions represent the acquisition of awareness of the external context through a series of sensory *stimuli*, filtered through intuitive, psychic and intellectual processes. It is the way in which the sensory-intellectual apparatus perceives external reality in relation to the ability of the individual response. By transposing perceptions in the field of information, it is understood how fundamental becomes to be exposed to external stimuli, and to frequent information flows, whose sources have undergone a profound change in recent years. The massive spread of social media alongside traditional news channels (TV, newspapers, books, internet) has profoundly affected the mechanisms of formation of collective and individual opinions and perceptions. The paper aims at analysing young people's perceptions of the phenomenon of foreign immigration affecting Italy and Puglia, as one of the main migration routes towards Europe. Although immigration is a widely discussed issue, some misperceptions with respect to crucial aspects have emerged. The survey was carried out in February 2019, when Italy was the country of first reception in a European emergency phase, and the phenomenon has also been a battleground in the political and social debate. Public opinion was split up between those who supported the policies of hospitality and their opposites, who leveraged on suspicion and reduction of the sense of security due to immigrants' presence. Then, the research "Immigration and integration: the reality and perception of young people" was carried out among Apulian high schools' students. Besides investigating the perception of this phenomenon, a further issue is understanding the impact of media in conditioning people's perceptions, especially of that part of the population that has not yet developed an autonomous critical sense because of the young age and more likely to be influenced. In a globalised society, reality becomes increasingly difficult to understand, and therefore public perception risks to move further and further away from real data. This distance is defined misperception or cognitive bias and refers to a systematic pattern of deviation from the norm or rationality in judgment. In Psychology, it indicates a tendency to create one's own subjective reality, not necessarily corresponding to the evidence, developed on the basis of the interpretation of the information hold, which, therefore, may lead to an error of judgment or lack of objectivity in many fields [2,3]. Then, by means of some specific questions, the existence and magnitude of cognitive biases on the phenomenon of immigration is verified by comparing the sample's responses with the official information. The paper is organized as follows: section 2 deals with a description of the survey's and the questionnaire, section 3 with the statistical procedures and the discussion on the main findings about misperception measurement, exploratory and multiple correspondence analyses; section 4 briefly concludes.

2 The survey and the data

The survey involved a representative sample of high schools in Puglia; students interviewed were given a questionnaire of 32 questions divided into four sections: I. Knowledge of quantitative data of the phenomenon and comparison to real data; II. Perception of the phenomenon and integration; III. Impact of immigration on the country's living system; IV. Initiatives to share national political choices. Students were asked to express their level of agreement/disagreement with a set of 10 statements, in Section III, related to the problem being investigated, using a five-point Likert scale [4] in which 1 indicates "not at all agree" and 5 "completely agree". The statements are the following and the acronyms of the corresponding variables are also specified:

1. Immigrants contribute to the cultural development of our country (CULTDEV);
2. Immigrants contribute to the economic development of our country (ECONDEV);
3. Immigrants are necessary to compensate for the demographic decline caused by the progressive ageing of the Italian population (DEMODECL);
4. Immigrants spread behaviours contrary to our traditions and put Italian cultural identity at risk (IDENTITY);
5. Immigrants introduce and spread diseases (DISEASE);
6. Immigrants introduce dangerous ideologies into the host country (IDEOLOGY);
7. Immigrants exacerbate public order problems (PUBORDER);
8. The presence of immigrants is a danger to social security (SOCIALSEC);
9. Immigrants compete with the Italian workforce, thus causing job losses and lower wages (JOBLOSSES);
10. Immigrants accept illegal jobs and contribute to the spread of “black work” also for Italians (ILLEGALWORK).

We collected 1,222 online questionnaires, reduced to 1,196 after the phase of data cleaning. Data are analysed by means of explorative and multivariate techniques.

3. Main results and discussion

3.1 Informative misperception among young people

Italy, along with Germany, Great Britain, France and Spain is one of the five EU countries with the highest concentration of immigrants. To measure the main misperceptions, let us now compare some official data [5] with the students’ perceptions as collected by the sample (Tab.1). Most of them believe that immigrants come almost exclusively from Africa, then from Asia, Europe and America. The reality, however, is quite different, as 50.2% of immigrants come from European countries, namely Romania. It is the same if we consider the underestimation of the number of foreign people in Italy.

Another issue concerns the reasons for foreigners staying and, in this case, the perception of the sample does not differ much from the real situation, as the majority believes that the main reason is the family reunion, followed by humanitarian crises and asylum, and finally the working reason. Table 1 summarizes the main findings by showing the real data, the perceived data, and the misperception index, obtained as the difference between the two values.

Table 1: Misperception measurements on some information about immigration

Variables	***Real***	***Perceived***	***Misperception***
Number of immigrants (mean)	5,225,03	3,120,602	2,104,901
Countries (%)			
Europe	50.2	10.7	39.5
Africa	21.7	69.4	-47.7
Asia	20.8	18.1	2.7
America	7.2	1.8	5.4
Reasons (%)			
Family reunion	52.4	49.5	2.9
Asylum, Humanitarian crisis	41.6	41.2	0.4
Job	6.0	9.3	-3.3

3.2 Exploratory analyses

The main statistics synthetizing the responses given by the students to the ten statements about immigration, introduced in Section 2, are shown in Table 2. Since the variables are ordinal, the central tendency measures of interest are the median and the mode, but these indicators are not good at discriminating the different attitude of the interviewed in relation to the statements of the set, especially when they have similar distributions. Considering that the attitude is a continuum, on which individuals can be located according to their answers, each variable can be considered as continuous, so we can compute a numeric summary. This numeric summary is the mean value of the scores, which can be interpreted as a proxy of the average value of the continuous variable "attitude toward the phenomenon". To evaluate the accuracy of the answers collected, that is the reliability concerned with the study, some variability measures fitting ordinal variables need to be selected [1]. Then, we first consider Gini heterogeneity index in its standardised form and, in addition, two other indexes that can be obtained as monotonic functions of the index: Frosini index (F) and Laasko and Taagepera index (A). All the indexes assume values in [0,1] and the results are recapped in Table 2: among the three indexes, the one selected to complete the analysis is the Laasko and Taagepera index (A), because it has the widest range, so it is supposed to be more selective and able to discern better between heterogeneous situations. The following Fig. 1 displays the ten variables in relation to the mean and the A index values. It can be observed that all the mean values range from 2 to little more than 3: in particular, the value of 3 (which indicates the indifference state) is exceeded just by the variable "Illegal Work". Regarding dispersion, this appears to be rather high, since A index overtakes the value of 0.5 for all the variables; the highest measures are linked to the variables "Illegal Work" and "Demographic decline".

Table 2: Mean, Median, Mode and Variability indexes for the ten items

Variables	***Mean***	***Median***	***Mode***	***Gini Index***	***Frosini Index***	***Laasko Index***
Cultural development	2.758	3	3	0.948013	0.771993	0.784812
Economic development	2.471	2	2	0.941275	0.757668	0.762228
Demographic decline	2.817	3	3	0.981822	0.865171	0.915267

Identity	2.315	2	1	0.937928	0.750858	0.751372
Diseases	2.277	2	1	0.930207	0.735816	0,727194
Ideology	2.197	2	2	0.910427	0.700713	0.670275
Public order	2.415	2	2	0.938610	0.752223	0.753564
Social security	2.171	2	2	0.899530	0.683030	0.641661
Job losses	2.436	2	1	0.958447	0.796154	0.821845
Illegal work	3.009	3	3	0.992014	0.910635	0.961305

3.3 Multiple correspondence analysis

Another relevant research issue deals with the assessment of the real willingness to provide shelter, as a multidimensional latent construct to be observed trough some direct measurements. This latent variable investigates students' behaviours towards immigrants, beyond the simple statements of principle, mostly inspired by the "social desirability". The Multiple correspondence analysis highlights the proximity relationships among the responses collected with reference to the most representative five statements of the set (Fig. 2). A clear opposition among three groups is drawn: on the left, we find the students who consider immigration a resource for Italian economy, with a positive contribution to labour forces and no other problems for social security or Health. Near them, those who prefer to adopt a neutral behaviour, by selecting the intermediate point equivalent to 3 (labelled with DK). On the right, we find those that we may call the "conservatives", considering

the immigration almost a threat. The model shows a good fitting, explaining the 62.4% of the variance.

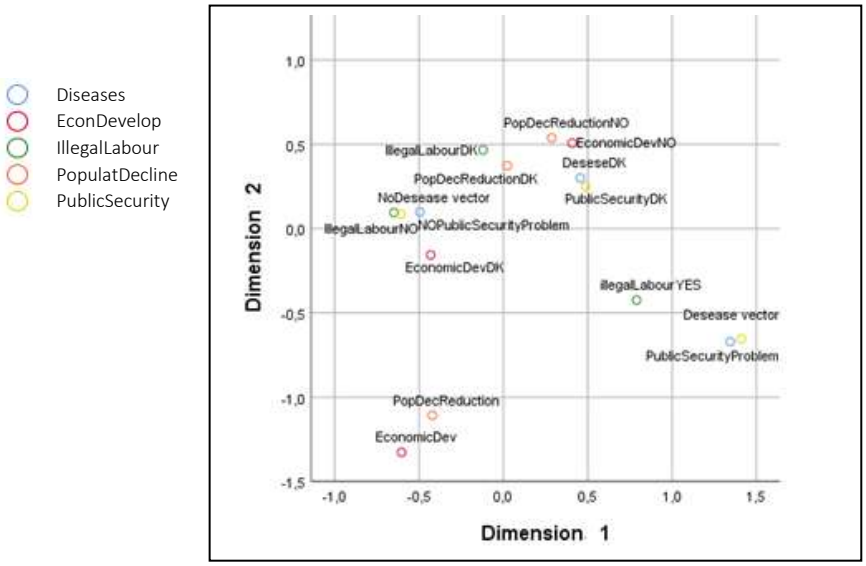

Figure 2: Conjoint plot of variables of Multiple correspondence analysis

4 Some conclusive remarks

The research on youths' perception of immigration, carried out as a part of the National Scientific Degree Plan-PLS project, showed interesting results both regarding the role of the media in affecting misperceptions, and the evidence that inaccurate information produce distrust and closure towards the phenomenon.
It is a fundamental task of educational institutions to support the development of a critical spirit in students, making them autonomous in judgment, and lay the foundation for the future society.
